ABSTRACT

The first measurement of the inclusive cross section for top quark pairs ($t\bar{t}$) produced in association with two additional charm jets is presented. The analysis uses the dileptonic final states of $t\bar{t}$ events produced in proton-proton collisions at a centre-of-mass energy of 13 TeV. The data correspond to an integrated luminosity of 41.5 fb^{-1} , recorded by the CMS experiment at the LHC. A new charm jet identification algorithm provides input to a neural network that is trained to distinguish among $t\bar{t}$ events with two additional charm ($t\bar{t}c\bar{c}$), bottom ($t\bar{t}b\bar{b}$), and light-flavour or gluon ($t\bar{t}LL$) jets. By means of a template fitting procedure, the inclusive $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ cross sections are simultaneously measured, together with their ratios to the inclusive $t\bar{t}$ + two jets cross section. This provides measurements of the $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ cross sections of 10.1 ± 1.2 (stat) ± 1.4 (syst) pb and 4.54 ± 0.35 (stat) ± 0.56 (syst) pb, respectively, in the full phase space. The results are compared and found to be consistent with predictions from two different matrix element generators with next-to-leading order accuracy in quantum chromodynamics, interfaced with a parton shower simulation.

1. Introduction

The modelling of top quark pair ($t\bar{t}$) production in association with jets from the hadronization of bottom (b) or charm (c) quarks, referred to as b jets and c jets, respectively, in proton-proton (pp) collisions at the CERN LHC is challenging. Calculations of the production cross section for top quark pairs with additional pairs of b jets ($t\bar{t}b\bar{b}$) are available at next-to-leading order (NLO) in quantum chromodynamics (QCD) [1–5], but suffer from large uncertainties due to the choice of factorization (μ_F) and renormalization (μ_R) scales. The uncertainties arise from the different energy (or mass) scales in $t\bar{t}b\bar{b}$ production, which range from the large scales associated with the top quark mass (m_t), to the relatively small scales associated with additional jets resulting mostly from gluon splitting into $b\bar{b}$ pairs. To better understand the $t\bar{t}b\bar{b}$ process, the ATLAS and CMS experiments have conducted several measurements in pp collisions at centre-of-mass energies of 7, 8, and 13 TeV [6–13].

The production of a $t\bar{t}$ pair with an additional pair of c jets ($t\bar{t}c\bar{c}$) has received far less attention, both theoretically and experimentally. Whereas the experimental signature of a b jet looks quite different from that of a light-flavour (LF) or gluon jet, the

differences are much less pronounced for c jets. This explains the challenge of simultaneously separating $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ events from a large background of $t\bar{t}$ events with additional LF or gluon jets ($t\bar{t}LL$). With the development of a charm jet identification algorithm (“c tagger”) [14], these signatures can now be more efficiently disentangled. We present the first measurement of the inclusive $t\bar{t}c\bar{c}$ cross section and its ratio to the inclusive $t\bar{t}$ + two jets ($t\bar{t}jj$) cross section. A fully consistent treatment of the different additional jet flavours is ensured using a technique that simultaneously extracts the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ cross sections. The measurement is performed in the dileptonic decay channel of the $t\bar{t}$ events using a data sample of pp collisions at a centre-of-mass energy of 13 TeV, collected with the CMS detector in 2017, corresponding to an integrated luminosity of 41.5 fb^{-1} [15]. This data set benefits from the upgrade of the pixel tracking detector [16], which was installed in winter 2016–2017 and which has been shown to significantly improve the performance of heavy-flavour (HF) jet identification [17].

Although the additional b jets in $t\bar{t}b\bar{b}$ events are predominantly produced via gluon splitting into $b\bar{b}$ pairs, they can also originate from the decay of a Higgs boson (H). Previous measurements of Higgs boson production in association with a top quark pair, where the Higgs boson decays into a pair of b quarks ($t\bar{t}H$, $H \rightarrow b\bar{b}$) [18–21], suffer from a nonresonant background of gluon-

^{*} E-mail address: cms-publication-committee-chair@cern.ch.

induced $t\bar{t}b\bar{b}$ events, and to a lesser extent also from $t\bar{t}c\bar{c}$ events due to the misidentification of c jets as b jets. The techniques described here provide a basis for a simultaneous measurement of the $t\bar{t}b\bar{b}$ and $t\bar{t}c\bar{c}$ processes from data that can be adopted in future $t\bar{t}H$ analyses to significantly reduce the uncertainties related to these backgrounds.

2. The CMS detector

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter, providing a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL), each composed of a barrel and two endcap sections. The silicon tracker measures charged particles within the pseudorapidity range $|\eta| < 2.5$. During the LHC running period when the data used for this analysis were recorded, the silicon tracker consisted of 1856 silicon pixel and 15 148 silicon strip detector modules. For nonisolated particles of $1 < p_T < 10$ GeV and $|\eta| < 2.5$, the track resolutions are typically 1.5% in p_T and 20–75 μm in the transverse impact parameter [22]. Forward calorimeters extend the η coverage provided by the barrel and endcap detectors. Muons are detected in gas-ionization chambers embedded in the steel flux-return yoke outside the solenoid. A more detailed description of the CMS detector, together with a definition of the coordinate system used and the relevant kinematic variables, can be found in Ref. [23].

Events of interest are selected using a two-tiered trigger system [24]. The first level, composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events at a rate of around 100 kHz within a fixed time interval of about 4 μs . The second level, known as the high-level trigger, consists of a farm of processors running a version of the full event reconstruction software optimized for fast processing, and reduces the event rate to around 1 kHz before data storage.

3. Event simulation

Samples of signal and background events are simulated using Monte Carlo (MC) event generators based on a fixed-order perturbative QCD calculation with up to four noncollinear high- p_T partons, supplemented with parton showering (PS) and multiparton interactions. The matrix element (ME) generation of $t\bar{t}$ events is performed with POWHEG (v2) [25–29] at NLO in QCD using the five-flavour scheme, followed by a simulation of the PS using PYTHIA8.230 [30] (referred to as PYTHIA8 in the following), using the CP5 underlying event tune [31] and the NNPDF3.1 [32] parton distribution functions (PDFs). The first additional hard radiation from the $t\bar{t}$ system is included in the NLO ME calculation, whereas higher additional jet multiplicities result from radiation simulated in the PS. A value of $m_t = 172.5$ GeV is used in the event generation and the values of μ_R and μ_F are set to a dynamic scale given by $\sqrt{m_t^2 + p_{T,t}^2}$, where $p_{T,t}$ denotes the transverse momentum of the top quark in the $t\bar{t}$ rest frame. The $t\bar{t}$ cross section is scaled to a theoretical prediction at next-to-next-to-leading order in QCD including resummation of next-to-next-to-leading logarithmic soft-gluon terms, which yields $\sigma_{t\bar{t}} = 832^{+39.9}_{-45.8}$ pb [33]. The results are also compared to those from $t\bar{t}$ production simulated with the MADGRAPH5_AMC@NLO (v2.4.2) [34] ME generator at NLO accuracy using the five-flavour scheme, with FxFx jet matching [35] and including up to two jets in addition to the $t\bar{t}$ system in the NLO ME calculation. No dedicated simulations have been used to model separately $t\bar{t}c\bar{c}$ or $t\bar{t}b\bar{b}$ events, ensuring a consistent treatment between $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ events in the inclusive $t\bar{t}$ samples mentioned above.

Fig. 1. Example of a Feynman diagram at the lowest order in QCD, describing the dileptonic decay channel of a top quark pair with an additional $c\bar{c}$ pair produced via gluon splitting.

The background processes for this analysis consist mainly of Drell–Yan (DY) and single top quark events, with additional minor contributions from $W + \text{jets}$, diboson, triboson, $t\bar{t}Z$, $t\bar{t}W$, and $t\bar{t}H$ events (collectively referred to as rare backgrounds). For all these samples, the PS is simulated using PYTHIA8. The ME generation of the DY, $W + \text{jets}$, triboson, $t\bar{t}Z$, and $t\bar{t}W$ events is handled using MADGRAPH5_AMC@NLO at leading order in QCD, with MLM jet matching [36]. The $t\bar{t}H$ events are generated at NLO using POWHEG. Single top quark production in the t and s channels are simulated at NLO in the four-flavour scheme using POWHEG and MADGRAPH5_AMC@NLO, respectively, while the tW channel is simulated at NLO with POWHEG in the five-flavour scheme. The diboson samples are simulated at leading order in QCD using PYTHIA8 for both the ME calculations and PS description.

The interactions between particles and the material in the CMS detector are simulated using GEANT4 (v10.02) [37]. The effect of additional pp interactions in the same or nearby beam crossings as the hard-scattering process (pileup) is modelled by adding simulated minimum bias collisions generated in PYTHIA8.

4. Signal definition

A typical Feynman diagram describing the dileptonic $t\bar{t}c\bar{c}$ process is shown in Fig. 1. To provide an unambiguous interpretation of the results, a generator-level definition of the event categories is needed, based on the flavours of the additional jets. The HF jets are identified at the generator level using the procedure of ghost matching [38], where in addition to the reconstructed final-state particles, the generated b and c hadrons are clustered into the jets. However, the modulus of the hadron four-momentum is set to a small number to prevent these generated hadrons from affecting the reconstructed jet momentum and to ensure that only their directional information is retained. Jets that contain both b and c hadrons are labelled as b jets, since the c hadrons most likely originate from a decay of a b hadron. The results of this measurement are reported in terms of the fiducial and full phase spaces.

Fiducial phase space: In the definition of the fiducial phase space, all of the final-state particles (except for the neutrinos) resulting from the decay chain: $pp \rightarrow t\bar{t}jj \rightarrow \ell^+ \nu_\ell b \ell^- \bar{\nu}_\ell \bar{b} j j$ are required to be within the region of the detector in which these objects can be properly reconstructed. The fiducial phase space is therefore defined by the presence of two oppositely charged electrons, muons, or τ leptons (ℓ) at the generator level with $p_T > 25$ GeV and $|\eta| < 2.4$. Each lepton is required to originate from a decay of a W boson, which in turn results from a top quark decay. Particle-level jets are defined by clustering generated final-state particles with a mean lifetime greater than 30 ps, excluding neutrinos, us-

ing the anti- k_T algorithm [39,40] with a distance parameter of 0.4. We demand two particle-level b jets from the top quark decays with $p_T > 20$ GeV and $|\eta| < 2.4$. Besides these two b jets, at least two additional particle-level jets must be present, with the same kinematic requirements imposed. Jets that lie within $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.4$ of either one of the leptons from the W boson decays, where ϕ denotes the azimuthal angle, are excluded. The above requirements define the inclusive $t\bar{t}jj$ signal, which is then subdivided based on the flavour content of the additional particle-level jets (not from the top quark decays) into the following categories:

- $t\bar{t}b\bar{b}$: At least two additional b jets are present, each containing at least one b hadron.
- $t\bar{t}bL$: Only one additional b jet is present, containing at least one b hadron. In addition, at least one additional LF or c jet is present. This category results from $t\bar{t}b\bar{b}$ events in which one of the two additional b jets is outside the acceptance, or two b jets are merged into one.
- $t\bar{t}c\bar{c}$: No additional b jets are present, but at least two additional c jets are found, each containing at least one c hadron.
- $t\bar{t}cL$: No additional b jets are present, and only one additional c jet is found, containing at least one c hadron. In addition, at least one additional LF jet is present. This category results from $t\bar{t}c\bar{c}$ events in which one of the two additional c jets is outside the acceptance, or two c jets are merged into one.
- $t\bar{t}LL$: No additional b or c jets are present, but at least two additional LF jets are within the acceptance.

All other $t\bar{t}$ events that do not fit in any of the above categories, because they do not fulfill the acceptance requirements described in the definition of the fiducial phase space, are labelled as “ $t\bar{t}$ +other”. These could for example be events with semileptonic or fully hadronic $t\bar{t}$ decays that pass the event selection criteria outlined in Section 6, or dileptonic $t\bar{t}$ events for which the leptons or the particle-level jets as described above are not within the fiducial detector volume. These contributions are estimated from the same simulations as those used for the signal events.

Full phase space: The definition of the full phase space comprises dileptonic, semileptonic, and fully hadronic $t\bar{t}$ decays that contain in addition at least two particle-level jets with $p_T > 20$ GeV and $|\eta| < 2.4$. These jets must not originate from the decays of the top quarks or W bosons. There are no requirements imposed on the generator-level leptons or on the particle-level jets that result from the top quark and W boson decays. The measurement in the fiducial phase space is extrapolated to the full phase space by applying an acceptance factor, estimated from simulations, to each signal category based on the additional jet flavours.

The definition of the fiducial phase space is much closer to the reconstructed phase space in which the measurement is performed, and therefore expected to suffers less from theoretical uncertainties that affect the extrapolation from the fiducial to the full phase space. However, the full phase space definition is better suited for comparison with theoretical calculations.

5. Object reconstruction

The global event reconstruction is based on the particle-flow algorithm [41], which aims to reconstruct and identify each individual particle in an event by combining information from the various elements of the CMS detector. The energy of photons is obtained from the ECAL measurement. The energy of electrons is determined from a combination of the electron momentum at the primary interaction vertex as determined by the tracker, the energy of the corresponding ECAL cluster, and the energy sum of all bremsstrahlung photons spatially compatible with originating from

the electron track. The energy of muons is obtained from the curvature of the corresponding track. The energy of charged hadrons is determined from a combination of their momentum measured in the tracker and the matching ECAL and HCAL energy deposits, corrected for zero-suppression effects and for the response function of the calorimeters to hadronic showers. Finally, the energy of neutral hadrons is obtained from the corresponding corrected ECAL and HCAL energies.

For each event, hadronic jets are clustered from these reconstructed particles using the infrared and collinear safe anti- k_T algorithm with a distance parameter of 0.4. Jet momentum is determined as the vectorial sum of all particle momenta in the jet, and is found from simulations to be, on average, within 5 to 10% of the true momentum over the whole p_T spectrum and detector acceptance. Pileup interactions can contribute additional tracks and calorimetric energy depositions, increasing the apparent jet momentum. To mitigate this effect, tracks identified as originating from pileup vertices are discarded and an offset correction is applied to correct for remaining contributions. Jet energy corrections are derived from simulation studies so that the average measured response of jets becomes identical to that of particle-level jets. In situ measurements of the momentum balance in dijet, photon+jets, Z + jets, and multijet events are used to determine any residual differences between the jet energy scale in data and simulations [42], and appropriate corrections are made. Additional selection criteria are applied to each jet to remove jets potentially dominated by instrumental effects or reconstruction failures.

The missing transverse momentum vector \vec{p}_T^{miss} is computed as the negative of the vector sum of the \vec{p}_T of all the particle-flow candidates in an event, and its magnitude is denoted as p_T^{miss} [43]. The \vec{p}_T^{miss} is modified to account for corrections to the energy scale of the reconstructed jets in the event.

The candidate vertex with the largest value of summed physics-object p_T^2 is taken to be the primary pp interaction vertex. The physics objects are the jets and the associated p_T^{miss} .

Jets originating from the hadronization of b and c quarks are identified using the deep combined secondary vertex (DeepCSV) algorithm [14], which uses information on the decay vertices of long-lived mesons and the impact parameters of the charged particle tracks as input to a deep neural network (NN) classifier. For the identification of b jets, a medium working point is chosen, corresponding to a $\approx 70\%$ efficiency for correctly selecting b jets and a misidentification probability for LF (c) jets of $\approx 1(12)\%$, derived from simulated $t\bar{t}$ events. The same algorithm also provides discriminators to distinguish c jets from LF and b jets, which are collectively referred to as c tagging discriminators. The information from the distributions of these observables plays a key role in this analysis, and the calibration of the c tagger is further discussed in Section 8.

6. Event selection

An event selection has been employed to select a subset of events that consists almost exclusively (more than 95% as evaluated from simulations) of dileptonic $t\bar{t}$ events with at least two additional jets. Exactly two reconstructed, oppositely charged leptons (either electrons or muons) are required to be present. This procedure also selects τ leptons that decay into an electron or a muon. The electrons and muons are required to have $p_T > 25$ GeV and $|\eta| < 2.4$, and should be isolated from other objects in the event. At least four jets are required in the event, all of which must be spatially separated from the isolated leptons by imposing $\Delta R(\ell, \text{jet}) > 0.5$. Only jets with $p_T > 30$ GeV and $|\eta| < 2.4$ are considered. An assignment of the jets to the expected partons is made to identify the b jets from top quark decays and jets originating from additional radiation (described in detail in Section 7). The

two jets assigned to the b quarks from the top quark decays are required to be b tagged. Neutrinos from leptonically decaying W bosons are not detected, but instead contribute to the p_T^{miss} , which is required to exceed 30 GeV in events with two electrons (ee) or two muons ($\mu\mu$), in order to reduce contributions from DY events. In events with one electron and one muon ($e\mu$), no requirement is imposed on p_T^{miss} . In order to further reduce the contribution from DY production in ee and $\mu\mu$ events, the invariant mass of the two leptons ($m_{\ell\ell}$) is required to be outside of the Z boson mass window, $m_{\ell\ell} \notin [m_Z - 15, m_Z + 15]$ GeV, with $m_Z = 91.2$ GeV [44]. For all events, it is required that $m_{\ell\ell} > 12$ GeV in order to minimize contributions from low-mass resonances.

7. Matching jets to partons

The distinction among the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}L\bar{L}$ categories relies on the correct identification of the additional jets not coming from the decay of the top quarks. Assuming a 100% branching fraction for the decay $t \rightarrow bW$, and focusing on the dileptonic decay channel, two b jets are expected from the top quark decays and at least two additional jets are required through the other event selection criteria. In practice, not all b jets from top quark decays will be reconstructed within the acceptance of the detector and additional jets will also not necessarily pass the reconstruction and selection criteria. In this section, a matching procedure is described to achieve the most accurate correspondence between the final-state jets and the expected partons. This is done by considering all possible permutations of four jets in the collection of jets passing the selection criteria described in Section 6 and training a NN to identify the correct jet-parton assignment.

Whether a given permutation corresponds to a correct jet-parton assignment can be inferred from different quantities, such as the jet kinematic variables, b and c tagging discriminators, and angular separations and invariant masses between pairs of jets (and between jets and leptons). The NN processes, for each event, all possible jet-parton assignments and is trained on the aforementioned observables to give the highest possible score to the correct permutation. For the $t\bar{t}L\bar{L}$, $t\bar{t}c\bar{c}$, and $t\bar{t}cL$ categories, the b and c tagging discriminators dominate the decision made by the NN. For the $t\bar{t}b\bar{b}$ category all four partons have the same flavour, so the correct assignment of the four b jets relies mainly on the angular separations and invariant masses between jets or leptons. The best assignment for the $t\bar{t}bL$ category benefits from a combination of all these observables.

The main objective is to identify additional HF jets in the event. In the assignment of b jets from the $t\bar{t}$ decays, it does not matter which b jet is matched to the decay of the top quark or anti-quark. Any permutation for which these b jets are reversed can still be considered appropriate for this measurement. If at least one additional b or c jet is present, a correct permutation has to identify these as the first or second additional jets. The NN is also trained to choose a permutation in which the first additional jet has a larger b tagging discriminator value than the second additional jet. With these considerations in mind, three output classes are defined. One of the NN outputs denotes the probability for a given permutation to correspond to the correct jet-parton assignment (P^+). Another output class refers to those permutations for which the additional jets are correctly matched, but the b jets from the $t\bar{t}$ decays are reversed as explained above (P^\times). The third output represents all permutations for which the matching is wrong (P^-), meaning that either at least one of the b jets from the $t\bar{t}$ decays is not correctly matched, or an additional HF jet is found but is not identified as either the first or the second additional jet. The best jet-parton assignment is then identified by selecting the permutation with the highest value of:

Fig. 2. Comparison between data (points) and simulated predictions (histograms) for the distribution of the NN score for the best permutations of jet-parton assignments found in each event. Underflow is included in the first bin. The distributions are found after the event selections outlined in Section 6, but before fitting the predicted signal yields to the data. The lower panel shows the ratio of the yields in data to those predicted in simulations. The vertical bars represent the statistical uncertainties in data, while the hatched bands show the statistical uncertainty in the simulated predictions.

$$\max\left(\frac{P^+}{P^+ + P^-}, \frac{P^\times}{P^\times + P^-}\right). \quad (1)$$

The NN is trained using the KERAS deep learning library [45], interfaced to TENSORFLOW [46] as a back end. Its architecture is composed of two fully connected hidden layers with 50 neurons each, and with a rectified linear unit activation function. The training is performed using an independent data set of simulated $t\bar{t}$ events that pass all the event selections outlined in Section 6, except for the b tagging requirement. Only events for which the two generator-level b quarks from top quark decays lie within $\Delta R < 0.3$ of a reconstructed b jet are used for the training. These constitute $\approx 76\%$ of the simulated $t\bar{t}$ events with at least two additional jets. Of those, the NN correctly identifies the two additional c (b) jets in 50 (30)% of the cases for $t\bar{t}c\bar{c}$ ($t\bar{t}b\bar{b}$) events. For $t\bar{t}b\bar{b}$ events, the matching is more challenging because the HF tagging information cannot help in separating additional b jets from those originating from top quark decays. A comparison between data and simulations of the NN score for the best permutation in each event is shown in Fig. 2, indicating good agreement between the two.

8. Charm jet identification and calibration

The DeepCSV HF tagging algorithm has a multiclass output structure that predicts the probabilities for each jet to contain a single b hadron ($P(b)$), two b hadrons ($P(bb)$), one or more c hadrons ($P(c)$), or no b or c hadrons ($P(\text{udsg})$). The b tagger used throughout this analysis is constructed from the sum $P(b) + P(bb)$. However, different combinations of output values provide different types of discrimination. Since the displacements of tracks and secondary vertices for c jets are on average smaller than those for b jets and larger than those for LF jets, a charm jet identification algorithm uses a combination of two discriminators. The first is used to distinguish c jets from LF jets (CvsL) and the second separates c jets from b jets (CvsB). The CvsL and CvsB discriminators are defined from the multiclass output structure of the DeepCSV algorithm as:

$$\begin{aligned} \text{CvsL} &= \frac{P(c)}{P(c) + P(\text{udsg})}, \\ \text{CvsB} &= \frac{P(c)}{P(c) + P(b) + P(\text{bb})}. \end{aligned} \quad (2)$$

The c tagging discriminators require calibration with the data, given that these algorithms are trained on simulated events and are therefore prone to mismodelling effects in the input variables. The observed initial discrepancies between the data and the simulated predictions can be as large as 50%, as can be seen from the distributions before calibration in Appendix A. In order to use these c tagger discriminators for the fit of the template distributions (as discussed in Section 9), the shape of the two-dimensional (CvsL, CvsB) distribution is corrected to reproduce the distribution observed in data. To this end, a novel calibration technique is employed that uses three control regions selecting for semileptonic $t\bar{t}$, $W + c$, and $DY + \text{jets}$ events, which are enriched in b , c , and LF jets, respectively [47]. By means of an iterative fit in these three control regions, a set of scale factors for each jet flavour is derived, as a function of both the CvsL and CvsB discriminator values of a given jet. The effectiveness of this calibration for different jet flavours has been validated in the three corresponding control regions outlined above, showing that the calibrated distributions in simulations indeed match those in data within the associated uncertainties. Additionally, the method shows no bias when applied to pseudo-data constructed from simulated events that have artificial scale factors applied to them.

After applying this calibration to the simulated events, the distributions of the CvsL and CvsB discriminators provide a good description of the data, as shown in Fig. 3 for the first (upper row) and second (lower row) additional jet. The uncertainties related to this calibration are further discussed in Section 10.

9. Fit to an event-based neural network discriminator

The extraction of the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ cross sections proceeds by means of a template fit to an observable that can distinguish among the different flavour categories. Since the differentiation relies mainly on the additional-jet flavour, the c tagging discriminators of the first and second additional jets provide a natural choice for separating the different signals. The CvsL discriminator distinguishes the $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ from the $t\bar{t}LL$ events, whereas the CvsB discriminator provides additional information that can be used to distinguish between the $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ events. The flavour tagging information for the second additional jet allows the $t\bar{t}cL$ and $t\bar{t}bL$ processes to be identified. Additional information is extracted from two kinematic variables. The first is the angular separation ΔR between the two additional jets. In the $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ processes, the additional jets arise predominantly from gluon splitting into $c\bar{c}$ and $b\bar{b}$ pairs, respectively, and are therefore expected to be more collimated. The second is the NN score for the best permutation (shown in Fig. 2), which is expected to be larger on average for $t\bar{t}LL$ events because the additional jets are well distinguished from the b jets from top quark decays. This observable indirectly incorporates information on the event kinematic features through its input variables.

Using the six aforementioned observables, a NN is trained. Given the relatively small number of inputs, an architecture for the NN is chosen with one hidden layer that comprises 30 neurons with a rectified linear unit activation function. This NN predicts output probabilities for five output classes: $P(t\bar{t}c\bar{c})$, $P(t\bar{t}cL)$, $P(t\bar{t}b\bar{b})$, $P(t\bar{t}bL)$, and $P(t\bar{t}LL)$. To obtain the distributions that are used in the fit, these probabilities are projected onto a two-dimensional phase space spanned by two derived discriminators:

Table 1

Selection efficiencies and acceptance factors for events in different signal categories. The values are obtained from simulated $t\bar{t}$ events.

Event category	$t\bar{t}b\bar{b}$	$t\bar{t}bL$	$t\bar{t}c\bar{c}$	$t\bar{t}cL$	$t\bar{t}LL$

$$\begin{aligned} \Delta_b^c &= \frac{P(t\bar{t}c\bar{c})}{P(t\bar{t}c\bar{c}) + P(t\bar{t}b\bar{b})}, \\ \Delta_L^c &= \frac{P(t\bar{t}c\bar{c})}{P(t\bar{t}c\bar{c}) + P(t\bar{t}LL)}. \end{aligned} \quad (3)$$

These discriminators can be interpreted as topology-specific c tagger discriminators that augment the information on the jet flavour of the two additional jets with additional event kinematic features to optimally distinguish different signal categories. The two-dimensional distributions of these discriminators, normalized to unit area, are shown in Fig. 4 for simulated dileptonic $t\bar{t}$ events. The different signal categories occupy different parts of this phase space, demonstrating that a fit of templates derived from these distributions to the data can be used to extract the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ cross sections. It can be seen that the lower right corner of this phase space is almost exclusively populated with $t\bar{t}b\bar{b}$ events, whereas the upper right corner is dominated by $t\bar{t}c\bar{c}$ events.

Templates are constructed separately for each dilepton channel (ee , $\mu\mu$, and $e\mu$) and are fitted simultaneously to data by means of a binned maximum likelihood fit assuming Poisson statistics. The negative logarithm of the likelihood is minimized using the ‘‘Combine’’ framework developed for the combined Higgs boson measurements performed by ATLAS and CMS [48,49]. Uncertainties are included as nuisance parameters in the definition of the likelihood.

A first fit is performed to extract the absolute cross section (σ) of the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ events in the fiducial phase space, where the expected yield in each bin is parametrized using the function:

$$\begin{aligned} F_i(\sigma_{t\bar{t}c\bar{c}}, \sigma_{t\bar{t}b\bar{b}}, \sigma_{t\bar{t}LL}) = \\ \mathcal{L}^{\text{int}} \left\{ \sigma_{t\bar{t}c\bar{c}} \epsilon_{t\bar{t}c\bar{c}} \left(f_{t\bar{t}c\bar{c},i}^{\text{norm}} + \frac{N_{t\bar{t}c\bar{c}}^{\text{MC}}}{N_{t\bar{t}c\bar{c}}^{\text{MC}}} f_{t\bar{t}cL,i}^{\text{norm}} \right) \right. \\ + \sigma_{t\bar{t}b\bar{b}} \epsilon_{t\bar{t}b\bar{b}} \left(f_{t\bar{t}b\bar{b},i}^{\text{norm}} + \frac{N_{t\bar{t}bL}^{\text{MC}}}{N_{t\bar{t}b\bar{b}}^{\text{MC}}} f_{t\bar{t}bL,i}^{\text{norm}} \right) \\ \left. + \sigma_{t\bar{t}LL} \epsilon_{t\bar{t}LL} \left(f_{t\bar{t}LL,i}^{\text{norm}} + \frac{N_{t\bar{t}+other}^{\text{MC}}}{N_{t\bar{t}LL}^{\text{MC}}} f_{t\bar{t}+other,i}^{\text{norm}} \right) \right\} \\ + \mathcal{L}^{\text{int}} \sigma_{\text{bkg}} f_{\text{bkg},i}^{\text{norm}}. \end{aligned} \quad (4)$$

Here, \mathcal{L}^{int} denotes the total integrated luminosity and f_i^{norm} represents a given bin (with index i) of the simulated two-dimensional template, normalized to unit area. The measurements in the reconstructed phase space are corrected to the fiducial phase space through an efficiency (ϵ). To extract the result in the full phase space, an additional acceptance factor, \mathcal{A} , is applied to the extracted fiducial cross section to account for the difference in acceptance between the fiducial and full phase spaces. The efficiency and acceptance factors are summarized in Table 1, and are calculated from simulations. The largest contribution to the acceptance can be attributed to the extrapolation from the dileptonic to the fully inclusive decays of the $t\bar{t}$ pairs. The remaining contributions are due to changes in kinematic requirements on the generator-level objects. As discussed in Section 4, the $t\bar{t}cL$ and $t\bar{t}bL$ categories result from $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ events, respectively, where one of the additional HF jets is outside the acceptance or both are merged

Fig. 3. Comparison between data (points) and simulated predictions (histograms) for the CvsL (left column) and CvsB (right column) c tagging discriminator distributions of the first (upper row) and second (lower row) additional jet after applying the c tagging calibration. The distributions are found after the event selections outlined in Section 6, but before fitting the predicted signal yields to the data. The lower panels show the ratio of the yields in data to those predicted in simulations. The vertical bars represent the statistical uncertainties in data, while the hatched bands show the systematic uncertainty from the c tagging calibration only.

Fig. 4. Normalized two-dimensional distributions of Δ_b^c vs. Δ_L^c in simulated dileptonic $t\bar{t}$ events, for each of the event categories outlined in Section 4. The colour scale on the right shows the normalized event yields.

into one jet. Therefore, these components are scaled with the same factors as the $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ templates, respectively, such that the relative yield of $t\bar{t}cL$ ($t\bar{t}bL$) with respect to $t\bar{t}c\bar{c}$ ($t\bar{t}b\bar{b}$) events is fixed to that predicted in the simulations. The predicted yields from the simulations are denoted by N_k^{MC} , where k denotes the signal process. The $t\bar{t}$ +other component is scaled with the same factor as the $t\bar{t}LL$ component, motivated by their similar LF content. Uncertainties in the ratios of simulated yields are taken into account in the fit. The background processes are summed together into one template and their yield is fixed to the predictions from simulations, with uncertainties taken into account as discussed in Section 10. The sum of the cross sections for the background processes (obtained from simulations) is denoted as σ_{bkg} .

A second binned maximum likelihood fit is performed assuming Poisson statistics to extract the ratios of the $t\bar{t}c\bar{c}$ and $t\bar{t}b\bar{b}$ cross sections to the overall inclusive $t\bar{t}jj$ cross section (denoted R_c and R_b , respectively) in the fiducial phase space, with the expected yield in bin i calculated using the function:

$$F_i(\sigma_{t\bar{t}jj}, R_c, R_b) = \mathcal{L}^{\text{int}} \sigma_{t\bar{t}jj} \left\{ R_c \epsilon_{t\bar{t}c\bar{c}} \left(f_{t\bar{t}c\bar{c},i}^{\text{norm}} + \frac{N_{t\bar{t}cL}^{MC}}{N_{t\bar{t}c\bar{c}}^{MC}} f_{t\bar{t}cL,i}^{\text{norm}} \right) + R_b \epsilon_{t\bar{t}b\bar{b}} \left(f_{t\bar{t}b\bar{b},i}^{\text{norm}} + \frac{N_{t\bar{t}bL}^{MC}}{N_{t\bar{t}b\bar{b}}^{MC}} f_{t\bar{t}bL,i}^{\text{norm}} \right) + (1 - R_c - R_{cL} - R_b - R_{bL}) \epsilon_{t\bar{t}LL} \left(f_{t\bar{t}LL,i}^{\text{norm}} + \frac{N_{t\bar{t}+other}^{MC}}{N_{t\bar{t}LL}^{MC}} f_{t\bar{t}+other,i}^{\text{norm}} \right) \right\} + \mathcal{L}^{\text{int}} \sigma_{bkg} f_{bkg,i}^{\text{norm}},$$

with

$$\begin{cases} R_{cL} = R_c \left(\frac{N_{t\bar{t}cL}^{MC} \epsilon_{t\bar{t}c\bar{c}}}{N_{t\bar{t}c\bar{c}}^{MC} \epsilon_{t\bar{t}cL}} \right), \\ R_{bL} = R_b \left(\frac{N_{t\bar{t}bL}^{MC} \epsilon_{t\bar{t}b\bar{b}}}{N_{t\bar{t}b\bar{b}}^{MC} \epsilon_{t\bar{t}bL}} \right). \end{cases} \quad (6)$$

The parameters R_{cL} and R_{bL} are used to denote, respectively, the ratios of the $t\bar{t}cL$ and $t\bar{t}bL$ cross sections to the inclusive $t\bar{t}jj$ cross section, and are defined as a function of R_c and R_b in Eq. (6).

10. Systematic uncertainties

This section summarizes the systematic uncertainties related to the extraction of the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ cross sections (and the ratios R_c and R_b), as well as corrections applied to the simulated events to account for differences with respect to data. Systematic uncertainties are treated as nuisance parameters in the template fit to data that can affect both the shapes of the templates and the yields of the signal and background processes. A smoothing procedure [50] is applied to the templates that describe the uncertainty variations affecting the template shape. The sources of systematic uncertainties are subdivided into experimental and theoretical components and are discussed below.

Experimental uncertainties: These uncertainties affect both the shape and normalization of the templates. The jet energy resolution is known to be worse in data than in simulations, and a corresponding additional smearing is applied to the simulated jet energies [42]. Systematic uncertainties are estimated by varying the smearing of the jet energy within its uncertainties in the calculation of the cross sections. Similarly, we take into account corrections and uncertainties from observed differences in the jet

energy scale. These corrections are evaluated and applied in different regions of jet p_T and $|\eta|$. Observed differences in electron and muon identification, isolation, reconstruction, and trigger efficiencies between data and simulations are taken into account through p_T - and η -dependent scale factors, with the corresponding uncertainties accounted for. The distribution of the number of pileup collisions in simulated events is reweighted to match the distribution observed in data, using an inelastic pp cross section of 69.2 mb [51]. An uncertainty related to this correction is applied by varying this inelastic cross section by $\pm 4.6\%$. An uncertainty of 2.3% [15] in the total integrated luminosity is also taken into account. The scale factors extracted from the c tagging calibration are applied to the simulated events, and corresponding uncertainties are considered. Uncertainties related to this calibration are found to be dominated by the choice of μ_R and μ_F in the $W + c$ and $DY + jets$ control regions, affecting scale factors for c and LF jets, respectively, and by PS uncertainties in semileptonic $t\bar{t}$ events that affect scale factors for b jets, together with a significant contribution from statistical uncertainties for all jet flavours. Most of the theoretical and experimental sources of uncertainty are in common between the control regions in which the c tagging calibration is derived and the $t\bar{t}$ dileptonic signal region considered in this analysis. In such cases, the common uncertainties are considered fully correlated and evaluated simultaneously.

Theoretical uncertainties: In the ME calculation, the choice of μ_R and μ_F can have an impact on the kinematic distributions of the final-state objects. Uncertainties in these scales are taken into account by rescaling μ_F and μ_R up or down by a factor of two at the ME level [52,53]. The choice was made not to include the difference between PYTHIA and alternative PS simulations as a systematic uncertainty in this analysis. Instead a variety of parameters in PYTHIA, sensitive to the PS and hadronization, are consistently varied to assess the uncertainty in an unambiguous way. In the PS, the uncertainty in the value of the strong coupling constant (α_S) evaluated at m_Z is taken into account by varying the renormalization scale of QCD emissions in the initial- and final-state radiation up and down by a factor of two. Similarly, uncertainties in the momentum transfer from b quarks to b hadrons (b fragmentation) in the PS have been included. The b fragmentation in PYTHIA is parametrized using a Bowler–Lund model [54–56], with uncertainties calculated by tuning the internal parameters of this model to measurements from the ALEPH [57], DELPHI [58], OPAL [59] and SLD [60] experiments. In practice, it was found that this parametrization can be varied within its uncertainties by a reweighting at the generator level of the so-called “transfer function”, $x_b = p_T(b \text{ hadron})/p_T(b \text{ jet})$. No such detailed assessment of the c fragmentation uncertainties has yet been performed, but a similar level of variation is observed when comparing the available experimental measurements [61] with the default PYTHIA tune used in this analysis [62]. We verified that variations of the c jet transfer function ($x_c = p_T(c \text{ hadron})/p_T(c \text{ jet})$) induce similar variations of the c jet p_T and c tagging discriminator distributions as the analogous variations in b fragmentation for b jets, and found that these effects are comfortably covered by an uncertainty a factor of two larger than that for b fragmentation. This uncertainty is modelled as an uncertainty in the $t\bar{t}c\bar{c}$ and $t\bar{t}cL$ yields in the fit in the fiducial phase space, and an additional uncertainty in the acceptance correction from the full to the fiducial phase space. Uncertainties associated with the PDF, as well as with the value of α_S in the PDF of the proton are considered, following the PDF4LHC prescription [63]. For all of the aforementioned theoretical sources of uncertainty (except for the c fragmentation uncertainty), the effects of these variations on the shape of the fitted templates are taken into account in the fit, whereas their impact on the signal yields is considered as an uncertainty in the theoretical prediction to which the measurement is compared in Section 11. The resid-

Table 2

Sources of theoretical uncertainties in the acceptance, used to extrapolate the results from the fiducial to the full phase space, for different signal categories, together with their individual impact in percent. The last row of the table quotes the total relative uncertainty in the acceptance, calculated by adding in quadrature the effects from individual sources. A dash indicates that the uncertainty is not applicable for that signal category.

Sources	Uncertainty in the acceptance (%)

Total	5.9	4.3	5.0	4.2	3.4

ual theoretical uncertainty that enters the measured cross sections through the ϵ_i terms in Eqs. (4) and (5) is accounted for by a separate theoretical uncertainty in the efficiency. The experimental uncertainties in the efficiency are already taken into account through the uncertainties in the normalization of the templates. The matching between the ME and PS is governed by a parameter called h_{damp} . The value of this parameter is varied according to $h_{\text{damp}} = \left(1.379^{+0.926}_{-0.505}\right) m_t$ [31] in a separate simulation. Since the size of this simulated data set is insufficient to reliably estimate the effect on the shapes of the templates, this uncertainty is conservatively estimated through its effect on the overall yield. The remnants of the pp collisions that do not take part in the hard scattering are referred to as the underlying event. Their kinematic distributions are tuned in the generators to match those observed in the data [31]. The resulting parametrization of the CP5 tune, used in this analysis, is varied within its uncertainties in separate simulations. Here too the effect of the uncertainty in the overall yield, rather than in the template shapes, is propagated to the measured cross sections. The effects of the theoretical uncertainties listed above on the fixed ratios of $t\bar{t}bL$ to $t\bar{t}b\bar{b}$, $t\bar{t}cL$ to $t\bar{t}c\bar{c}$, and $t\bar{t}$ -other to $t\bar{t}LL$ yields, taken from simulations in Eqs. (4) and (5), are also included in the fit. An uncertainty of 25% is assigned to the total cross section of all background processes, based on the precision of recent measurements of the dominant background processes [64,65]. The statistical uncertainty due to the finite size of the simulated samples is taken into account in the fit. In extrapolating the results from the fiducial to the full phase space, some of these theoretical uncertainties also affect the acceptance for the different signal categories. The individual and combined impacts of different sources of uncertainty in the acceptance are summarized in Table 2.

The individual impacts from each source of uncertainty in the cross sections (and ratios) for the fiducial phase space after the fit are summarized in Table 3. The fitted nuisance parameters do not deviate significantly from their initial values and are not significantly constrained. No strong correlations between any of the nuisance parameters and the fitted cross sections or ratios are observed. The dominant systematic uncertainties are related to the c tagging calibration, followed by jet energy scale and fragmentation uncertainties, as well as uncertainties related to the matching between ME and PS, and the choice of μ_R and μ_F scales in the ME calculation.

11. Results

The binning of the two-dimensional Δ_L^c vs. Δ_b^c distribution is chosen to be:

Fig. 5. A one-dimensional representation of the two-dimensional Δ_L^c vs. Δ_b^c distributions, in the simulations (histograms) and in data (points), after normalizing the simulated templates according to the fitted cross sections. The lower panel shows the ratio of the yields in data to those predicted in the simulations. The brown and grey uncertainty bands denote, respectively, the statistical and total uncertainties from the fit. The factors (μ) by which the templates of the different processes (using the POWHEG ME generator) are scaled, are also displayed, together with their combined statistical and systematic uncertainties.

$$\Delta_L^c \otimes \Delta_b^c : \quad (7)$$

$$[0, 0.55, 0.65, 0.85, 1.0] \otimes [0, 0.35, 0.5, 0.6, 1.0].$$

This gives a total of 16 bins with varying compositions of signal categories. From these 16 bins, a one-dimensional histogram is created in which the first four bins correspond to the first bin in Δ_b^c , with increasing values of Δ_L^c , and then analogously for the remainder of the bins. This histogram is shown in Fig. 5 after normalizing the simulated templates according to the fitted cross sections. The factors by which the templates of the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ processes (using the POWHEG ME generator) are scaled to match the data are denoted $\mu_{t\bar{t}c\bar{c}}$, $\mu_{t\bar{t}b\bar{b}}$, and $\mu_{t\bar{t}LL}$, respectively. Their measured values from the fit are displayed in the top panel of Fig. 5, together with their combined statistical and systematic uncertainties. An improved agreement between data and simulated predictions is also observed for the c tagging discriminators of the first and second additional jets after normalizing the simulated templates according to the fitted cross sections. This is demonstrated in Appendix B and can be directly compared to the agreement before the fit in Fig. 3.

The measured cross sections in the fiducial and full phase spaces, together with their statistical and systematic uncertainties, are summarized in Table 4 and compared to predictions using the POWHEG and MADGRAPH5_AMC@NLO ME generators. Uncertainties in the measured values of the cross sections and ratios are determined from the points where the decrease in the logarithm of the profiled likelihood from the best-fit value intersects with 0.5. The inclusive $t\bar{t}c\bar{c}$ cross section and the ratio R_c are measured here for the first time. They are in agreement with the predictions from both ME generators, within the uncertainties.

In addition, two-dimensional likelihood scans are performed over different combinations of cross sections or ratios. These are shown in Fig. 6 for the measurements in the fiducial phase space. The 68 and 95% confidence level contours are shown, along with the predictions from the POWHEG and MADGRAPH5_AMC@NLO ME generators. Agreement is observed at the level of one to two standard deviations between the measured values and simulated predictions for the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ processes. The most significant tension is observed in the ratio R_b , at the level of 2.5 standard deviations. Results for $\sigma_{t\bar{t}b\bar{b}}$ and R_b are consistent with previous measurements targeting specifically this signature [6–13] and show the

same tendency to be slightly above the predictions from simulations.

12. Summary

The production of a top quark pair ($t\bar{t}$) in association with additional bottom or charm jets at the LHC provides challenges both in the theoretical modelling and experimental measurement of this process. Whereas $t\bar{t}$ production with two additional bottom jets ($t\bar{t}b\bar{b}$) has been measured by the ATLAS and CMS Collaborations at different centre-of-mass energies [6–13], this analysis presents the first measurement of the cross section for $t\bar{t}$ production with two additional charm jets ($t\bar{t}c\bar{c}$). The analysis is conducted using data from proton-proton collisions recorded by the CMS experiment at a centre-of-mass energy of 13 TeV, corresponding to an integrated luminosity of 41.5 fb^{-1} . The measurement is performed in the dileptonic channel of the $t\bar{t}$ decays and relies on the use of recently developed charm jet identification algorithms (c tagging). A template fitting method is used, based on the outputs of

a neural network classifier trained to identify the signal categories defined by the flavour of the additional jets. This allows the simultaneous extraction of the cross section for the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}$ with two additional light-flavour or gluon jets ($t\bar{t}LL$) processes. A novel multidimensional calibration of the shape of the c tagging discriminator distributions is employed, such that this information can be reliably used in the neural network classifier.

The $t\bar{t}c\bar{c}$ cross section is measured for the first time to be $0.207 \pm 0.025 \text{ (stat)} \pm 0.027 \text{ (syst)} \text{ pb}$ in the fiducial phase space (matching closely the sensitive region of the detector) and $10.1 \pm 1.2 \text{ (stat)} \pm 1.4 \text{ (syst)} \text{ pb}$ in the full phase space. The ratio of the $t\bar{t}c\bar{c}$ to the inclusive $t\bar{t}$ + two jets cross sections is found to be $(3.01 \pm 0.34 \text{ (stat)} \pm 0.31 \text{ (syst)})\%$ in the fiducial phase space and $(3.36 \pm 0.38 \text{ (stat)} \pm 0.34 \text{ (syst)})\%$ in the full phase space. These results are compared with predictions from two different matrix element generators with next-to-leading order accuracy in quantum chromodynamics, in which an inclusive description of the $t\bar{t}$ process, with up to two additional radiated hard gluons at the

Table 3

Classes of systematic uncertainties in the measured parameters and their individual impact in percent after the fit for the fiducial phase space. The upper (lower) rows of the table list uncertainties related to the experimental conditions (theoretical modelling). For classes describing contributions from multiple nuisance parameters, the quoted numbers are obtained by adding the impacts from individual sources within that class in quadrature. The last row gives the overall systematic uncertainty in each quantity, which results from the nuisance parameter variations in the fit and is not the quadrature sum of the individual components.

The factors (μ) by which the templates of the different processes (using the POWHEG ME generator) are scaled, are also displayed, together with their combined statistical and systematic uncertainties.

ME level, is interfaced with a parton shower simulation to generate the additional radiation. Agreement is observed at the level of one to two standard deviations between the measured values and simulated predictions for the $t\bar{t}c\bar{c}$, $t\bar{t}b\bar{b}$, and $t\bar{t}LL$ processes. The observed ratio of the $t\bar{t}b\bar{b}$ to the inclusive $t\bar{t}$ + two jets cross sections exceeds the predictions by about 2.5 standard deviations, consistent with the tendency seen in previous measurements.

Declaration of competing interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centres and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMBWF and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, FAPERGS, and FAPESP

(Brazil); MES (Bulgaria); CERN; CAS, MOST, and NSFC (China); COLCIENCIAS (Colombia); MSES and CSF (Croatia); RIF (Cyprus); SENESCYT (Ecuador); MoER, ERC PUT and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); NKfIA (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); MSIP and NRF (Republic of Korea); MES (Latvia); LAS (Lithuania); MOE and UM (Malaysia); BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI (Mexico); MOS (Montenegro); MBIE (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Dubna); MON, ROSATOM, RAS, RFBR, and NRC KI (Russia); MESTD (Serbia); SEIDI, CPAN, PCTI, and FEDER (Spain); MoSTR (Sri Lanka); Swiss Funding Agencies (Switzerland); MST (Taipei); ThEPCenter, IPST, STAR, and NSTDA (Thailand); TUBITAK and TAEK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF (USA).

Appendix A. Charm tagging discriminators before calibration

The c tagging algorithms are trained on simulated events and are therefore prone to mismodelling effects in the input variables. The initial C_{vsL} and C_{vsB} c tagging discriminator distributions of the first and second additional jet are shown in Fig. 7. Discrepancies between the data and the simulated predictions of up to 50% are observed, demonstrating the need for the c tagging calibration described in Section 8.

Appendix B. Charm tagging discriminators after scaling to the fitted cross sections

After scaling the simulated templates of the c tagging discriminators to their fitted yields, the agreement between data and simulations is shown in Fig. 8. This can be compared to the agreement before the fit was performed in Fig. 3, and indeed shows an improved agreement especially in those bins which have a relatively large contribution from $t\bar{t}b\bar{b}$ and $t\bar{t}c\bar{c}$ events.

ABSTRACT: This document aims to provide an assessment of the potential of future colliding beam facilities to perform Higgs boson studies. The analysis builds on the submissions made by the proponents of future colliders to the European Strategy Update process, and takes as its point of departure the results expected at the completion of the HL-LHC program. This report presents quantitative results on many aspects of Higgs physics for future collider projects of sufficient maturity using uniform methodologies.

KEYWORDS: e⁺-e⁻ Experiments, Electroweak interaction, Higgs physics

1 Introduction

This article presents the results of the Standard Model (SM) Higgs boson studies performed by the *Higgs@FutureColliders* group based on the input submitted to the Update of the European Strategy by the various proponents of new high-luminosity energy-frontier particle accelerator projects beyond the *High Luminosity LHC* (HL-LHC). This report fulfils part of the mandate given to this group by the restricted ECFA (REFCA) committee, see appendix A. The exploration of the Higgs boson through direct searches and precision measurements at future colliders is among the most important aspects of their scientific programmes.

The colliders considered for this document are High-Energy LHC (HE-LHC), Future Circular Colliders (FCC-ee,eh,hh) [1], the Circular Electron-Positron Collider (CEPC) [2], the International Linear Collider (ILC) [3, 4], the Compact Linear Collider (CLIC) [5], and the Large Hadron electron Collider [6] (LHeC or HE-LHeC¹). The physics results that are expected by the completion of HL-LHC are assumed to represent the scenario from where these future colliders would start. Furthermore, a muon collider is also briefly illustrated, but given the less advanced stage, it is not part of the default analyses performed. The potential of a $\gamma\gamma$ collider (based on an e^+e^- collider and laser beams) for Higgs boson physics has been studied a while ago [7, 8] and more recently again in context of plasma-wakefield driven accelerators [9]. Plasma-wakefield driven accelerators also offer promise to provide multi-TeV e^+e^- colliders (e.g. [9]) and are addressed briefly later in this report.

A table of the colliders and their parameters (type, \sqrt{s} , polarisation \mathcal{P} , integrated luminosity \mathcal{L} , the run time) is given in table 1. A graphical display of the time line and luminosity values is shown in figure 1. The parameters used are taken from the references also given in that table. For the purpose of this study, only inputs as provided by the various collaborations are used, and there is no attempt to make any judgement on the validity of the assumptions made in estimating the projected measurement uncertainties (see also mandate in appendix A). In addition to the collider runs shown in table 1, a few other scenarios are considered such as FCC-hh with $\sqrt{s} = 37.5$ TeV [10] and $\mathcal{L} = 15$ fb⁻¹, FCC-ee with 4 instead of 2 IPs (doubling the total integrated luminosity), and CLIC and ILC with a dedicated running period of 1–3 years to collect $\mathcal{L} = 100$ fb⁻¹ at $\sqrt{s} \approx M_Z$ [4, 11]. These are discussed in appendix F.

¹For HE-LHeC no analysis was performed here, but it is expected that the relative improvements w.r.t. LHeC are expected to be similar as from HL-LHC to HE-LHC.

Collider	Type	\sqrt{s}	\mathcal{P} [%] [e^-/e^+]	N(Det.)	$\mathcal{L}_{\text{inst}}$ [10^{34}] $\text{cm}^{-2}\text{s}^{-1}$	\mathcal{L} [ab^{-1}]	Time [years]	Refs.	Abbreviation
HL-LHC	pp	14 TeV	—	2	5	6.0	12	[13]	HL-LHC

Table 1. Summary of the future colliders considered in this report. The number of detectors given is the number of detectors running concurrently, and only counting those relevant to the entire Higgs physics programme. The instantaneous and integrated luminosities provided are those used in the individual reports, and for e^+e^- colliders the integrated luminosity corresponds to the sum of those recorded by the detectors. For HL-LHC this is also the case while for HE-LHC and FCC_{hh} it corresponds to 75% of that. The values for \sqrt{s} are approximate, e.g. when a scan is proposed as part of the programme this is included in the closest value (most relevant for the Z , W and t programme). For the polarisation, the values given correspond to the electron and positron beam, respectively. For HL-LHC, HE-LHC, FCC, CLIC and LHeC the instantaneous and integrated luminosity values are taken from ref. [12]. For these colliders the number of seconds per year is 1.2×10^7 based on CERN experience [12]. CEPC (ILC) assumes 1.3×10^7 (1.6×10^7) seconds for the annual integrated luminosity calculation. When two values for the instantaneous luminosity are given these are before and after a luminosity upgrade planned. The last column gives the abbreviation used in this report in the following sections. When the entire programme is discussed, the highest energy value label is used, e.g. ILC₁₀₀₀ or CLIC₃₀₀₀. It is always inclusive, i.e. includes the results of the lower-energy versions of that collider. Also given are the shutdowns (SDs) needed between energy stages of the machine. SDs planned during a run at a given energy are included in the respective energy line. (*) For FCC-hh a value of $\sqrt{s} = 37.5$ TeV is also considered, see appendix F. Additional scenarios where ILC/CLIC accumulate 100 fb^{-1} on the Z -pole, and where FCC-ee has 4 IPs are also discussed in appendix F.

	T_0	+5	+10	+15	+20	...	+26
ILC	0.5/ab 250 GeV		1.5/ab 250 GeV	1.0/ab 500 GeV	0.2/ab $2m_{top}$	3/ab 500 GeV	
CEPC	5.6/ab 240 GeV		16/ab M_Z	$\frac{2.6}{ab}$ $2M_W$			SppC =>
CLIC	1.0/ab 380 GeV			2.5/ab 1.5 TeV			5.0/ab => until +28 3.0 TeV
FCC	150/ab ee, M_Z	10/ab ee, $2M_W$	5/ab ee, 240 GeV		1.7/ab ee, $2m_{top}$		hh.eh =>
LHeC	0.06/ab		0.2/ab	0.72/ab			
HE-LHC	10/ab per experiment in 20y						
FCC eh/hh	20/ab per experiment in 25y						

Figure 1. Time line of various collider projects starting at time T_0 as submitted to the European Strategy Update process. Some possible extensions beyond these baseline run plans have been discussed and are presented in more detail in appendix F. For the clarification of the meaning of a year of running, see the caption of table 1. Figure 13 in appendix C shows an alternative version of this figure using the earliest possible start date (i.e. the calendar date of T_0) given by the proponents.

For the following sections the tables and plots are labelled using the acronyms given in table 1. The energy subscript indicates the highest energy stage of the given collider, and the results always assume that it is combined with results from the lower energy stages.

At the heart of the Higgs physics programme is the question of how the Higgs boson couples to Standard Model elementary particles. Within the SM itself, all these couplings are uniquely determined. But new physics beyond the SM (BSM) can modify these couplings in many different ways. The structure of these deformations is in general model-dependent. One important goal of the Higgs programme at the future colliders is to identify, or at least constrain, these deformations primarily from the measurements the Higgs production cross section, σ , times decay branching ratio, BR.² Ultimately, these studies will be used to assess the fundamental parameters of the new physics models. For the time being, in the absence of knowledge of new physics, we need to rely on a parametrisation of our ignorance in terms of continuous deformations of the Higgs boson couplings. Different assumptions allow to capture different classes of new physics dynamics. First, in the so-called κ -framework [16, 17], often used to interpret the LHC measurements, the Higgs couplings to the SM particles are assumed to keep the same helicity structures as in the SM. While it offers a convenient exploration tool that does not require other computations than the SM ones and still captures the dominant effects of well motivated new physics scenarios on a set of on-shell Higgs observables, the κ -framework suffers from some limitations that will be discussed later and it includes some biases that will prevent to put the Higgs programme in perspective with other measurements, see e.g. the discussion in

²The Higgs couplings could be constrained less directly from processes with no Higgs in the final state or without even a non-resonant Higgs. But the main focus of the study presented in this report will be on the information obtained from the measured $\sigma \times BR$. Still, note that, at lepton colliders, the ZH associated production can be measured without the decay of the Higgs.

ref. [18] and at the beginning of section 3. An alternative approach, based on *Effective Field Theory* (EFT), considers new Higgs couplings with different helicity structures, with different energy dependence or with different number of particles. They are not present in the SM but they can potentially be generated by new heavy degrees of freedom.

Furthermore, the sensitivity of the data to the Higgs self-coupling is analysed based on single-Higgs and di-Higgs production measurements by future colliders. Due to lack of access to the simulated data of the collaborations, in particular differential kinematical distributions, it is not possible in this case to perform a study for the Higgs self-coupling with similar rigour as the analysis of the single-Higgs-coupling described in the previous paragraph.

The Higgs width determination is also discussed as is the possible decay of the Higgs bosons into new particles that are either “invisible” (i.e. observed through missing energy - or missing transverse energy) or “untagged”, to which none of the Higgs analyses considered in the study are sensitive. Rare decays and CP aspects are also discussed.

All colliders have provided extensive documentation on their Higgs physics programme. However, sometimes different choices are made e.g. on which parameters to fit for and which to fix, what theoretical uncertainties to assume, which operators to consider in e.g. the EFT approach. This would lead to an unfair comparison of prospects from different future colliders, with consequent confusing scientific information. In this report, we aim to have a single clear and reasonable approach to the assumptions made when comparing the projections for the future.

In general, one should not over-interpret 20% differences between projected sensitivities for partial widths of different future projects. In many cases, these are likely not significant. For instance, CEPC and FCC-ee at $\sqrt{s} = 240$ GeV expect to acquire a very similar luminosity and should obtain very similar results if both use two optimized detectors and analyses. Differences between the projected sensitivities, when considering only results from the $\sqrt{s} = 240$ GeV run, originate likely from different choices made in the analyses at this stage or, in some cases, because an analysis has not yet been performed. For the EFT analysis the measurements at different \sqrt{s} values play an important role, and this results in significant differences as CEPC and FCC-ee have proposed different integrated luminosities at the different \sqrt{s} values and CEPC lacks a run at $\sqrt{s} = 365$ GeV. It is also useful to keep in mind that the target luminosity values have some uncertainties, and historically colliders have sometimes exceeded them (e.g. LHC by a factor of about two in instantaneous luminosity) and sometimes fallen short.

In this document only inclusive cross section times branching ratio measurements, and in some cases ratios of inclusive measurements, are used. It is well known that probing the Higgs boson at high p_T enhances the sensitivity to new physics and the analysis presented here does not capture this. As a result of this, the true power of high-energy colliders (where $\sqrt{\hat{s}} \gg m_H$) for probing Higgs physics is underestimated.

This document is organised as follows. Section 2 discusses the methodology, including the systematic uncertainties on the theoretical calculations which are common to all colliders. Section 3 presents the study made on the Higgs boson couplings to SM elementary particles. The results found in the context of the κ -framework (briefly summarised in sec-

tion 3.1) are presented in section 3.2. Likewise, the results from the EFT fits (summarised in section 3.3) are collected in section 3.4. The impact of theory uncertainties on the Higgs projections is discussed in section 3.5. Particular attention is dedicated to the Higgs self-coupling in section 4 and the Higgs boson rare decays, in section 5. The prospects for measurements of Higgs boson CP properties are given in section 6, and the prospects for precision measurements of the mass and width are summarized in section 7.

Section 8 presents future studies that would be important to deepen to get a more complete view of the Higgs physics potential at future colliders. The Muon Collider (section 8.1) and plasma-wakefield accelerators (section 8.2) are discussed first, and then phenomenological studies that relate the precision measurements to new physics models are discussed (section 8.3).

In the appendix, all theoretical and experimental input parameters related to the Higgs observables are provided, and some results that seemed too detailed for the main body, are also shown.

2 Methodology

The various colliders measure values for the cross sections times branching ratios, $\sigma \times \text{BR}$. At hadron colliders the main processes are gluon-gluon-fusion (ggF), vector boson fusion (VBF), Higgs-strahlung (VH, where $V = Z, W$) and $t\bar{t}H$ production. At lepton colliders, Higgs-strahlung (ZH) dominates at low values of \sqrt{s} , while at high \sqrt{s} values the VBF process becomes dominant. At lepton-hadron colliders, the Higgs boson is dominantly produced via WW or ZZ fusion in the t -channel.

The extraction of the couplings of the Higgs boson relies on a simultaneous fit of all the projected measurements of $\sigma \times \text{BR}$, and their comparison to the SM values. As such, it is sensitive to both the experimental uncertainties as well as theoretical uncertainties on the production cross sections and branching ratios.

At the HL-LHC, these theoretical uncertainties are taken from the S2 scenario of the HL-LHC [13], which assumes that the current uncertainties can be reduced by a factor of two by the end of the HL-LHC running in twenty years.³ For the studies at future lepton colliders we use the future projections for the theory uncertainties on the partial width values given in table 19. At the FCC-hh a 1% total uncertainty is assumed, combined for the luminosity and cross section normalisation [1]. It is expected that this 1% is dominated by the luminosity uncertainty and that theory uncertainties will be negligible in comparison, also thanks to the PDF uncertainty reduction from FCC-eh and/or LHeC. For HL-LHC and HE-LHC a luminosity uncertainty of 1% is assumed. For LHeC the theoretical uncertainties on the charged-current and neutral-current production processes are taken to be 0.5% [19]. For the decays the uncertainties as given in table 19 are used.

Some caution must be taken when studying the HE-LHC results provided here. They are derived from the same inputs as the HL-LHC ones evolved with integrated luminosity and increased cross section. This is a simplified approach, and all the HE-LHC results are

³Apart from improved theoretical calculations, part of this reduction would require a more precise knowledge of PDFs and α_S , which could be possible with an ep machine such as the LHeC.

thus approximations. As in ref. [13], we consider 2 scenarios: one where we use the same S2 assumptions as for the HL-LHC; and a second scenario, denoted S2', which assumes a further reduction in the signal theoretical systematic uncertainties by another factor of two with respect to the S2 scenario at the HL-LHC, i.e. roughly four times smaller than current studies from Run 2. It must be noted that such reduction of the uncertainty is not motivated on solid theoretical grounds and it is simply a hypothesis, based on the reasoning that the time available to make progress is significantly longer for HE-LHC than HL-LHC. When combined with the HL-LHC, the theory systematics are assumed to be fully correlated between HL-LHC and HE-LHC, using the same uncertainties, S2 or S2', for both colliders.

For the purpose of the analyses presented here, it is assumed that all observables of relevance have the SM value and there are no new physics effects present in the simulated data. If new physics effects are observed e.g. in the data from the 2nd or 3rd LHC run, either in the Higgs sector or otherwise, the analysis method and assumptions made will likely change significantly.

The combination of any future data with HL-LHC results is done assuming no correlations between the colliders, except for those between HL-LHC and HE-LHC which are treated as discussed above.

In the input HL-LHC predictions it is assumed that the intrinsic theory systematic uncertainties for the various production modes are uncorrelated. A consequence of this assumption is that, when Higgs model parameters are constructed that represent (directly or indirectly) an average over independent measurements with independent theory uncertainties that are all interpreted to measure the same physics quantity (e.g. the global signal strength μ , or the EFT parameter c_ϕ in eq. (3.19) below), such averages can have smaller (theory) uncertainties than the component measurements. This reduced average uncertainty occurs by virtue of the choices:

- to consider the input systematic uncertainties to be independent;
- to interpret different classes of measurement to measure the same physics.

The impact of the choice of correlation between theory systematic uncertainties should be carefully investigated in the future, but was not possible with the set of inputs provided for the preparation of this document. Where the effect of theory error averaging was observed to be prominent in the presented results, e.g. in section 3.4, it is mentioned.

Electroweak precision observables also contribute significantly in the EFT-based analysis. At present, LEP still provides the best constraints in many cases, and these are used here, except when new higher precision measurements are expected to be made by the given collider. For instance, for the HL-LHC and HE-LHC projections, LEP values are used for the constraints on electroweak precision observables, whilst all FCC machines use the values expected from FCC-ee.

The fits presented in this report have been produced using the fitting framework of the `HEPfit` package [20], a general tool to combine information from direct and indirect searches and test the Standard Model and its extensions [21–24]. We use the Markov-Chain

Monte-Carlo implementation provided by the Bayesian Analysis Toolkit [25], to perform a Bayesian statistical analysis of the sensitivity to deformations from the SM at the different future collider projects. The experimental projections for the different observables included in the fits are implemented in the likelihood assuming Gaussian distributions, with SM central values and standard deviations given by the corresponding projected uncertainties. Model parameters are assumed to have flat priors. Finally, theory uncertainties, when included, are introduced via nuisance parameters with Gaussian priors.

The projected uncertainties of all measurements of observables, relevant to the various analyses presented in this article, are listed in appendix C.

3 The Higgs boson couplings to fermions and vector bosons

Within the SM, all the Higgs couplings are uniquely fixed in terms of the Fermi constant and the masses of the different particles. Measuring the Higgs couplings thus requires a parametrization of the deviations from the SM induced by new physics. The κ -framework is the simplest parametrization directly related to experimental measurements of the Higgs boson production and decay modes. For this reason, it has been widely used by the community. It only compares the experimental measurements to their best SM predictions and does not require any new BSM computations *per se*. From a more theoretical perspective, its relevance arises from the fact that it actually fully captures the leading effects in single Higgs processes of well motivated scenarios. For instance, in the minimal supersymmetric standard model with R-parity, all dominant corrections to the Higgs couplings induced by the new super-partners are of order m_H^2/m_{SUSY}^2 relative to the SM predictions (m_{SUSY} is the mass of the new particles) and they appear as shifts of the Higgs couplings with the *same* SM helicity structures while new helicity structures are only generated as subleading effects further suppressed by a loop factor. In scenarios where the Higgs boson arises from a strongly-interacting sector as a composite (pseudo-Goldstone) boson, the leading deformations to the SM scale like $\xi = (g_\star^2/g_{\text{SM}}^2) m_W^2/m_\star^2$ (m_\star and g_\star are the overall mass scale of the strong sector resonances and their mutual coupling respectively) and they all preserve the helicity structure of the interactions already present in the SM. The constraints derived in the κ analysis can thus be readily exploited to derive constraints on the new physics parameters. This kappa-framework has, however, its own limitations when Higgs measurements need to be put in perspective and compared to processes with different particle multiplicities or combined with other measurements done in different sectors or at different energies. An effective field theory (EFT) approach naturally extends the kappa-framework. First, it allows to exploit polarisation- and angular-dependent observables that a κ -analysis will remain blind to. Second, an EFT analysis constitutes a useful tool to probe the Higgs boson in the extreme kinematical regions relevant for colliders operating far above the weak scale, exploring the tails of kinematical distributions, even though these observables have not been fully exploited yet in the studies presented by the different future collider collaborations. Third, the EFT offers a consistent setup where predictions can be systematically improved via the inclusion of both higher loop corrections in the SM couplings and further new physics corrections encoded in operators of even higher dimensions.

Both approaches will be studied in this document and we will report the fits to the experimental projected measurements obtained in these two frameworks. As an illustration, a concrete interpretation of the results obtained will be done in the context of composite Higgs models.

3.1 The kappa framework

3.1.1 Choice of parametrization

The kappa framework, described in detail in ref. [16, 17], facilitates the characterisation of Higgs coupling properties in terms of a series of Higgs coupling strength modifier parameters κ_i , which are defined as the ratios of the couplings of the Higgs bosons to particles i to their corresponding Standard Model values. The kappa framework assumes a single narrow resonance so that the zero-width approximation can be used to decompose the cross section as follows

$$(\sigma \cdot \text{BR})(i \rightarrow H \rightarrow f) = \frac{\sigma_i \cdot \Gamma_f}{\Gamma_H}, \quad (3.1)$$

where σ_i is the production cross section through the initial state i , Γ_f the partial decay width into the final state f and Γ_H the total width of the Higgs boson. The κ parameters are introduced by expressing each of the components of eq. (3.1) as their SM expectation multiplied by the square of a coupling strength modifier for the corresponding process at leading order:

$$(\sigma \cdot \text{BR})(i \rightarrow H \rightarrow f) = \frac{\sigma_i^{\text{SM}} \kappa_i^2 \cdot \Gamma_f^{\text{SM}} \kappa_f^2}{\Gamma_H^{\text{SM}} \kappa_H^2} \rightarrow \mu_i^f \equiv \frac{\sigma \cdot \text{BR}}{\sigma_{\text{SM}} \cdot \text{BR}_{\text{SM}}} = \frac{\kappa_i^2 \cdot \kappa_f^2}{\kappa_H^2}, \quad (3.2)$$

where μ_i^f is the rate relative to the SM expectation (as given in tables 18 and 19) and κ_H^2 is an expression that adjusts the SM Higgs width to take into account of modifications κ_i of the SM Higgs coupling strengths:

$$\kappa_H^2 \equiv \sum_j \frac{\kappa_j^2 \Gamma_j^{\text{SM}}}{\Gamma_H^{\text{SM}}}. \quad (3.3)$$

When all κ_i are set to 1, the SM is reproduced. For loop-induced processes, e.g. $H \rightarrow \gamma\gamma$, there is a choice of either resolving the coupling strength modification in its SM expectation, i.e. $\kappa_\gamma(\kappa_t, \kappa_W)$ or keeping κ_γ as an effective coupling strength parameter.

For the results presented in the document, we choose to describe loop-induced couplings with effective couplings, resulting in a total of 10 κ parameters: $\kappa_W, \kappa_Z, \kappa_c, \kappa_b, \kappa_t, \kappa_\tau, \kappa_\mu$, and the effective coupling modifiers κ_γ, κ_g and $\kappa_{Z\gamma}$. The couplings $\kappa_s, \kappa_d, \kappa_u$ and κ_e that are only weakly constrained from very rare decays are not included in the combined κ -framework fits presented in this section, their estimated limits are discussed separately in section 5. We note the parameter κ_t is only accessible above the tH threshold as the processes involving virtual top quarks are all described with effective coupling modifiers

$(\kappa_g, \kappa_{Z\gamma}, \kappa_\gamma)$, hence standalone fits to low-energy (lepton) colliders have no sensitivity to κ_t in the κ -framework fits considered here.⁴

3.1.2 Modeling of invisible and untagged Higgs decays

The κ -framework can be extended to allow for the possibility of Higgs boson decays to invisible or untagged BSM particles. The existence of such decays increases the total width Γ_H by a factor $1/(1 - BR_{\text{BSM}})$, where BR_{BSM} is the Higgs branching fraction to such BSM particles. Higgs boson decays to BSM particles can be separated in two classes: decays into invisible particles, which are experimentally directly constrained at all future colliders (e.g $ZH, H \rightarrow \text{invisible}$), and decays into all other ‘untagged’ particles.

Reflecting this distinction we introduce two branching fraction parameters BR_{inv} and BR_{unt} so that:

$$\Gamma_H = \frac{\Gamma_H^{\text{SM}} \cdot \kappa_H^2}{1 - (BR_{\text{inv}} + BR_{\text{unt}})}, \tag{3.4}$$

where κ_H^2 is defined in eq. (3.3).

For colliders that can directly measure the Higgs width, BR_{unt} can be constrained together with κ_i and BR_{inv} from a joint fit to the data. For standalone fits to colliders that cannot, such as the HL-LHC, either an indirect measurement can be included, such as from off-shell Higgs production, or additional theoretical assumptions must be introduced. A possible assumption is $|\kappa_V| \leq 1$ ($V = W, Z$), which is theoretically motivated as it holds in a wide class of BSM models albeit with some exceptions [26] (for more details see [17], section 10).

3.1.3 Fitting scenarios

To characterise the performance of future colliders in the κ -framework, we defined four benchmark scenarios, which are listed in table 2. The goal of the kappa-0 benchmark is to present the constraining power of the κ -framework under the assumption that there exist no light BSM particles to which the Higgs boson can decay. The goal of benchmarks kappa-1,2 is to expose the impact of allowing BSM Higgs decays, in combination with a measured or assumed constraint on the width of the Higgs, on the standalone κ results. Finally, the goal of the kappa-3 benchmark is to show the impact of combining the HL-LHC data with each of the future accelerators. In all scenarios with BSM branching fractions, these branching fractions are constrained to be positive definite.

Experimental uncertainties — defined as statistical uncertainties and, when provided, experimental systematic uncertainties, background theory uncertainties and signal-acceptance related theory uncertainties — are included in all scenarios. Theory uncertainties on the Higgs branching fractions predictions for all future colliders and uncertainties

⁴At high Higgs/jet p_T , $gg \rightarrow H$ becomes directly sensitive to κ_t . However, high- p_T regions are not separately considered in the κ -framework fits reported here. Furthermore, there is no sensitivity to the sign of the κ parameters as the loop-induced processes with sensitivity to the sign have all been described with effective modifiers. Single top production is sensitive to the sign but not used in the κ fits presented here (but used in the CP studies). Finally, note that, for vector-boson-fusion, the small interference effect between W- and Z boson fusion is neglected.

Scenario	BR_{inv}	BR_{unt}	include HL-LHC
kappa-0	fixed at 0	fixed at 0	no
kappa-1	measured	fixed at 0	no
kappa-2	measured	measured	no
kappa-3	measured	measured	yes

Table 2. Definition of the benchmark scenarios used to characterize future colliders in the κ -framework.

on production cross section predictions for hadron colliders, as described in section 2, are partially included; intrinsic theory uncertainties, arising from missing higher-order corrections, are *not* included in any of the benchmarks, while parametric theory uncertainties arising from the propagation of experimental errors on SM parameters *are* included in all scenarios. A detailed discussion and assessment of the impact of theory uncertainties is given in section 3.5.

3.2 Results from the kappa-framework studies and comparison

The κ -framework discussed in the previous section was validated comparing the results obtained with the scenarios described as kappa-0 and kappa-1 to the original results presented by the Collaborations to the European Strategy. In general, good agreement is found.

The results of the kappa-0 scenario described in the previous section are reported in table 3. In this scenario, no additional invisible or untagged branching ratio is allowed in the fits, and colliders are considered independently. This is the simplest scenario considered in this report, and illustrates the power of the kappa framework to constrain new physics in general, and in particular the potential to constrain new physics at the proposed new colliders discussed in this report. In general the precision is at the per cent level, In the final stage of the future colliders a precision of the order of a few per-mille would be reachable for several couplings, for instance κ_W and κ_Z . Cases in which a particular parameter has been fixed to the SM value due to lack of sensitivity are shown with a dash (-). Examples of this are κ_c , not accessible at HL-LHC and HE-LHC, and κ_t , only accessible above the ttH/tH threshold. Not all colliders reported results for all possible decay modes in the original reference documentation listed in table 1, the most evident example of this being the $Z\gamma$ channel. In this standalone collider scenario, the corresponding parameters were left to float in the fits. They are indicated with * in the tables.

This kappa-0 scenario can be expanded to account for invisible decays (kappa-1) and invisible and untagged decays (kappa-2), still considering individual colliders in a standalone way. The overall effect of this additional width is a slight worsening of the precision of the kappa parameters from the kappa-0 scenario to the kappa-1, and further on to the kappa-2. It is most noticeable for κ_W , κ_Z and κ_b . For comparison of the total impact, the kappa-2 scenario results can be found in tables 28 and 29 in appendix E.

Table 4 shows the expected precision of the κ parameters in the final benchmark scenario discussed in this paper in which 95% CL limits on BR_{unt} and BR_{inv} are set, for

kappa-0	HL-LHC	LHeC	HE-LHC		ILC			CLIC			CEPC	FCC-ee		FCC-ee/eh/hh

Table 3. Expected relative precision (%) of the κ parameters in the kappa-0 scenario described in section 2 for future accelerators. Colliders are considered independently, not in combination with the HL-LHC. No BSM width is allowed in the fit: both BR_{unt} and BR_{inv} are set to 0, and therefore κ_V is not constrained. Cases in which a particular parameter has been fixed to the SM value due to lack of sensitivity are shown with a dash (–). A star (★) indicates the cases in which a parameter has been left free in the fit due to lack of input in the reference documentation. The integrated luminosity and running conditions considered for each collider in this comparison are described in table 1. FCC-ee/eh/hh corresponds to the combined performance of FCC-ee₂₄₀+FCC-ee₃₆₅, FCC-eh and FCC-hh. In the case of HE-LHC, two theoretical uncertainty scenarios (S2 and S2') [13] are given for comparison.

the three possibilities using the LHC tunnel: HL-LHC, LHeC, and HE-LHC. The results correspond to the kappa-3 scenario.

As discussed before, for these hadron colliders a constraint on $|\kappa_V| \leq 1$ is applied in this case, as no direct access to the Higgs width is possible.

Table 5 shows the corresponding kappa-3 scenario for the different lepton colliders and a final FCC-ee/eh/hh combination, all combined with the HL-LHC results. The integrated luminosity and running conditions considered for each collider in this comparison are taken for table 1. The constraints on Γ_H derived from the fit parameters using eq. (3.4) are discussed in detail in section 7. In this case when HL-LHC is combined with a lepton collider the assumption $|\kappa_V| \leq 1$ is no longer necessary, and therefore it is not used as a constrain in these kappa-3 fits. For those particular analyses not reported in the original reference documentation listed in table 1 (e.g. $\kappa_{Z\gamma}$) the HL-LHC prospects drive the combination. They are indicated with * in the tables.

We have examined the correlations of the lepton collider kappa-3 fits. In the initial stage of ILC (ILC₂₅₀), κ_W , κ_g , κ_b , κ_t and κ_τ show sizeable correlations (> 70%), with the largest corresponding to κ_b and κ_τ (93%). There is practically no correlation between κ_W and κ_Z (8%). The untagged branching fraction is not particularly correlated with the couplings, with the largest correlation corresponding to κ_Z (50%), and an anti correlation (-20%) seen for $\kappa_{Z\gamma}$ where the only information comes from the HL-LHC data. In the case of FCC-ee₃₆₅, we see a slight correlation between κ_Z and κ_W (30%), and a similar correlation

Figure 2. Expected relative precision (%) of the κ parameters in the kappa-3 scenario described in section 2. For details, see tables 4 and 5. For HE-LHC, the S2' scenario is displayed. For LHeC, HL-LHC and HE-LHC a constrained $\kappa_V \leq 1$ is applied.

between these and the untagged branching fraction (30–50%). The correlations between κ_b , κ_τ , κ_g and κ_W are mild, with the largest value corresponding once again to κ_b and κ_τ (74%). In this case there is also no strong correlation between the untagged branching fraction and the couplings, with the largest correlation corresponding to κ_Z (50%), followed by κ_b (30%). Again an anti correlation (-20%) is seen for $\kappa_{Z\gamma}$. For CLIC₃₀₀₀ the situation is markedly different, with large correlations between κ_Z and κ_W (80%), and between the untagged branching fraction and κ_Z , κ_W and κ_b (90%, 80%, 70% respectively). The correlations between κ_b , κ_Z , κ_τ , κ_g and κ_W are not negligible, with the highest corresponding to κ_b and κ_W (70%). In this case, κ_b and κ_τ are correlated to 45%. These correlations can be seen graphically in figure 14 in the appendix.

The results of the kappa-3 benchmark scenario are also presented graphically in figure 2. Note that while hadron colliders and lepton colliders are shown together, the caveat that a bound on $|\kappa_V| \leq 1$ is required for HL-LHC, HE-LHC and LHeC still applies. Parameters fixed to the Standard Model value are not displayed.

Intrinsic theoretical uncertainties for future lepton colliders are omitted in tables 3, 4 and 5. Their effect is discussed in detail in section 3.5.

3.3 Effective field theory description of Higgs boson couplings

As already discussed, the κ -framework provides a convenient first parametrization of new physics in single Higgs processes. By construction, it is perfectly suitable to spot a deviation from the SM, but it does not provide a systematic description of new physics. As such it does not permit to correlate different processes nor to describe their energy dependence, which is certainly a drawback when trying to develop a strategic perspective. When aiming at a more systematic approach one must distinguish the two cases of light and heavy new physics. In the first case, there is no simple and systematic description. One must proceed case by case, perhaps with the aid of simplified models. While we are not aware of any

kappa-3	HL-LHC	HL-LHC &		
		LHeC	HE-LHC (S2)	HE-LHC (S2')

	4.	1.3	3.3	2.4

Table 4. Expected relative precision (%) of the κ parameters in the kappa-3 scenario described in section 2 for the HL-LHC, LHeC, and HE-LHC. A bound on $|\kappa_V| \leq 1$ is applied since no direct access to the Higgs width is possible, thus the uncertainty on κ_W and κ_Z is one-sided. For the remaining kappa parameters one standard deviation is provided in \pm . The corresponding 95%CL upper limit on BR_{inv} is also given. In this kappa-3 scenario BR_{unt} is a floating parameter in the fit, to propagate the effect of an assumed uncertain total width on the measurement of the other κ_i . Based on this constraint the reported values on BR_{unt} are inferred. Cases in which a particular parameter has been fixed to the SM value due to lack of sensitivity are shown with a dash (–). An asterisk (*) indicates the cases in which there is no analysis input in the reference documentation, and HL-LHC dominates the combination. In the case of κ_t sensitivity at the LHeC, note that the framework relies as input on $\mu_{t\bar{t}H}$, and does not take into consideration μ_{tH} . The integrated luminosity and running conditions considered for each collider in this comparison are described in table 1. In the case of HL-LHC and HE-LHC, both the S2 and the S2' uncertainty models [13] are given for comparison.

attempt at a general analysis, it should be noted that light degrees of freedom carrying electroweak quantum numbers seem disfavored, and that the less constrained options involve portal type interactions of the Higgs to SM singlets. Examples in the latter class can involve mixing with a new light CP-even scalar S , or the trilinear couplings to scalar (hS^2) or fermion ($h\bar{\psi}\psi$) bilinears. In these cases, besides the presence of new processes, e.g. the production of a sequential Higgs-like scalar, the effect on single Higgs production and decay are well described by the κ -framework, including the option for an invisible width into new physics states. Heavy new physics can instead be systematically described in the effective Lagrangian approach. This fact, and the richer set of consistent and motivated heavy new physics options, gives particular prominence to the effective Lagrangian approach. One can distinguish two broad classes of heavy new physics depending on the origin of the corresponding mass scale, which we henceforth indicate by Λ . In the first class, Λ is controlled by the Higgs VEV (v) and is expected to be bounded to be less than $4\pi v \sim 3 \text{ TeV}$. The

Table 5. Expected relative precision (%) of the κ parameters in the kappa-3 (combined with HL-LHC) scenario described in section 2 for future accelerators beyond the LHC era. The corresponding 95%CL upper limits on BR_{unt} and BR_{inv} and the derived constraint on the Higgs width (in %) are also given. No requirement on κ_V is applied in the combination with HL-LHC, since the lepton colliders provide the necessary access to the Higgs width. Cases in which a particular parameter has been fixed to the SM value due to lack of sensitivity are shown with a dash (-). An asterisk (*) indicates the cases in which there is no analysis input in the reference documentation, and HL-LHC dominates the combination. The integrated luminosity and running conditions considered for each collider in this comparison are described in table 1. FCC-ee/eh/hh corresponds to the combined performance of FCC-ee₂₄₀+FCC-ee₃₆₅, FCC-eh and FCC-hh.

effective Lagrangian corresponds here to the so-called Higgs-EFT, which cannot be written as a polynomial expansion in gauge invariant operators [27, 28]. In this scenario, which is in this respect analogous to Technicolor, deviations in Higgs couplings and EWPT are expected to exceed their present bounds, unless the new physics effect can be tuned to be small for each and every coupling, which makes it rather implausible. In the second class, basically including all the more plausible scenarios, Λ is not controlled by the Higgs VEV, and can virtually be arbitrarily large. In that case the effective Lagrangian corresponds to the so-called SMEFT. It is polynomial in gauge invariant operators and organised as an expansion in inverse powers of Λ :

$$\mathcal{L}_{\text{Eff}} = \mathcal{L}_{\text{SM}} + \frac{1}{\Lambda}\mathcal{L}_5 + \frac{1}{\Lambda^2}\mathcal{L}_6 + \frac{1}{\Lambda^3}\mathcal{L}_7 + \frac{1}{\Lambda^4}\mathcal{L}_8 + \dots, \quad \mathcal{L}_d = \sum_i c_i^{(d)} \mathcal{O}_i^{(d)}. \quad (3.5)$$

In the previous equation, each $\mathcal{O}_i^{(d)}$ is a local $SU(3)_c \times SU(2)_L \times U(1)_Y$ -invariant operator of canonical mass dimension d , built using only fields from the light particle spectrum. Moreover, \mathcal{L}_{SM} represents the renormalizable SM Lagrangian that nicely complies with basically all the measurements made so far in particle physics, with the exception of the tiny neutrino masses, which are however nicely described by the next term, \mathcal{L}_5 . The contribution of the higher order terms $\mathcal{L}_{d \geq 5}$ to physical amplitudes is suppressed by $(E/\Lambda)^{d-4}$, where E is the relevant energy scale of the process. The *Wilson coefficients* $c_i^{(d)}$ encode the virtual effects of the heavy new physics in low-energy observables. Their precise form in terms of masses and couplings of the new particles can be obtained via *matching* with an ultraviolet (UV) completion of the SM [29], or inferred using *power-counting* rules [30, 31].

The success of \mathcal{L}_{SM} in explaining the data indicates that either the scale of new physics Λ is large, or that the structure of the terms $\mathcal{L}_{d \geq 5}$ is particularly elaborate, or perhaps a combination of both. Moreover it is important to stress that in general we expect new physics at multiple and even widely separated scales, and that the parametrization in terms of a single scale Λ is a simplification. It is however clear that given the good but limited precision of future high energy experiments only the lowest scale is expected to matter. In particular, given the observed suppression of lepton and baryon number violation, the operators mediating such violation, which appear already in \mathcal{L}_5 and \mathcal{L}_6 , must be further suppressed if Λ is as low as to be interesting in collider physics. That suppression could be due to approximate symmetries or simply because the dynamics generating these processes is $\gg \Lambda$. The same remarks apply to flavour and CP violation.

Assuming lepton and baryon numbers are conserved independently, all relevant operators in the previous expansion are of even dimension. Therefore new physics effects start at dimension $d = 6$. In this report we work under the assumption that Λ is large enough for $d = 6$ to dominate over $d \geq 8$ (but see comment below) and restrict our studies to the effective Lagrangian truncated part $d = 6$. The resulting Lagrangian is that of the so-called dimension-6 Standard Model Effective Field Theory (SMEFT). In a bottom-up approach, one can write a complete basis for the dimension-6 SMEFT Lagrangian using a total of 59 types of operators [32], for a total of 2499 taking into account flavour indices [33]. For most of the calculations presented in this report we use the dimension-six basis first presented

in [32], the so-called *Warsaw basis*, with minor modifications.⁵ In the discussion presented in this section, however, we will use a different parameterization, which is usually deemed to be more transparent from the point of view of Higgs physics.

One must notice that in any realistic situation there will be structure in the coefficients of the 2499 operators of dimension 6. For instance, if they were a set of structureless $O(1)$ numbers, then the experimental constraints from flavour and/or CP violation on Λ would already be much stronger than from any foreseeable study of Higgs and EW processes. Moreover in realistic situations we should also expect structure in the coefficients of flavour preserving operators. In other words some coefficients may be significantly smaller than others. This remark, together with a sensitivity limited to Λ 's that are not very much above the energy of the processes, implies that it may in principle happen that operators of dimension 8 are equally or more important than the dimension 6 operators. We shall later mention a natural example of this phenomenon. In structured scenarios like the SILH [30], it is easy to address this caveat, also thanks to the fact that the operators that matter in \mathcal{L}_6 are much fewer than in the general case (even after imposing flavour violation). The message here is that the reduction to pure dimension 6, with full neglect of dimension 8, while reasonable and useful, contains nonetheless an assumption which may not be universally true for all observables even in simple motivated models.

When considering Higgs data, one can reasonably focus on a relatively small subset of the 2499 operators in \mathcal{L}_6 . In particular the vast subset of 4-fermion operators, whether flavour and CP preserving or not, can be more strongly constrained by other processes. Thus, it makes sense to neglect this whole class, with the exception of one particular four-fermion interaction that contributes to the muon decay and thus directly affects the Fermi constant, see caption in table 6. The dipole operators, instead do directly affect Higgs production, however under very general and plausible assumptions on the flavour structure of new physics, the coefficients of these operators display the same structure and the same chiral suppression of Yukawa couplings. The consequence is that, with the possible exception of processes involving the top quark, their effect in Higgs production is expected to be negligible given that the leading SM contribution (for instance in $e^+e^- \rightarrow ZH$) as well as the other new physics effects are not chirally suppressed. Furthermore, as far as Higgs decays are concerned, the dipole operators only contribute to three (or more)-body final states (for instance $H \rightarrow \bar{b}b\gamma$) and as such they are easily seen to be negligible. In what follows we shall thus neglect this whole class, and leave the consideration of their effect in top sector to future studies. Eliminating these two classes, there remain three other classes: 1) purely bosonic operators, 2) generalized Yukawas, 3) Higgs-fermion current operators. Neglecting CP violating operators in class 1, the corresponding structures are shown in table 6. Operators in class 2 and 3, per se, can still contain CP- or flavour-violating terms, on which experimental constraints are rather strong. In order to proceed we shall consider two alternative scenarios to minimize the remaining flavour and/or CP violations:

⁵By using a perturbative field redefinition we trade the operators $\mathcal{O}_{\phi WB}$ and $\mathcal{O}_{\phi D}$ in ref. [32] for the operators $iD^\mu \phi^\dagger \sigma_a D^\nu \phi W_{\mu\nu}^a$ and $iD^\mu \phi^\dagger D^\nu \phi B_{\mu\nu}$.

1. *Flavour Universality*, corresponding to

$$Y_u^{(6)} \propto Y_u, \quad Y_d^{(6)} \propto Y_d, \quad Y_e^{(6)} \propto Y_e, \quad \text{and} \quad \Delta_{ij}^{q,u,d,l,e,ud}, \Delta_{ij}^{lq}, \propto \delta_{ij}, \quad (3.6)$$

where $Y_f^{(6)}$ are the coefficients of dimension-6 operators of class 2, which control the flavour structure of the modifications to the SM Yukawa matrices Y_f . Similarly, Δ^f and Δ'^f represent the combinations of dimension-6 operators of class 3, which induce flavour-dependent modifications of the neutral and charged current couplings of the fermions to the EW vector bosons. In terms of the Wilson coefficients of the operators in table 6 one has $Y_f^{(6)} = c_{f\phi}$ ($f = u, d, e$); $\Delta^f = c_{\phi f}$ for the operators involving the right-handed fermion multiplets ($f = u, d, e, ud$); and $\Delta^f = c_{\phi f}^{(1)}$, $\Delta'^f = c_{\phi f}^{(3)}$ for the left-handed ones ($f = q, l$). The choice in (3.6) corresponds to *Minimal Flavour Violation* (MFV) [34] in the limit where terms only up to linear in the Yukawa matrices are considered. Notice that *Minimal Flavour Violation* corresponds to the assumption that the underlying dynamics respects the maximal flavour symmetry group $SU(3)^5$. A more appropriate name would then perhaps be *Maximal Flavour Conservation*.

2. *Neutral Diagonality*, corresponding to a scenario where $Y_{u,d,e}^{(6)}$ while not proportional to the corresponding Yukawa matrices are nonetheless diagonal in the same basis. That eliminates all flavour-changing couplings to the Higgs boson. Similarly the $\Delta_{ij}^{q,u,d,l,e,ud}$, Δ_{ij}^{lq} , while not universal, are such that no flavour-changing couplings to the Z-boson are generated. In fact we shall work under the specific assumption where flavour universality is respected by the first two quark families, and violated by the third quark family and by leptons. This choice, per se, does not correspond to any motivated or even plausible scenario (it is rather cumbersome to produce sizeable flavour non-universality without any flavour violation). We consider it principally to test the essential constraining power of future machines and because it is widely studied by the community. Moreover non-universality limited to the third quark family is an often recurring feature of scenarios motivated by the hierarchy problem. That is simply because the large top Yukawa makes it intricately involved in the EW symmetry breaking dynamics and calls for the existence of various top partners.

Working in the unitary gauge and performing suitable redefinition of fields and input parameters the effective Lagrangian can be conveniently expressed in the parameterization of [35, 36], the so-called *Higgs basis*. Considering only the terms that are relevant for our analysis, we can identify five classes of terms.⁶

Higgs trilinear:

$$\Delta\mathcal{L}_6^{\text{h,self}} = -\delta\lambda_3 v h^3. \quad (3.7)$$

The impact of this coupling in single Higgs processes and its extraction from Higgs pair production will be discussed in section 4.

⁶In this paper we shall refer to the doublet Higgs field as ϕ . After symmetry breaking the field for the Higgs boson will be referred to as h . The Higgs particle will be referred to as H .

	Operator	Notation	Operator	Notation	
Class 1	X^3	$\varepsilon_{abc} W_\mu^{a\nu} W_\nu^{b\rho} W_\rho^{c\mu}$	\mathcal{O}_W		
	ϕ^6	$(\phi^\dagger \phi)^3$	\mathcal{O}_ϕ		
	$\phi^4 D^2$	$(\phi^\dagger \phi) \square (\phi^\dagger \phi)$	$\mathcal{O}_{\phi \square}$	$(\phi^\dagger D_\mu \phi) ((D^\mu \phi)^\dagger \phi)$	$\mathcal{O}_{\phi D}$
	$X^2 \phi^2$	$\phi^\dagger \phi B_{\mu\nu} B^{\mu\nu}$	$\mathcal{O}_{\phi B}$	$\phi^\dagger \phi W_{\mu\nu}^a W^{a\mu\nu}$	$\mathcal{O}_{\phi W}$
$\phi^\dagger \sigma_a \phi W_{\mu\nu}^a B^{\mu\nu}$		$\mathcal{O}_{\phi WB}$	$\phi^\dagger \phi G_{\mu\nu}^A G^{A\mu\nu}$	$\mathcal{O}_{\phi G}$	
Class 2	$\psi^2 \phi^2$	$(\phi^\dagger \phi) (\bar{l}_L^i \phi e_R^j)$	$(\mathcal{O}_{e\phi})_{ij}$		
		$(\phi^\dagger \phi) (\bar{q}_L^i \phi d_R^j)$	$(\mathcal{O}_{d\phi})_{ij}$	$(\phi^\dagger \phi) (\bar{q}_L^i \tilde{\phi} u_R^j)$	$(\mathcal{O}_{u\phi})_{ij}$
Class 3	$\psi^2 \phi^2 D$	$(\phi^\dagger i \overleftrightarrow{D}_\mu \phi) (\bar{l}_L^i \gamma^\mu l_L^j)$	$(\mathcal{O}_{\phi l}^{(1)})_{ij}$	$(\phi^\dagger i \overleftrightarrow{D}_\mu^a \phi) (\bar{l}_L^i \gamma^\mu \sigma_a l_L^j)$	$(\mathcal{O}_{\phi l}^{(3)})_{ij}$
		$(\phi^\dagger i \overleftrightarrow{D}_\mu \phi) (\bar{e}_R^i \gamma^\mu e_R^j)$	$(\mathcal{O}_{\phi e})_{ij}$		
		$(\phi^\dagger i \overleftrightarrow{D}_\mu \phi) (\bar{q}_L^i \gamma^\mu q_L^j)$	$(\mathcal{O}_{\phi q}^{(1)})_{ij}$	$(\phi^\dagger i \overleftrightarrow{D}_\mu^a \phi) (\bar{q}_L^i \gamma^\mu \sigma_a q_L^j)$	$(\mathcal{O}_{\phi q}^{(3)})_{ij}$
		$(\phi^\dagger i \overleftrightarrow{D}_\mu \phi) (\bar{u}_R^i \gamma^\mu u_R^j)$	$(\mathcal{O}_{\phi u})_{ij}$	$(\phi^\dagger i \overleftrightarrow{D}_\mu \phi) (\bar{d}_R^i \gamma^\mu d_R^j)$	$(\mathcal{O}_{\phi d})_{ij}$
		$(\tilde{\phi}^\dagger i D_\mu \phi) (\bar{u}_R^i \gamma^\mu d_R^j)$	$(\mathcal{O}_{\phi ud})_{ij}$		

Table 6. Dimension six operators considered in the SMEFT analysis. The hermitian derivatives \overleftrightarrow{D} and \overleftrightarrow{D}^a are defined as: $\overleftrightarrow{D}_\mu \equiv \overrightarrow{D}_\mu - \overleftarrow{D}_\mu$ and $\overleftrightarrow{D}_\mu^a \equiv \sigma_a \overrightarrow{D}_\mu - \overleftarrow{D}_\mu \sigma_a$, while $B_{\mu\nu}$, $W_{\mu\nu}^a$ and $G_{\mu\nu}^A$ denote the SM gauge boson field-strengths. See text for details. Apart from these, the effects of the four-lepton operator $(\mathcal{O}_{ll})_{1221} = (\bar{l}_1 \gamma_\mu l_2) (\bar{l}_2 \gamma^\mu l_1)$, which modifies the prediction for the muon decay amplitude, must also be included in the fit since we use the Fermi constant as one of the SM input parameters.

Higgs couplings to vector bosons:

$$\begin{aligned}
 \Delta \mathcal{L}_6^{\text{hVV}} = & \frac{h}{v} \left[2\delta c_w m_W^2 W_\mu^+ W_\mu^- + \delta c_z m_Z^2 Z_\mu Z_\mu \right. \\
 & + c_{ww} \frac{g^2}{2} W_{\mu\nu}^+ W_{\mu\nu}^- + c_{w\square} g^2 (W_\mu^- \partial_\nu W_{\mu\nu}^+ + \text{h.c.}) \\
 & + c_{gg} \frac{g_s^2}{4} G_{\mu\nu}^a G_{\mu\nu}^a + c_{\gamma\gamma} \frac{e^2}{4} A_{\mu\nu} A_{\mu\nu} + c_{z\gamma} \frac{e\sqrt{g^2 + g'^2}}{2} Z_{\mu\nu} A_{\mu\nu} \\
 & \left. + c_{zz} \frac{g^2 + g'^2}{4} Z_{\mu\nu} Z_{\mu\nu} + c_{z\square} g^2 Z_\mu \partial_\nu Z_{\mu\nu} + c_{\gamma\square} g g' Z_\mu \partial_\nu A_{\mu\nu} \right], \quad (3.8)
 \end{aligned}$$

where only c_{gg} , δc_z , $c_{\gamma\gamma}$, $c_{z\gamma}$, c_{zz} , $c_{z\square}$ are independent parameters:

$$\begin{aligned}
 \delta c_w &= \delta c_z + 4\delta m, \\
 c_{ww} &= c_{zz} + 2 \sin^2 \theta_w c_{z\gamma} + \sin^4 \theta_w c_{\gamma\gamma}, \\
 c_{w\square} &= \frac{1}{g^2 - g'^2} [g^2 c_{z\square} + g'^2 c_{zz} - e^2 \sin^2 \theta_w c_{\gamma\gamma} - (g^2 - g'^2) \sin^2 \theta_w c_{z\gamma}], \\
 c_{\gamma\square} &= \frac{1}{g^2 - g'^2} [2g^2 c_{z\square} + (g^2 + g'^2) c_{zz} - e^2 c_{\gamma\gamma} - (g^2 - g'^2) c_{z\gamma}], \quad (3.9)
 \end{aligned}$$

where θ_w denotes the weak mixing angle while δm is an independent parameter from \mathcal{L}_6 controlling the deviation of m_W^2 with respect to its tree level SM value.

Trilinear gauge couplings:

$$\begin{aligned} \Delta\mathcal{L}^{\text{aTGC}} &= ie\delta\kappa_\gamma A^{\mu\nu}W_\mu^+W_\nu^- \\ &+ ig \cos\theta_w \left[\delta g_{1Z} (W_{\mu\nu}^+W^{-\mu} - W_{\mu\nu}^-W^{+\mu})Z^\nu + \left(\delta g_{1Z} - \frac{g'^2}{g^2}\delta\kappa_\gamma \right) Z^{\mu\nu}W_\mu^+W_\nu^- \right] \\ &+ \frac{ig\lambda_z}{m_W^2} (\sin\theta_w W_\mu^{+\nu}W_\nu^{-\rho}A_\rho^\mu + \cos\theta_w W_\mu^{+\nu}W_\nu^{-\rho}Z_\rho^\mu), \end{aligned} \quad (3.10)$$

where of the three coefficients $g_{1,z}$ and $\delta\kappa_\gamma$ depend on $c_{gg}, \delta c_z, c_{\gamma\gamma}, c_{z\gamma}, c_{zz}, c_{z\Box}$:

$$\begin{aligned} \delta g_{1,z} &= \frac{1}{2}(g^2 - g'^2) [c_{\gamma\gamma}e^2g'^2 + c_{z\gamma}(g^2 - g'^2)g'^2 - c_{zz}(g^2 + g'^2)g'^2 - c_{z\Box}(g^2 + g'^2)g^2], \\ \delta\kappa_\gamma &= -\frac{g^2}{2} \left(c_{\gamma\gamma}\frac{e^2}{g^2 + g'^2} + c_{z\gamma}\frac{g^2 - g'^2}{g^2 + g'^2} - c_{zz} \right), \end{aligned} \quad (3.11)$$

while λ_z is an independent parameter.

Yukawa couplings:

$$\Delta\mathcal{L}_6^{\text{hff}} = -\frac{h}{v} \sum_{f \in u,d,e} \hat{\delta}y_f m_f \bar{f}f + \text{h.c.}, \quad (3.12)$$

where $\hat{\delta}y_f m_f$ should be thought as 3×3 matrices in flavour space. FCNC are avoided when $\hat{\delta}y_f$ is diagonal in the same basis as m_f . Under the assumption of *Flavour Universality* ($\hat{\delta}y_f)_{ij} \equiv \delta y_f \times \delta_{ij}$, corresponding to a total of three parameters $\delta y_u, \delta y_d, \delta y_e$. The assumption of *Neutral Diagonality* corresponds instead to $(\hat{\delta}y_f)_{ij} \equiv \delta(y_f)_i \times \delta_{ij}$ (no summation) corresponding to 9 parameters $\delta_u, \delta_c, \delta_t$ for the ups and similarly for downs and charged leptons. In practice only $\delta_{t,c}, \delta_b$ and $\delta_{\tau,\mu}$ are expected to matter in plausible models and in the experimental situations presented by all future colliders. This adds two parameters with respect to *Flavour Universality*.

Vector couplings to fermions:

$$\begin{aligned} \Delta\mathcal{L}_6^{vff,hvff} &= \frac{g}{\sqrt{2}} \left(1 + 2\frac{h}{v} \right) W_\mu^+ \left(\hat{\delta}g_L^{W\ell} \bar{\nu}_L \gamma^\mu e_L + \hat{\delta}g_L^{Wq} \bar{u}_L \gamma^\mu d_L + \hat{\delta}g_R^{Wq} \bar{u}_R \gamma^\mu d_R + \text{h.c.} \right) \\ &+ \sqrt{g^2 + g'^2} \left(1 + 2\frac{h}{v} \right) Z_\mu \left[\sum_{f=u,d,e,\nu} \hat{\delta}g_L^{Zf} \bar{f}_L \gamma^\mu f_L + \sum_{f=u,d,e} \hat{\delta}g_R^{Zf} \bar{f}_R \gamma^\mu f_R \right] \end{aligned} \quad (3.13)$$

where, again, not all terms are independent:⁷

$$\hat{\delta}g_L^{W\ell} = \hat{\delta}g_L^{Z\nu} - \hat{\delta}g_L^{Ze}, \quad \hat{\delta}g_L^{Wq} = \hat{\delta}g_L^{Zu} V_{CKM} - V_{CKM} \hat{\delta}g_L^{Zd}. \quad (3.14)$$

⁷Here we choose a slightly different convention for the dependent couplings with respect to [35, 36], and we express everything in terms of the modifications of the neutral currents.

In the case of *Flavour Universality*, all the $\hat{\delta}g$ are proportional to the identity corresponding to a total of 8 parameters: $(\hat{\delta}g_L^{Zu})_{ij} \equiv \delta g_L^{Zu} \times \delta_{ij}$, etc. However the right handed charged current, associated with $\hat{\delta}g_R^{Wq}$ does not interfere with the SM amplitudes in the limit $m_q \rightarrow 0$ and can be neglected, reducing the number of parameters to 7.

In the case of *Neutral Diagonality*, the assumption $\hat{\delta}g_{ij} \propto \delta_{ij}$ is relaxed, allowing for the four coefficients associated with the third quark family $(\hat{\delta}g_L^{Zu})_{33}, (\hat{\delta}g_L^{Zd})_{33}, (\hat{\delta}g_R^{Zu})_{33}, (\hat{\delta}g_R^{Zd})_{33}$ as well as all diagonal coefficients associated with leptons to be different. This adds 10 further parameters with respect to the flavour Universal case.

In conclusion considering single Higgs and EW processes (i.e. neglecting the Higgs trilinear) in the scenarios of *Flavour Universality* and *Neutral Diagonality* we end up with respectively 18 and 30 independent parameters:⁸

$$\begin{aligned} \text{SMEFT}_{\text{FU}} \equiv & \{ \delta m, c_{gg}, \delta c_z, c_{\gamma\gamma}, c_{z\gamma}, c_{zz}, c_{z\Box}, \delta y_u, \delta y_d, \delta y_e, \lambda_z \} \\ & + \left\{ \delta g_L^{Zu}, \delta g_L^{Zd}, \delta g_L^{Z\nu}, \delta g_L^{Ze}, \delta g_R^{Zu}, \delta g_R^{Zd}, \delta g_R^{Ze} \right\}, \end{aligned} \quad (3.15)$$

$$\begin{aligned} \text{SMEFT}_{\text{ND}} \equiv & \{ \delta m, c_{gg}, \delta c_z, c_{\gamma\gamma}, c_{z\gamma}, c_{zz}, c_{z\Box}, \delta y_t, \delta y_c, \delta y_b, \delta y_\tau, \delta y_\mu, \lambda_z \} \\ & + \left\{ (\delta g_L^{Zu})_{q_i}, (\delta g_L^{Zd})_{q_i}, (\delta g_L^{Z\nu})_\ell, (\delta g_L^{Ze})_\ell, (\delta g_R^{Zu})_{q_i}, (\delta g_R^{Zd})_{q_i}, (\delta g_R^{Ze})_\ell \right\}_{\substack{q_1=q_2 \neq q_3, \\ \ell=e,\mu,\tau}}. \end{aligned} \quad (3.16)$$

While we have chosen to present the degrees of freedom used in the different fitting scenarios described above using the parameterization of the Higgs basis, one can of course do the same in any other basis. In particular, the mapping between the Higgs basis parameters in the previous Lagrangians and the Wilson coefficients in other popular dimension-6 bases in the literature can be found in section 3 and appendices A and B in [35].

The previous two scenarios will be used to study the sensitivity at future colliders to general departures from the SM in the global fit to EW precision observables (EWPO), Higgs boson rates and diboson production. We will, however, also consider another more simplified scenario, designed exclusively to study (1) the interplay between the EW and Higgs constraints, and (2) the impact of the SM theory uncertainties in Higgs boson processes. The impact of the EW precision constraints on Higgs boson measurements will be illustrated comparing the results of the fit in the SMEFT_{ND} scenario, with the analogous ones assuming the electroweak precision observables are known with infinite accuracy, both from experiment and theory. We will refer to this idealized case as a scenario with *perfect EW* constraints. In practice, this means that any new physics contributions to the EWPO are bounded to be exactly zero. This includes all possible corrections to the Vff vertices as well as any possible modification to the W mass, i.e.

$$\left\{ \delta m, (\delta g_L^{Zu})_{q_i}, (\delta g_L^{Zd})_{q_i}, (\delta g_L^{Z\nu})_\ell, (\delta g_L^{Ze})_\ell, (\delta g_R^{Zu})_{q_i}, (\delta g_R^{Zd})_{q_i}, (\delta g_R^{Ze})_\ell \right\} \equiv 0. \quad (3.17)$$

As also mentioned above, in this scenario it is also implicit that the SM theory uncertainties on EWPO are negligible, which makes it suitable to isolate the effect of the SM theory

⁸The impact at NLO of the relatively poorly constrained Higgs self-coupling on the determination of the single-Higgs couplings will be discussed in section 4.

uncertainties in Higgs processes in the fit. Imposing the previous constraints in eq. (3.16) we are thus left with a total of 12 parameters for this scenario assuming *perfect EW* constraints:

$$\text{SMEFT}_{\text{PEW}} \equiv \{ c_{gg}, \delta c_z, c_{\gamma\gamma}, c_{z\gamma}, c_{zz}, c_{z\Box}, \delta y_t, \delta y_c, \delta y_b, \delta y_\tau, \delta y_\mu, \lambda_z \}. \quad (3.18)$$

Finally, while the setup described above aims at some generality, it makes sense to add some perspective on the nature of the UV theory and to frame the EFT results in terms of particularly well-motivated scenarios. Understandably, heavy new physics is more visible in low energy observables the more strongly it is coupled. In this respect models with a Composite Higgs (CH) are the natural arena in which to perform indirect studies of new physics. The basic idea of CH models is that all the degrees of freedom of the SM apart from the Higgs are elementary. The Higgs instead arises as a bound state from a strong dynamics. In the simplest possible situation such dynamics is roughly described by two parameters, the overall mass scale and its overall coupling strength, respectively m_* and g_* . The prototypical template for such a two-parameter description is offered by large N gauge theories, which are characterized by the overall mass of their resonances (m_*) and by their mutual coupling $g_* \sim 4\pi/\sqrt{N}$. Concrete and largely calculable realizations of the scenario have been constructed in the context of warped compactifications and of their holographic interpretation, for reviews see e.g. [37, 38] (there are also attempts to build explicit composite models in 4D, see e.g. [39, 40]). Of course, as in all matters, it is easy to imagine more elaborate situations, but at the very least the minimal case can provide a first perspective on future machines. Indeed a more interesting variation concerns the top quark, which in motivated scenarios can become partially and even fully composite. Under the assumptions described in [30, 31], the low energy signatures of these kind of models can be parameterized in terms of the following effective Lagrangian:

$$\begin{aligned} \mathcal{L}_{\text{SILH}} = & \frac{c_\phi}{\Lambda^2} \frac{1}{2} \partial_\mu (\phi^\dagger \phi) \partial^\mu (\phi^\dagger \phi) + \frac{c_T}{\Lambda^2} \frac{1}{2} (\phi^\dagger \overleftrightarrow{D}_\mu \phi) (\phi^\dagger \overleftrightarrow{D}^\mu \phi) - \frac{c_6}{\Lambda^2} \lambda (\phi^\dagger \phi)^3 \\ & + \left(\frac{c_{y_f}}{\Lambda^2} y_{ij}^f \phi^\dagger \phi \bar{\psi}_{Li} \phi \psi_{Rj} + \text{h.c.} \right) \\ & + \frac{c_W}{\Lambda^2} \frac{ig}{2} \left(\phi^\dagger \overleftrightarrow{D}_\mu^a \phi \right) D_\nu W^{a\mu\nu} + \frac{c_B}{\Lambda^2} \frac{ig'}{2} \left(\phi^\dagger \overleftrightarrow{D}_\mu \phi \right) \partial_\nu B^{\mu\nu} \\ & + \frac{c_{\phi W}}{\Lambda^2} ig D_\mu \phi^\dagger \sigma_a D_\nu \phi W^{a\mu\nu} + \frac{c_{\phi B}}{\Lambda^2} ig' D_\mu \phi^\dagger \sigma_a D_\nu \phi B^{\mu\nu} \\ & + \frac{c_\gamma}{\Lambda^2} g'^2 \phi^\dagger \phi B^{\mu\nu} B_{\mu\nu} + \frac{c_g}{\Lambda^2} g_s^2 \phi^\dagger \phi G^{A\mu\nu} G_{\mu\nu}^A - \frac{c_{2W}}{\Lambda^2} \frac{g^2}{2} (D^\mu W_{\mu\nu}^a) (D_\rho W^{a\rho\nu}) \\ & - \frac{c_{2B}}{\Lambda^2} \frac{g'^2}{2} (\partial^\mu B_{\mu\nu}) (\partial_\rho B^{\rho\nu}) - \frac{c_{2G}}{\Lambda^2} \frac{g_s^2}{2} (D^\mu G_{\mu\nu}^A) (D_\rho G^{A\rho\nu}) \\ & + \frac{c_{3W}}{\Lambda^2} g^3 \varepsilon_{abc} W_\mu^a \nu W_\nu^b \rho W_\rho^c \mu + \frac{c_{3G}}{\Lambda^2} g_s^3 f_{ABC} G_\mu^A \nu G_\nu^B \rho G_\rho^C \mu, \end{aligned} \quad (3.19)$$

where the different Wilson coefficients can be written in terms of the couplings and masses of the resonances, denoted in short by $g_* \lesssim 4\pi$ and m_* , as

$$\begin{aligned} \frac{c_{\phi,6,y_f}}{\Lambda^2} & \sim \frac{g_*^2}{m_*^2} \equiv \frac{1}{f^2}, & \frac{c_T}{\Lambda^2} & \sim \frac{y_t^4}{16\pi^2 m_*^2}, \\ \frac{c_{W,B,\phi W,\phi B,\gamma,g}}{\Lambda^2} & \sim \frac{1}{m_*^2}, & \frac{c_{2W,2B,2G,3W,3G}}{\Lambda^2} & \sim \frac{1}{g_*^2} \frac{1}{m_*^2}, \end{aligned} \quad (3.20)$$

up to $O(1)$ factors. The expression for c_T has been derived under the most favorable hypothesis where the new physics preserves custodial symmetry. Note also that, for the relevant case of a pseudo-Nambu-Goldstone-boson (pNGB) Higgs, $c_{g,\gamma}$ benefit from a further suppression $\sim y_t^2/16\pi^2$. Moreover, in explicit constructions based on warped compactifications $c_{\phi W, \phi B, 3W, 3G}$ arise at “loop level” and have a further suppression $\sim g_*^2/16\pi^2$, which of course matters only when g_* is not maximally strong.

A few remarks concerning the above effective Lagrangian are in order. First, notice that the only effects enhanced by the strong coupling g_* are those on the first line and involving non linearities in the Higgs field. That is not surprising given that in CH, the Higgs itself is strongly interacting while the other SM degrees of freedom are not. In view of that, see discussion in section 8.3, in CH the measurements of Higgs couplings compete very well with much more precise measurements, like EWPT, which are not directly zooming in on the strongly coupled nature of the Higgs boson. Second, notice that in CH the whole set $\psi^2\phi^2D$ is subdominant and neglected in lowest approximation. However, the operator basis used above, which is the one naturally dictated by the structure of the model, is not precisely the one we used for our global analysis. In particular, the operators associated with $c_{2W, 2B, 2G}$ can be turned, by a field redefinition, into a particular combination of 4-fermion operators and one particular and flavour universal combination of the $\psi^2\phi^2D$. Third, the CH models, when considering $gg \rightarrow HH$ at high energy, offer a nice example of dim-8 operators potentially winning over dim-6 ones. Indeed, as mentioned above, when the Higgs is a composite pNGB, the coefficient of the dim-6 operator is further suppressed by a top loop factor $y_t^2/16\pi^2$ [41]. However that is not the case for the dim-8 operator $D_\rho\phi^\dagger D^\rho\phi G_{\mu\nu}^A G^{A\mu\nu}$ which simply comes with coefficient $\sim g_s^2/m_*^4$. One can then easily see that when the experimental accuracy in the measurement of $gg \rightarrow HH$ is worse than $O(y_t^2/16\pi^2)$, the sensitivity on m_* is dominated by the dim-8 operator.

Although the particular structure of the previous Lagrangian is not fully general, it provides a theoretically sound benchmark to interpret the results of our studies from a more BSM-oriented perspective. The contributions from the different SILH Wilson coefficients in the Lagrangian (3.19) to the parameters of the Higgs basis can be found in [35].

3.4 Results from the EFT framework studies

In the previous section we have detailed the counting of the degrees of freedom that enter in the different SMEFT fit scenarios using the so-called Higgs basis. While physical results do not depend on the choice of basis, in some cases a particular basis may be convenient for computational, presentational or interpretational purposes (note that the physical interpretation of each dimension-six operator does depend on the basis). From the point of view of the results presented in this section, however, we are mostly interested in comparing the sensitivity to deformations with respect to the SM in the Higgs couplings at the different future collider projects. To assess these deformations with respect to the SM in a basis-independent way one can *project* the results of the SMEFT fit onto a set of on-shell properties of the Higgs boson, via the following *Higgs effective couplings*:

$$g_{HX}^{\text{eff } 2} \equiv \frac{\Gamma_{H \rightarrow X}}{\Gamma_{H \rightarrow X}^{\text{SM}}}. \tag{3.21}$$

By definition, these quantities, constructed from physical observables, are basis independent. These definitions are also convenient to compare in a straightforward manner the SMEFT results with those of the κ framework for the single Higgs couplings. Such definition is, however, not phenomenologically possible for the top-Higgs coupling and the Higgs self-interaction. For the present report we will sidestep these issues by: (1) defining the effective top coupling in a similar way to all other fermions; (2) to connect and compare with all current studies of the Higgs self-interaction, we will define $g_{HHH} \equiv \lambda_3/\lambda_3^{\text{SM}}$.

Note that, at the dimension-six level and truncating the physical effects at order $1/\Lambda^2$ one can always express the previous effective couplings in terms of the dimension-six operators via a linear transformation. Provided one has a large enough set of such effective couplings, one can then map the effective coupling result into Wilson coefficients, and vice-versa (of course, the former are not a basis per se and the connection is only well-defined at a fixed order in perturbation theory and in the EFT expansion). The single Higgs couplings plus g_{HHH} are however not enough to match the number of free parameters in the SMEFT fits, even in the simplified scenario SMEFT_{PEW} in eq. (3.18). In particular, the on-shell couplings $g_{HZZ,HWW}^{\text{eff}}$ in eq. (3.21) do not capture all possible linear combinations of the different types of EFT interactions contributing to the HZZ and HWW vertices.⁹ For that reason we will also present our results by adding the predictions for the anomalous Triple Gauge Coupling (aTGC), a (pseudo)-observable obtained from the di-boson analysis. These extra parameters offer a measure of the Higgs couplings to gauge bosons with a non-SM Lorentz structure. As long as we restrict the analysis to observables around the Higgs mass scale, this approach with on-shell effective couplings and aTGC is perfectly appropriate. When high-energy observables are considered, like in section 3.4.2, it would have to be revisited. (In that section, however, we will present the results directly in terms of the Wilson coefficients, for easier interpretation in terms of BSM scenarios.) Even after adding the aTGC, in the SMEFT_{PEW} scenario where $\delta m \equiv 0$ the $g_{HZZ,HWW}^{\text{eff}}$ couplings are not independent, and therefore we will present the results reporting only the coupling to Z bosons.

In the global fit scenarios SMEFT_{FU} and SMEFT_{ND}, where we also add those combinations of operators that can contribute to EWPO, extra information needs to be added to illustrate the constraints on the different degrees of freedom included in the fit. Since δm is now a free parameter, we report separately the $g_{HZZ,HWW}^{\text{eff}}$ couplings. Following a similar approach as for the Higgs couplings, one can report the sensitivity to modifications in the effective couplings of the Z to fermions, which can be defined from the Z -pole measurements of the Z decays and asymmetries, e.g.

$$\Gamma_{Z \rightarrow e^+e^-} = \frac{\alpha M_Z}{6 \sin^2 \theta_w \cos^2 \theta_w} (|g_L^e|^2 + |g_R^e|^2), \quad A_e = \frac{|g_L^e|^2 - |g_R^e|^2}{|g_L^e|^2 + |g_R^e|^2}. \quad (3.22)$$

In what follows, we discuss the results of the SMEFT fit from the point of view of the expected sensitivity to modifications of the Higgs couplings in the scenarios SMEFT_{FU} and

⁹We note, however, that, from the point of view of the interpretation in terms of motivated scenarios like those described below eq. (3.20), the contributions to such interactions are dominated only by c_ϕ , unless $g_* \sim g$.

SMEFT_{ND}. As was done in the fits in the κ framework, we will present the results assuming that at future colliders only the SM theory uncertainties associated with the knowledge of the SM input parameters are non-negligible. (As also discussed there, for the HL-LHC and HE-LHC scenarios we always consider the uncertainties adopted by the studies in [13].) The impact of these and other SM theory uncertainties in Higgs processes will be discussed afterwards in section 3.5, using for that purpose the results in the benchmark SMEFT_{PEW}.

3.4.1 SMEFT fit results

The main results of this section are summarised in table 7, where we compare the 68% probability sensitivity to deviations in the Higgs couplings from the global SMEFT fit to Higgs, di-boson and EWPO at future colliders. We show the projections for the fits with and without flavour universality assumptions, given by the scenarios SMEFT_{FU} and SMEFT_{ND}, respectively. Note that the SMEFT_{ND} scenario not only has $g_{Htt}^{\text{eff}} \neq g_{Hcc}^{\text{eff}}$, $g_{H\tau\tau}^{\text{eff}} \neq g_{H\mu\mu}^{\text{eff}}$, but also treats in a family-dependent way the corrections to $Zf\bar{f}$ couplings, which typically leads to less stringent constraints from EWPO. The impact of the EWPO in the fit will be discussed below. The results for the more general scenario SMEFT_{ND} are also shown in figure 3 where we compare the results across colliders. In the lower panel of figure 3 we also show the relative improvement compared to the HL-LHC results. In both table and figure we illustrate the impact of the data taking at different energy stages at each collider. As in the previous sections, we distinguish between the initial energy stage when each collider can start operating as a Higgs factory, and subsequent upgrades to higher energies. In the case of FCC, we also consider the results in combination with the other collider options foreseen as part of the FCC integrated program.

Although in this section we will be mainly interested in the comparison of the sensitivities to modifications of Higgs couplings, for completeness we show in figure 4 and table 8 the results of the remaining degrees of freedom included in the SMEFT_{ND} fit, i.e. the precisions for the corresponding $Zf\bar{f}$ couplings. These are constrained mainly by the future projections for EWPO. In this regard, it must be noted that, unlike most of the Higgs results, where the uncertainties are expected to be controlled by the statistical component, the future projections for EWPO are expected to be dominated, in most cases, by systematic errors. Because of that, the results for the $Zf\bar{f}$ couplings have a significant dependence on what assumptions are made by the different collider projects in terms of these systematics. Whenever large differences between these assumptions were identified, we tried to unify them in order to provide a more coherent comparison. This is the case of the results for heavy flavour measurements of the Z properties ($A_{b,c}$ and $R_{b,c}$), where clearly different assumptions were made in terms of the expected size of future theory uncertainties associated with QCD corrections. These are expected to be collider independent (i.e. apply equally to linear or circular collider) and greatly affect the projections for the heavy flavor asymmetries A_f . Because of this, we chose 2 different scenarios for the systematics applied to these observables. We take as a base scenario one where the systematic uncertainties on the asymmetries are given by the main “collider-dependent” uncertainty quoted by each project. For linear colliders, where A_f are determined from a left-right forward backward asymmetry, this is the uncertainty on the knowledge of the

beam polarization. In absence of polarization, at circular colliders the A_f parameters are derived from an unpolarized forward-backward asymmetry, $A_{FB}^f = \frac{3}{4}A_e A_f$, and therefore are subject to the uncertainty associated to the knowledge of A_e . To illustrate the impact of the QCD uncertainties, in figure 4 we compare the result of this first scenario with a different one, obtained assuming the QCD uncertainties at future lepton colliders will be reduced by a factor of 2 compared to LEP. (The results for this latter scenario are indicated with the red marks in the figure.) In any case, the difference in the results between similar machines must therefore be interpreted with caution. For instance, the final CEPC capabilities from the point of view of the EWPO should not be significantly different than those for FCC-ee, at least regarding those measurement possible below 240 GeV.¹⁰ Finally, the scenarios considered here for linear colliders correspond to the baseline presented by the corresponding projects, which do not foresee a Z -pole run. Some results including that possibility, i.e. the Giga- Z factory, are presented in appendix F.

Focusing our attention on the results for the Higgs couplings, from the results we observe that the LHeC and HE-LHC would help in pushing the knowledge of some of the Higgs couplings close to the 2% level. This may be surprising compared to the results obtained in the κ framework (kappa-0), especially for the LHeC case, where the couplings to W and Z bosons were obtained with slightly below 1% accuracy. This deterioration in the precision of the EFT results is due to the absence of projections for improved measurements of the aTGC. This limits the constraining power on the non-SM tensor structures that are present in the EFT formalism but not in the κ framework. One must also note that the improvement at the HE-LHC S'_2 on the Higgs couplings is mostly dominated by the assumptions on the reduction of theory and systematics with respect to HL-LHC which, as explained in section 2, are reduced by fiat, rather than by a detailed workplan for the reduction of uncertainties. If such hypothesised improvement is not realised, the HE-LHC reach would be, with a few exceptions, not far from the HL-LHC one, as illustrated by the HE-LHC S_2 results in table 7. A future lepton collider could achieve below 1-percent accuracy for several of the g_{HX}^{eff} parameters.

Even at a low energy run, all future lepton colliders can bring the precision of the Higgs coupling to vector bosons to the 0.5% level or below (note also that lepton colliders are the only type of Higgs factory able to provide an absolute normalization for the Higgs couplings, via the measurement of the $e^+e^- \rightarrow ZH$ cross section using the recoil mass method). With similar luminosities collected at 240 GeV, the overall performances of CEPC and the 240 GeV run of FCC-ee are expected to be comparable.¹¹ In particular, both machines would be able to measure the effective HZZ coupling with a precision of $\sim 0.5\%$. After running at 365 GeV and completing the 14 year physics program of the FCC-ee collider¹² the precision of the HZZ coupling would be further reduced to $\sim 0.3\%$,

¹⁰The absence of a run around the $t\bar{t}$ threshold would, however, prevent measuring the top quark mass with increased precision, which is also a key observable in the EWPO analysis.

¹¹The differences between the CEPC and FCC-ee results at 240 GeV are simply due to the details of the available projections from each collider project. In particular, the better sensitivity to the $HZ\gamma$ coupling at CEPC is simply due to the absence of a projections for the $H \rightarrow Z\gamma$ channel at the FCC-ee.

¹²Note that this also includes the runs at the Z pole and WW threshold, which are crucial for the EW precision program. The total run time as Higgs factory is 8 years.

nearly a factor of 2 improvement. This of course could also be achieved at the CEPC, if a similar run at such energies were included in their physics program. For the ILC, running at 250 GeV would bring a precision of $\sim 0.4\%$ for g_{HZZ}^{eff} . This would be pushed down to 0.2% with an increase of the centre-of-mass energy to 500 GeV and after collecting 4 ab^{-1} of data, with a total combined run time of 22 years. A further ILC upgrade to energies of 1 TeV would bring an extra $\sim 30\%$ gain in precision. Finally, the determination of the different Higgs couplings to W and Z bosons obtained from the 380 GeV run of CLIC would be comparable to that of the circular colliders at 240 GeV. As in the ILC case, the CLIC data taken at high-energies would help to reach/surpass the two per-mille accuracy on the Higgs coupling to vector bosons after the 1.5 TeV/3 TeV run, concluding a 23-year program.

Turning our attention to the Higgs couplings to fermions, a similar pattern of improvements can be observed for the couplings to bottom quark and τ lepton. The top quark Yukawa is not directly accessible for lepton colliders running below the ttH threshold. Indeed, below threshold the top quark coupling can only be accessed via its contribution to the SM loop-induced processes, e.g. $H \rightarrow gg$. In the EFT framework, however, these can also receive corrections from new local operators, preventing the extraction of g_{Htt}^{eff} . In these cases, only a minor improvement can be achieved in the SMEFT_{ND} scenario,¹³ due to the more precise determinations of the other couplings involved in the extraction of g_{Htt}^{eff} from the ttH channels at the HL-LHC. The high-energy runs of the lepton machines would give access to the ttH threshold. ILC studies at 500 GeV –included in this study– project a determination of g_{Htt}^{eff} with a precision $\sim 6\text{--}7\%$. This could be significantly improved by running slightly above threshold, at 550 GeV, where due to the increased statistics it would be possible to access the same coupling at the 3% level [3]. Similar precision is projected for the CLIC run at 1500 GeV. Note that in order to take full advantage of these studies it is necessary to also have an adequate determination of the $Zt\bar{t}$ couplings. These also contribute to the ttH process and are not precisely constrained by current data. Here we use the results from [42] for ILC at 500 GeV and from [3, 43] for CLIC. In any case, these projected uncertainties for g_{Htt}^{eff} would still be similar to the one from the HL-LHC determination of the top Yukawa coupling. Only the FCC project would be able to surpass that precision on its own, after including in the picture the measurements possible at the 100 TeV pp collider. The improvement in this case comes from the measurement of the ttH/ttZ cross sections, which then also relies on a precise measurement of the $Zt\bar{t}$ coupling. For the FCC this would come from the FCC-ee run at 365 GeV [44]. It should be recalled that in all these studies of the ttH or ttZ processes, both at hadron and lepton colliders, we are making explicit use of the assumption that other interactions such as four-fermion or dipole operators can be neglected. A fully global analysis of these processes has to include those operators as well, including the corresponding constraints.

Finally, even after the full physics program of any of the future leptonic machines, there are several couplings whose precision are still above the one percent threshold, mainly those

¹³We remind that in the SMEFT_{FU} scenario, the corrections to the Yukawa interactions of the different fermion families are universal. Therefore, in that scenario, the apparent improvement on the top coupling is in most instances directly linked to the percent level precision of the measurement of the coupling to charm quarks.

associated to rare decays and that are statistically limited. Only a future lepton collider combined with a high-luminosity hadron machine like the FCC-hh would be able to bring down all the main Higgs couplings below 1%, as can be seen in the last column in table 7. In this regard, we also note the role of the FCC-eh measurements, which would help to further increase the precision in the determination of the couplings to vector bosons and b quarks, after the completion of the FCC-ee program.

A comparison between the results of the global fit with those obtained assuming perfect EW measurements –scenario SMEFT_{PEW}– illustrates the relative importance of the EWPO in the extraction of the different Higgs couplings from the global fit [45]. Figure 5 compares the two results for the future Higgs factories at lepton colliders. For what concerns the Higgs couplings, in most cases the impact is quite mild and, in the case of FCC-ee and CEPC, almost nonexistent due to the rich program for measuring the EWPO at the Z pole and above. The default analysis presented in this report includes the preliminary studies of the radiative return process $e^+e^- \rightarrow Z\gamma$ at 250 GeV (380 GeV) with polarized beams at ILC (CLIC). The results are also shown for the case when a Giga- Z run is also included, with on 100 fb^{-1} of data at $\sqrt{s} \sim m_Z$. It is seen that for ILC and CLIC₃₈₀ there is a clear degradation of the uncertainty on the g_{HVV} without the Giga- Z run, which is largely reduced by a dedicated Giga- Z run [3, 4, 11] since the uncertainties on the fermion asymmetries and partial width ratios are reduced by a factor of ~ 10 (see table 27). For these W and Z couplings, such loss of precision can also be minimized by including the information from a high-energy run, as can be seen for CLIC₃₀₀₀, where there is little impact on the precision of the same HVV effective couplings. However, for the aTGC parameters δg_{1Z} and $\delta\kappa_\gamma$, there is still a substantial degradation compared to perfect knowledge of the EWPO values. A significant improvement in the measurements of the electron EW interactions is therefore still needed, if one wants to extract the maximum precision across all the different couplings at e^+e^- colliders [45].

One must take into account that, with the set of projections available from each future collider project, the global fit results presented here are, in some cases, not entirely consistent, due to some approximations present in the projections for $e^+e^- \rightarrow W^+W^-$. Indeed, these are typically reported in terms of the precision on the aTGC but, except for the CLIC studies presented in [46], they are obtained assuming that new physics can only modify δg_{1Z} , $\delta\kappa_\gamma$ and λ_Z , but not the other couplings involved in the production or decays of the WW pairs.¹⁴ This explains the large difference for those parameters in the CLIC results between the global fit and the ones computed under the assumption of perfect EW measurements, see figure 5. The *aTGC dominance* assumption was a good approximation at LEP2, due to the comparatively more precise constraints from the Z -pole measurements at LEP/SLD, but is something to be tested at future colliders, especially for those projects where a run at the Z -pole will not happen. In those cases, the results presented here must therefore be interpreted with caution [45].

¹⁴For the ILC studies [3, 18, 47] part of this dependence is taken into account, adding those contributions from dimension-6 operator coefficients that are enhanced by a factor $s/2m_W^2$. This approximation, justified in the high-energy limit, may not be a good assumption for the ILC run at 250 GeV, but should work well for the aTGC projections at 500 GeV. (These were not available in [3] and we take them from [18].)

Table 8. Sensitivity at 68% probability to deviations in the different effective EW couplings from a global fit to the projections available at each future collider project. Results obtained for the Global SMEFT fit benchmark denoted as SMEFT_{ND} in the text. The numbers for all future colliders are shown *in combination* with the HL-LHC results. The results for ILC and CLIC are shown without a dedicated Giga-Z run. Appendix F includes the results with a Giga-Z run in table 34.

Figure 3. Sensitivity at 68% probability to deviations in the different effective Higgs couplings and aTGC from a global fit to the projections available at each future collider project. Results obtained within the SMEFT framework in the benchmark SMEFT_{ND}. The HE-LHC results correspond to the S_2^J assumptions for the theory systematic uncertainties in Higgs processes [13].

3.4.2 Results for BSM-motivated effective Lagrangians

In this subsection, we adopt a more BSM-oriented perspective and present the global fit results in a way that can be easily matched to theory-motivated scenarios, such as composite Higgs models. For that purpose, we will restrict the results to the set of dimension-6 interactions in the effective Lagrangian in eq. (3.19) and adopt the usual presentation of results in terms of the bounds on the dimension-6 operator coefficients. We will also extend the global fits presented in previous sections, adding further studies available in the literature about high-energy probes of the EFT. These are designed to benefit from the growth with energy of the contributions of certain dimension-6 operators in physical processes, leading to competitive constraints on new physics, without necessarily relying on extreme experimental precision. In this regard, we note that these studies are usually not performed in a fully global way within the EFT framework, but rather focus on the most important effects at high energies. Therefore, the results when such processes dominate in the bounds on new physics should be considered with a certain amount of caution, although they should offer a reasonable approximation under the assumptions in (3.19) and (3.20). In particular, we will add the following high-energy probes using di-boson and

Figure 4. Sensitivity at 68% probability to deviations in the different EW couplings from a global fit to the projections available at each future collider project. Results obtained within the SMEFT framework in the benchmark SMEFT_{ND}. Note that Z-radiative return measurements at ILC and CLIC are included in the fit. Two different assumptions are considered for the systematic errors. The HE-LHC results correspond to the S'_2 assumptions for the theory systematic uncertainties in Higgs processes [13]. See text for details.

di-fermion processes:

- The constraints on the W and Y oblique parameters [48] (which can be mapped into $c_{2W;2B}$) from fermion pair production at the HL-LHC, HE-LHC [13], FCC-hh [49], ILC at 250, 500 and 1000 GeV [4] and CLIC [46].¹⁵

It must be noted that, for the HE-LHC, only the sensitivity to W and Y from $pp \rightarrow \ell^+ \ell^-$ is available in [13]. There is no sensitivity reported from charged-current process, which can constrain W independently. No studies on the reach for the W and Y parameters were available for CEPC or the FCC-ee. For this section for these two lepton colliders it has been estimated following the studies in ref. [4, 46].¹⁶

¹⁵The studies in [46] and [4] make use of significantly different assumptions for the systematic uncertainties and efficiencies for each $e^+e^- \rightarrow f\bar{f}$ channel. The apparent small difference in terms of reach at the highest energy stages for CLIC/ILC is, however, due to the high luminosity assumed at ILC, as well as the use of positron polarization, which allow to partially compensate the lower energy achievable compared to CLIC.

¹⁶We obtain alues of $\delta W_{\text{CEPC}} \sim 5.3 \times 10^{-5}$, $\delta Y_{\text{CEPC}} \sim 4.7 \times 10^{-5}$, with a correlation of -0.5 ; $\delta W_{\text{FCC-ee}(240)} \sim 5.4 \times 10^{-5}$, $\delta Y_{\text{FCC-ee}(240)} \sim 4.9 \times 10^{-5}$, with the same -0.5 correlation; and $\delta W_{\text{FCC-ee}} \sim 3.2 \times 10^{-5}$, $\delta Y_{\text{FCC-ee}} \sim 2.9 \times 10^{-5}$, with a correlation of -0.53 .

Figure 5. 68% probability reach on Higgs couplings and aTGC values for the different lepton colliders from the Global fit SMEFT_{ND}, compared with the results obtained assuming infinite precision for the EWPO (scenario SMEFT_{PEW}). The difference (partially) illustrates the impact of the EW constraints on the Higgs results. See text for discussion and caveats which apply to this study. The measurements based on Z bosons from radiative return at ILC and CLIC are included in the default fit, and the horizontal red marks indicate the coupling reach when additionally a dedicated Z -pole run is taken.

- The study in ref. [50] of the M_{ZH} distribution in $pp \rightarrow ZH, H \rightarrow b\bar{b}$ in the boosted regime for the HL-LHC [13] and FCC-hh [1]. (This was not available for the HE-LHC.) Note that both CLIC (and to a lesser extent ILC) have access to similar physics in the leptonic case, from the ZH measurements at 1.5/3 TeV (500/1000 GeV). Current ILC projections for Higgs production at 1 TeV [4] are only available for the W boson fusion channel. For the fits presented in this section, for $\sigma_{ZH} \times BR(H \rightarrow b\bar{b})$ at ILC at 1 TeV an uncertainty of 1.3% is assumed for each polarization [51].
- The p_{TV} distribution in $pp \rightarrow WZ$ from ref. [52] for the HL-LHC, HE-LHC and FCC-hh.

These are of course only a sample of the high-energy precision probes that could be tested at future colliders (and at HL-LHC) so the results presented are not an exhaustive study of the potential of the different machines in this regard (see e.g. [53, 54].)

The results of this fit are shown in figure 6 after the full run of each future collider project, and in table 9. Apart from the 68% probability bounds for each operator from the global fit, we also present the results assuming only one operator is generated by the UV dynamics. The difference between both results is indicative of the correlations between the different operators in the fit. These can, in some cases, be rather large. A full study of such correlations goes beyond the scope of this report, but it is worth mentioning that some of the largest correlations typically occur between $\mathcal{O}_\gamma, \mathcal{O}_{\phi W}, \mathcal{O}_{\phi B}, \mathcal{O}_W, \mathcal{O}_B$ where

all contribute to the Higgs interactions with neutral vector bosons. Large correlations also connect \mathcal{O}_g and \mathcal{O}_{y_u} . These are typically constrained along the $H \rightarrow gg$ direction with better precision than the one obtained for \mathcal{O}_{y_u} from the corresponding ttH process at the different colliders.

For those operators whose effects are mainly constrained by Higgs observables, e.g. \mathcal{O}_ϕ and \mathcal{O}_{y_f} , the evolution of the results in the table follows essentially the same pattern as in the discussion of the Higgs coupling results of the SMEFT fit. Likewise, similar considerations must be taken into account when comparing the results across colliders, in particular regarding the dependence of the HE-LHC results on the assumptions of the reduction of the theory/systematic uncertainties, which control most of the improvement with respect to HL-LHC. (See comment on the S2' assumptions in section 2.) Also regarding the results at high luminosity/energy upgrades of the LHC, some of the numbers in table 9, namely those involving a single operator fit to c_ϕ , may look surprising, given that the projections for most Higgs observables at such machines are expected to be dominated by the theory/systematic uncertainties. These results are marked with a \dagger in the table. For instance, the HL-LHC result corresponds to a precision in an overall Higgs coupling modification at the level of 0.8%. This is below the dominant signal theory uncertainties assumed in the HL-LHC S2 hypothesis. As explained in section 2, this is a consequence of the assumptions in the treatment of theory/systematic uncertainties in the simplified set of inputs used in this report for the HL-LHC fits. A rough estimate of the bound that would result from assuming 100% correlated signal theory uncertainties would return, for the same case, $c_\phi/\Lambda^2 \sim 0.42 \text{ TeV}^{-2}$, illustrating the impact of the choice of assumption in the treatment of these theory systematics. Given the implications of these bounds in terms of constraining BSM scenarios (as will be illustrated below, c_ϕ sets some of the most important constraints in composite Higgs models), this is an issue that should be carefully studied at hadron colliders, as it will become (even more) relevant at the end of the HL-LHC era. There is another caveat affecting the results presented in the table 9 that concerns the HE-LHC limits for c_{2B} and c_{2W} , also marked with a \dagger . In this case, the reaches for c_{2B} and c_{2W} , which can be mapped into the W and Y oblique parameters, are limited by the lack of constraints from the charged current channel at HE-LHC since no projections were provided at this time. The charged current channel is sensitive to the W parameter and, via its correlation with Y , can also affect the results for the latter in the global fit.

A meaningful interpretation of these results in terms of a broad class of composite Higgs models can be obtained under the assumptions leading to the dependence of the Wilson coefficients on new physics coupling, g_\star , and mass, m_\star , described in eq. (3.20) and below (i.e. we assume $c_{g,\gamma}$ and $c_{\phi V,3V}$ are loop suppressed in y_t and g_\star , respectively). In figure 7 we translate the results of the fit in figure 6 in terms of the 95% probability constraints in the (g_\star, m_\star) plane under such assumptions, and setting all $O(1)$ coefficients exactly to 1, i.e.

$$\begin{aligned}
 \frac{c_{\phi,6,y_f}}{\Lambda^2} &= \frac{g_\star^2}{m_\star^2}, & \frac{c_{W,B}}{\Lambda^2} &= \frac{1}{m_\star^2}, & \frac{c_{2W,2B,2G}}{\Lambda^2} &= \frac{1}{g_\star^2} \frac{1}{m_\star^2}, & \frac{c_T}{\Lambda^2} &= \frac{y_t^4}{16\pi^2} \frac{1}{m_\star^2}, \\
 \frac{c_{\phi W,\phi B}}{\Lambda^2} &= \frac{g_\star^2}{16\pi^2} \frac{1}{m_\star^2}, & \frac{c_{\gamma,g}}{\Lambda^2} &= \frac{y_t^2}{16\pi^2} \frac{1}{m_\star^2}, & \frac{c_{3W,3G}}{\Lambda^2} &= \frac{1}{16\pi^2} \frac{1}{m_\star^2}.
 \end{aligned}
 \tag{3.23}$$

Table 9. 68% probability reach on the different Wilson coefficients in the Lagrangian eq. (3.19) from the global fit. In parenthesis we give the corresponding results from a fit assuming only one operator is generated by the UV physics. See text for details, in particular regarding the results marked with a †.

Figure 6. Global fit to the EFT operators in the Lagrangian (3.19). We show the marginalized 68% probability reach for each Wilson coefficient c_i/Λ^2 in eq. (3.19) from the global fit (solid bars). The reach of the vertical “T” lines indicate the results assuming only the corresponding operator is generated by the new physics. The HE-LHC results correspond to the S'_2 assumptions for the theory systematic uncertainties in Higgs processes [13].

We focus the comparison, again, on the full physics program at each future collider project (solid regions), but also show the region delimited by the low energy runs, or the FCC-ee for the case of the FCC project (the boundaries are indicated by the dashed lines). In the right panel of that figure we also show, for illustration purposes, the individual constraints set by several of the operators in (3.19) for the FCC fit. The modifications of the on-shell Higgs properties discussed in this report are mainly controlled, within the SILH assumptions, by the contributions to the operators \mathcal{O}_ϕ and \mathcal{O}_{y_f} , both of which set similar constraints in the global fit for this collider. These give the leading constraints in strongly coupled scenarios. Electroweak precision measurements, on the other hand, are more affected by a combination of $\mathcal{O}_{W,B}$ and set bounds independently of the new physics coupling. Finally, some of the high-energy probes included in the analysis provide the most efficient way of testing weakly coupled scenarios.

3.5 Impact of Standard Model theory uncertainties in Higgs calculations

As important as it is to have very precise experimental measurements of the different Higgs processes, it is also fundamental from the point of view of their physical interpretation to

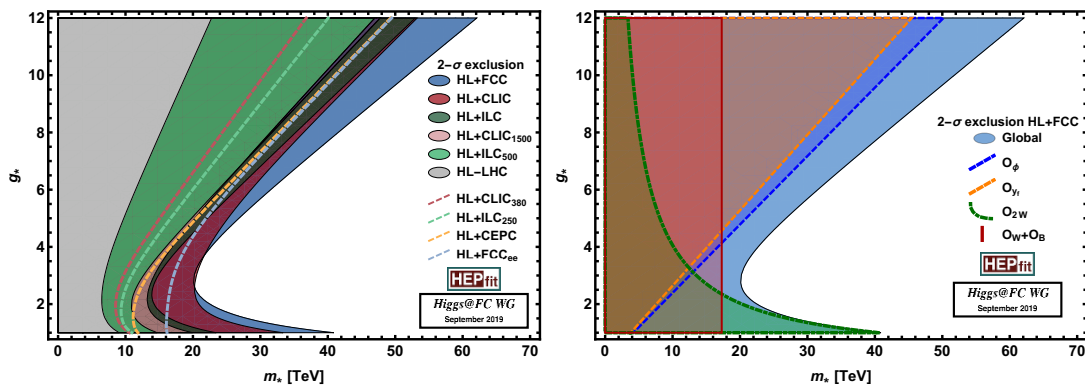

Figure 7. (Left) $2\text{-}\sigma$ exclusion regions in the (g_*, m_*) plane from the fit presented in figure 6, using the SILH power-counting described in eq. (3.20) and below (solid regions). Dashed lines indicate the regions constrained by the corresponding low-energy runs (or FCC-ee only for the case of the FCC project). (Right) The same comparing the results from the global fit with the constraints set by some of the operators individually, for the illustrative case of the HL-LHC+FCC-ee/eh/hh. In this case, the constraints from the on-shell Higgs measurements mainly affect \mathcal{O}_ϕ and \mathcal{O}_{y_f} .

have theoretical calculations for the predictions of such processes with comparable or better precision. In this sense, to quantify to what extent an experimental measurement with uncertainty δ_{exp} can be translated into a constraint on new physics,¹⁷ one needs to know the corresponding uncertainty δ_{SM} for the SM prediction. In order to extract the maximum experimental information, ideally, $\delta_{\text{SM}} \ll \delta_{\text{exp}}$. The sources of the SM uncertainty are typically separated in two types of contributions:

- *Parametric theory uncertainties* (Th_{Par}). For a given observable O , this is the error associated to the propagation of the experimental error of the SM input parameters to the SM prediction O_{SM} .
- The second source of uncertainty is due to the fact that, in practice, O_{SM} is only known to a finite order in perturbation theory. The estimate of the net size associated with the contribution to O_{SM} from missing higher-order corrections is usually referred to as *intrinsic theory uncertainty* (Th_{Intr}).

Of course, in the interpretation of any measurement in a particular extension of the SM, there are also errors associated with the missing corrections in the expansion(s) including the new physics parameters. In the particular case of the EFT framework, these would come from NLO corrections in the perturbative expansion including dimension-6 interactions or, from the point of view of the EFT expansion, from q^4/Λ^4 effects coming from either the square of the dimension-6 contributions to the amplitudes, or the SM interference with amplitudes involving dimension-8 operators or double insertions of the dimension-6 ones. Note that all these corrections affect the interpretation of a measurement in terms of pinpointing what is the source of the deformation from the SM, i.e. which particular operator and how large its coefficient can be, but not on the size of the overall deformation

¹⁷Or, equivalently, to what extent a measurement agrees with the SM.

per se. The latter is only controlled by the SM theoretical uncertainty. Because of that, and in the absence of a fully developed program including such contributions in the SMEFT framework, we restrict the discussion in this section to SM uncertainties only.

In the previous sections the results for future colliders after the HL/HE-LHC era were presented taking into account parametric uncertainties only. This was done to illustrate the final sensitivity to BSM deformations in Higgs couplings, as given directly by the experimental measurements of the different inputs (i.e. Higgs rates, diBoson measurements, EWPO or the processes used to determine the values of the SM input parameters). On the other hand, for this scenario to be meaningful, it is crucial to also study the effect in such results of the projections for the future intrinsic errors. This is needed to be able to quantify how far we will be from the assumption that such intrinsic errors become subdominant and, therefore, which aspects of theory calculations should the theory community focus on to make sure we reach the maximum experimental sensitivity at future colliders.

In this section we discuss more in detail the impact of the two types of SM theory errors described above, from the point of view of the calculations of the predictions for Higgs observables. This will be done both within the κ framework and also in the context of the EFT results. For the results from the κ -framework we will use the most general scenario considered in section 3.1, i.e. kappa-3, which allows non-SM decays. On the EFT side, we will use the scenario SMEFT_{PEW}, where the uncertainty associated with the precision of EWPO has already been “factorized”. In this scenario each fermion coupling is also treated separately, thus being sensitive to the uncertainties in the different $H \rightarrow f\bar{f}$ decay widths. Finally, we will also restrict the study in this subsection to the case of future lepton colliders only (we always consider them in combination with the HL-LHC projections). For the latter we keep the theory uncertainties as reported by the WG2 studies [13]).

In table 10 we show the results of the κ fit for the benchmark scenario kappa-3, indicating the results obtained including/excluding the different sources of SM theory uncertainties. Similarly, table 11 shows the results of the EFT fit for the benchmark scenario SMEFT_{PEW}. For the EFT results the impact of the different theory uncertainties is also illustrated in figure 8. As can be seen, if the SM errors were reduced to a level where they become sub-dominant, the experimental precision would allow to test deviations in some of the couplings at the one per-mille level, e.g. the coupling to vector bosons at CLIC in the SMEFT framework (the presence of extra decays would however reduce the precision to the 0.4% level, as shown in the kappa-3 results). The assumed precision of the SM theory calculations and inputs, however, prevents reaching this level of sensitivity. The most notable obstacle to achieve this close to per-mille level of precision are the intrinsic uncertainties for the $e^+e^- \rightarrow ZH$ and, especially, in $e^+e^- \rightarrow H\bar{\nu}\nu$, estimated to be $\sim 0.5\%$. In reaching this level of theoretical precision it was assumed that predictions at NNLO in the EW coupling for both processes will be available. This is within reach for ZH production, but it may be more challenging for $e^+e^- \rightarrow H\bar{\nu}\nu$ (and $H \rightarrow VV^* \rightarrow 4f$). However, with enough effort on the theory side [55–57], this type of uncertainties can be reduced. If the necessary resources are dedicated to develop these types of calculations, it should be possible to achieve, or even surpass, the required level of precision. This is not the case for the SM parametric errors, which depend on the experimental measurements of the corresponding input parameters.

From the results of the fits, the largest effect of this type of uncertainty on the determination of the fermion couplings affects the effective coupling of the bottom to the Higgs. The corresponding SM error in $H \rightarrow b\bar{b}$ depends on the precision of the bottom quark mass, whose projected future determination was assumed to be ~ 13 MeV. Taking into account the projected improvements from Lattice QCD calculations, this should be a conservative estimate [55]. Other parametric uncertainties, e.g. in $H \rightarrow c\bar{c}, gg$ and associated with m_c and α_S , are larger than the one for $H \rightarrow b\bar{b}$ but have a smaller effect in the results due to the also larger experimental errors expected in the corresponding channels. From the point of view of the Higgs decays into vector bosons, the predictions of $H \rightarrow ZZ^*, WW^*$ have a strong dependence on the value of the Higgs mass. It is therefore important to accompany the precise measurements of the Higgs couplings with equally precise measurements of the Higgs mass, to the level of 10 MeV. This would be possible at 240/250 GeV lepton colliders but more challenging at CLIC, where the final precision on M_H is expected at the level of 20–30 MeV (see section 7). In the kappa-framework, the fact that the dependence of the production e^+e^- Higgs cross sections on M_H is less severe helps to reduce the impact of the M_H uncertainty in the CLIC results. This is no longer the case once we move to the more general description of the SMEFT. In that case, non-SM like interactions contribute to the effective HZZ and HWW couplings, and the information on $H \rightarrow WW^*$ becomes relevant to determine g_{HZZ}^{eff} . The measurement of M_H at the HL-LHC at the 10–20 MeV level prevents this from becoming an issue at the lower energy stages at CLIC. But there is still a factor ~ 2 deterioration in the precision of the g_{HZZ}^{eff} coupling in the final CLIC results, emphasising again the necessity of a precise determination of M_H .

4 The Higgs boson self-coupling

The Higgs field is responsible for the spontaneous breaking of the electroweak symmetry, and for the generation of all the SM particle masses, because its potential features a global minimum away from the origin. Within the SM, this potential is fully characterised by two parameters, the Higgs mass m_h , and v , which can be experimentally inferred from the measurements of the Fermi constant ($v = 1/\sqrt{\sqrt{2}G_F} \approx 246$ GeV).

$$V(h) = \frac{1}{2}m_H^2 h^2 + \lambda_3 v h^3 + \frac{1}{4}\lambda_4 h^4, \quad \text{with} \quad \lambda_3^{\text{SM}} = \lambda_4^{\text{SM}} = \frac{m_H^2}{2v^2}. \quad (4.1)$$

However, the Higgs potential could show sizeable departures from the SM form, described in eq. (4.1). The understanding of EW symmetry breaking will remain hypothetical until experimental measurements reconstruct the shape of the Higgs potential. The *measurement* of the Higgs potential is therefore a high priority goal on the physics programme of all future colliders.

Unfortunately, the Higgs self-interactions, apart from the simple kinematical 2-point interaction that corresponds to the Higgs boson mass, are not physical observables. Therefore, a theoretical framework is needed to infer their values from experimental measurements. One needs a general parametrisation of the departures from the SM that allows the various Higgs couplings to vary continuously. Within this framework, one makes accurate predictions of various observables as a function of the modified Higgs couplings and

Table 11. Comparison, within the SMEFT_{PEW} fit, of the sensitivity at 68% probability to deviations in the different effective Higgs couplings and aTGC under different assumptions for the SM theory uncertainties. We compare the results obtained neglecting both intrinsic and parametric uncertainties, including each of them separately, and finally adding the full SM uncertainty.

Figure 8. Impact of the different sources of SM theory uncertainties in the coupling reach at the different lepton-collider projects based on the SMEFT_{PEW} fit. Using dark to light shades we show the results without SM theory uncertainties (darkest shade), only with the intrinsic uncertainty (medium), and the full SM error (lightest shade). The solid line indicates the result with SM parametric uncertainties only. The most significant differences are found for the effective coupling to vector bosons (dominated by intrinsic uncertainties) and to bottom quarks (controlled by the parametric error associated with m_b). See table 11 and text for details.

a global fit then leads to a determination of all these couplings. Effective Field Theory offers us such a theoretically sound framework in which higher order calculations can be performed to provide solid and improvable predictions able to cope with systematic and statistic experimental uncertainties. As in section 3.3, we will focus our attention on EFT where the EW symmetry is linearly realised, i.e. under the assumption that no new heavy degree of freedom acquires its mass from the Higgs expectation value. In that case, there are only two dimension-6 operators that induce a deviation of the Higgs self-couplings

$$\mathcal{L} = \mathcal{L}^{\text{SM}} + \frac{c_\phi}{2\Lambda^2} \partial_\mu |\phi|^2 \partial^\mu |\phi|^2 - \frac{c_6 \lambda_3^{\text{SM}}}{\Lambda^2} |\phi|^6$$

$$\Rightarrow \kappa_3 \equiv \frac{\lambda_3}{\lambda_3^{\text{SM}}} = 1 + \left(c_6 - \frac{3}{2} c_\phi \right) \frac{v^2}{\Lambda^2}, \quad \kappa_4 \equiv \frac{\lambda_4}{\lambda_4^{\text{SM}}} = 1 + \left(6c_6 - \frac{25}{3} c_\phi \right) \frac{v^2}{\Lambda^2}. \quad (4.2)$$

In particular, the operator proportional to c_ϕ requires a non-linear field definition to keep the Higgs boson kinetic term canonically normalised. The modifications of the cubic and quartic self-interactions are related in this model. Independent modifications are only obtained when operators of dimension 8 are considered.

The most direct way to assess the Higgs cubic self-interaction is through the measurement of double Higgs production either at hadron colliders, where the production is

dominated by gluon fusion, $gg \rightarrow HH$, or at lepton colliders via double Higgs-strahlung, $e^+e^- \rightarrow ZHH$, particularly relevant at low energies, or via vector boson fusion (VBF), $e^+e^- \rightarrow HH\nu_e\bar{\nu}_e$, more important at centre-of-mass energies of 1 TeV and above. At leading order, double Higgs production receives a contribution proportional to the cubic coupling, for both pp and e^+e^- collisions, as shown in figure 9. Figure 10 shows the dependence of the inclusive double Higgs production cross section when the value of the Higgs cubic coupling is varied, assuming no other deviation from the SM. Gluon fusion production at a hadron collider has been computed within the SM at NNLO accuracy in the infinite top mass limit [58–61] and at NLO with the full top mass dependence [62–64], leading to a prediction whose theoretical and parametric uncertainties are of the order of a few percent.

For the LHC at 14 TeV, the cross section is predicted to be $36.69^{+2.1\%}_{-4.9\%}$ fb, about three orders of magnitude smaller than the single Higgs production, which makes the double Higgs channel a challenging process to observe. The most up-to-date analysis relies on the combination of the $b\bar{b}\gamma\gamma$ and $b\bar{b}\tau\tau$ decay channels to reach almost 5 standard deviation evidence for double Higgs production at HL-LHC (see table 55 and figure 65 of ref. [13]), which can be translated into a 68% CL bound of order 50% on the deviation of the Higgs cubic coupling relative to the SM prediction. Note that the mapping of the inclusive $gg \rightarrow HH$ cross section onto a value of the Higgs cubic self-coupling is not unique: for instance, at 14 TeV LHC, a value of the cross section equal to the SM prediction corresponds either to $\kappa_3 = 1$ or to $\kappa_3 \approx 6.2$. This ambiguity can however be resolved by analysing the shape of the invariant mass distribution of the reconstructed two Higgs boson system: the larger the value of κ_3 , the closer to threshold the m_{HH} distribution is peaked. This kinematic information is a crucial element of Boosted Decision Trees (BDT) based analysis performed at HL-LHC. However the BDT and the final selection cuts are often devised to optimise the significance of the SM cross section for double Higgs production and therefore it is not necessarily optimised for the determination of the Higgs self-coupling directly, leaving room for possible improvement towards an even higher sensitivity. At lepton colliders, double Higgs-strahlung, $e^+e^- \rightarrow ZHH$, gives stronger constraints on positive deviations ($\kappa_3 > 1$), while VBF is better in constraining negative deviations, ($\kappa_3 < 1$). While at HL-LHC, values of $\kappa_3 > 1$, as expected in models of strong first order phase transition, result in a smaller double-Higgs production cross section due to the destructive interference, at lepton colliders for the ZHH process they actually result in a larger cross section, and hence into an increased precision. For instance at ILC₅₀₀, the sensitivity around the SM value is 27% but it would reach 18% around $\kappa_3 = 1.5$.

Modified Higgs self-interactions can also affect, at higher orders, the single Higgs processes [67–69] and even the electroweak precision observables [70–72]. Since the experimental sensitivities for these observables are better than for double Higgs production, one can devise alternative ways to assess the value of the Higgs self-interactions. For a 240 GeV lepton collider, the change of the ZH production cross section at NLO induced by a deviation of the Higgs cubic coupling amounts to

$$\sigma_{ZH}^{\text{NLO}} \approx \sigma_{ZH}^{\text{NLO,SM}}(1 + 0.014 \delta\kappa_3). \tag{4.3}$$

Figure 9. Representative Feynman diagrams for the leading contribution to double Higgs production at hadron (left) and lepton (right) colliders. Extracting the value of the Higgs self-coupling, in red, requires a knowledge of the other Higgs couplings that also contribute to the same process. See table 18 for the SM rates. At lepton colliders, double Higgs production can also occur via vector boson fusion with neutral currents but the rate is about ten times smaller. The contribution proportional to the cubic Higgs self-coupling involves an extra Higgs propagator that dies off at high energy. Therefore, the kinematic region close to threshold is more sensitive to the Higgs self-coupling.

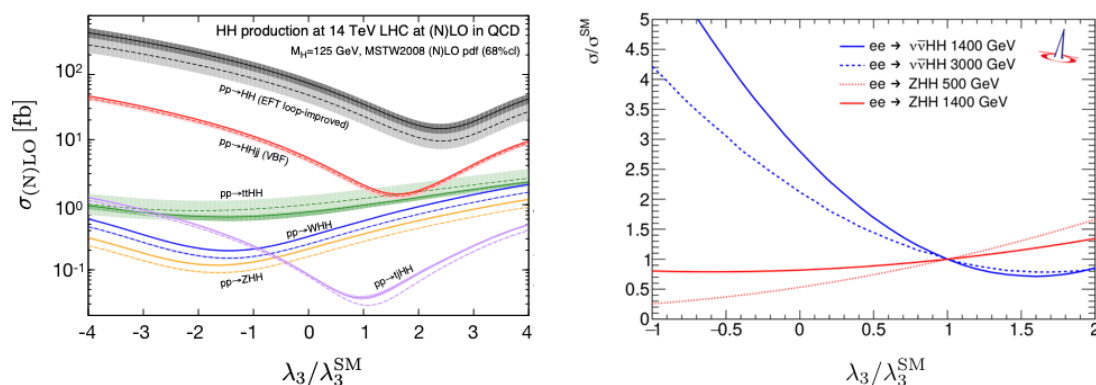

Figure 10. Double Higgs production at hadron (left) [65] and lepton (right) [66] colliders as a function of the modified Higgs cubic self-coupling. See table 18 for the SM rates. At lepton colliders, the production cross sections do depend on the polarisation but this dependence drops out in the ratios to the SM rates (beam spectrum and QED ISR effects have been included).

Thus, to be competitive with the HL-LHC constraint, the ZH cross section needs to be measured with an accuracy below 1%, but this is expected to be achieved by e^+e^- Higgs factories at 240/250 GeV. However, one needs to be able to disentangle a variation due to a modified Higgs self-interaction from variations due to another deformation of the SM. This cannot always be done relying only on inclusive measurements [73, 74] and it calls for detailed studies of kinematical distributions with an accurate estimate of the relevant uncertainties [75]. Inclusive rate measurements performed at two different energies also help lifting the degeneracy among the different Higgs coupling deviations (see for instance the κ_3 sensitivities reported in table 12 for FCC-ee₂₄₀ vs FCC-ee₃₆₅; it is the combination

of the two runs at different energies that improve the global fit, a single run at 365 GeV alone would not improve much compared to a single run at 240 GeV).

In principle, large deformations of κ_3 could also alter the fit of single Higgs processes often performed at leading order, i.e. neglecting the contribution of κ_3 at next-to-leading order. The results presented in section 3.4 were obtained along that line. It was shown in [73] that a 200% uncertainty on κ_3 could for instance increase the uncertainty in g_{Htt} or g_{Hgg}^{eff} by around 30–40%. The fact that HL-LHC from the double Higgs channel analysis will limit the deviations of κ_3 to 50% prevents such a large deterioration of the global fits to single Higgs couplings when also allowing κ_3 to float. In the effective coupling basis we are considering in this report, the effect of κ_3 would be mostly in the correlations among the single Higgs couplings. In other bases, like the Warsaw basis, there would be a deterioration up to 15-20% in the sensitivity of the operator $\mathcal{O}_{\phi\Box}$. Anyway, one should keep in mind that such a deterioration only concerns specific models where the deviations of the Higgs self-coupling is parametrically larger than the deviations of the single Higgs couplings and in generic situations, the results of section 3.4 hold.

In order to set quantitative goals in the determination of the Higgs self-interactions, it is useful to understand how large the deviations from the SM could be while remaining compatible with the existing constraints on the different single Higgs couplings. From an agnostic point of view, the Higgs cubic coupling can always be linked to the independent higher dimensional operator $|H|^6$ that does not alter any other Higgs couplings. Still, theoretical considerations set an upper bound on the deviation of the trilinear Higgs couplings. Within the plausible linear EFT assumption discussed above, perturbativity imposes a maximum deviation of the Higgs cubic self-interaction, relative to the SM value, of the order of [27, 73]

$$|\kappa_3| \lesssim \text{Min}(600 \xi, 4\pi), \tag{4.4}$$

where ξ is the typical size of the deviation of the single Higgs couplings to other SM particles [30]. However, the stability condition of the EW vacuum, i.e. the requirement that no other deeper minimum results from the inclusion of higher dimensional operators in the Higgs potential, gives the bound [27, 76]

$$|\kappa_3| \lesssim 70 \xi. \tag{4.5}$$

At HL-LHC, ξ can be determined with a precision of 1.5% at best, corresponding to a sensitivity on the Higgs self-coupling of about 100%, and thus somewhat inferior but roughly comparable to the direct sensitivity of 50% [13]. Parametric enhancements of the deviations of Higgs cubic self-coupling relative to the single Higgs couplings require a particular dynamics for the new physics. An example is encountered in Higgs portal models where the Higgs boson mixes with a SM neutral scalar field, possibly contributing to the dark matter relic abundance [41, 73]. In more traditional scenarios addressing the hierarchy problem, such as supersymmetric or composite models, the deviation of κ_3 is expected to be of the order ξ and is likely to remain below the experimental sensitivity.

The sensitivity of the various future colliders to the Higgs cubic coupling can be obtained using five different methods (1, 2(a), 2(b), 3, and 4):

1. an exclusive analysis of HH production, i.e., a fit of the double Higgs cross section considering only deformation of the Higgs cubic coupling;
2. a global analysis of HH production, i.e., a fit of the double Higgs cross section considering also all possible deformations of the single Higgs couplings that are constrained by single Higgs processes;
 - (a) the global fit does not consider the effects at higher order of the modified Higgs cubic coupling to single Higgs production and to Higgs decays;
 - (b) these higher order effects are included;
3. an exclusive analysis of single Higgs processes at higher order, i.e., considering only deformation of the Higgs cubic coupling; technically, this will be a one-dimensional EFT fit where only the linear combination of the two operators of eq. (4.2) corresponding to the κ_3 deformation is turned on;
4. a global analysis of single Higgs processes at higher order, i.e., considering also all possible deformations of the single Higgs couplings. Technically, this will be a 30-parameter EFT fit done within the scenario SMEFT_{ND} scenario of eq. (3.16). The contribution of κ_3 to EWPO at 2-loop could also be included but for the range of κ_3 values discussed here, the size of effects would be totally negligible.

Most of the studies of the Higgs self-couplings at Future Colliders were done following Method (1). In order to maximize the sensitivity to λ_3 , the analyses rely on sophisticated BDTs, and a simple recasting within an EFT framework is not an easy task. A pragmatic approach was followed along the line of what was proposed in [73]: different bins in m_{HH} are considered and the experimental uncertainty on the total rate is distributed in the different bins according to their number of expected events. This certainly ignores the bin-to-bin correlations and it does not take into account either that the background itself has a non-trivial shape as a function of m_{HH} . Nevertheless, the results obtained that way are in good agreement with those quoted by the different collaborations. This approach has the advantage that it can be easily generalised to a global EFT analysis that considers all the operators modifying also the single Higgs couplings, Methods (2). One should keep in mind that the bounds derived that way represent a crude estimate that waits for a proper experimental study.¹⁸

For most colliders, the single Higgs constraints are strong enough that they give a contribution to the double Higgs production below its experimental sensitivity. And Method (1) and Method (2) lead to rather similar bound on κ_3 . A notable exception is at FCC-hh where the 1% uncertainty on the top Yukawa coupling results in a deviation of the double Higgs production rate at a level comparable to the one induced by a shift of κ_3 by

¹⁸A detailed m_{HH} binned analysis was not available for HE-LHC, hence we could not estimate the κ_3 sensitivity along Method (2) for that collider. Similarly, for CLIC₃₀₀₀, the granularity of the available information was not sufficient to match the announced sensitivity, and therefore we did not venture into a complete study along Method (2) either. In both cases, our checks led to the conclusion that there will not be any noticeable difference between the sensitivity obtained in Methods (1) and (2).

5%. While a parametric enhancement of the deviation in κ_3 compared to the other Higgs couplings deviations could make its higher order contributions to single Higgs processes as important as the leading order ones and thus could in principle modify the global fit, in practice, the constraints set by the double Higgs production are strong enough that there is hardly any difference in the results obtained using Methods (2a) and (2b). Methods (3) and (4) are particularly relevant for low-energy colliders below the double Higgs production threshold. Above this threshold, these methods can still be relevant to complement results from the double Higgs analysis, for instance by helping to resolve the degeneracy between the SM and a second minimum of the likelihood. While this does not modify the 1σ bound on κ_3 , it can impact the bound starting at the 2σ level due to the non-Gaussian profile of the likelihood. It should be remembered that the single Higgs data used in Methods (3) and (4) have not been optimised for the extraction of the Higgs self-coupling that would benefit from further differential information. Therefore, the bounds on κ_3 should be considered as conservative and are certainly improvable.

Table 12 reports the sensitivity at the various colliders for the Higgs cubic coupling determination. For the global EFT fits, we limit ourselves to the SMEFT_{ND} scenario, see eq. (3.16), extended with eq. (3.7). For all results a simple combination with the HL-LHC results is done, i.e. by using a 50% uncertainty on κ_3 . It is seen that the results for Methods (1) and (2) are very similar, showing that the determination of κ_3 is dominated by the di-Higgs measurements when these are included. When comparing Methods (3) and (4) one observes that the exclusive results appear to be more constraining than the global results. But they overestimate the sensitivity as *a priori* it is not known which operator coefficients to fix and the same single-Higgs data should be used to constrain all operators. Method (4) is significantly more robust than Method (3). In the following we focus on Methods (1) and (4).

The results are also summarised in figure 11 for these two methods. Even though the likelihood is not a symmetric function of κ_3 , the current level of precision in this EFT analysis is not good enough to robustly assess an asymmetric error and we report only symmetrised bounds in the figure.

Based on di-Higgs measurements, with a 50% sensitivity on κ_3 , HL-LHC will exclude the absence of the Higgs self-interaction ($\kappa_3 = 0$) at 95%CL. Several of the proposed FCs (HE-LHC, LE-FCC and LHeC) will reach a sensitivity of order 20% based on di-Higgs production, thus establishing the existence of the self-interaction at 5σ . Even more remarkable, CLIC₃₀₀₀ and ILC₁₀₀₀ are expected to reach a sensitivity of order 10% and FCC_{hh} of the order of 5%, where one could start probing the size of the quantum corrections to the Higgs potential directly.

With single-Higgs production at FCC-ee and ILC₅₀₀ and ILC₁₀₀₀, in combination with di-Higgs results from HL-LHC, a sensitivity of $\sim 30\%$ can be reached. For FCC-ee with 4 interaction points (IPs) this is reduced to 24%. For the other collider options with $\sqrt{s} < 400$ GeV no improvement w.r.t. the HL-LHC result is seen.

Even though we do not report any sensitivity on κ_3 at muon-collider, we note that preliminary studies [77] indicate that a 10 TeV (resp. 30 TeV) machine could reach a 3% (resp. 1%) sensitivity.

collider	di-Higgs		single-Higgs		
	(1) excl.	(2.a) glob.	(3) excl.		(4) glob.

Table 12. Sensitivity at 68% probability on the Higgs cubic self-coupling at the various future colliders. All the numbers reported correspond to a simplified combination of the considered collider with HL-LHC, which is approximated by a 50% constraint on κ_3 . The numbers in the first column (i.e. “di-H excl.” or Method (1)) correspond to the results given by the future collider collaborations and in parenthesis, we report our derived estimate obtained in the binned analysis described in the text. In the three last columns, i.e. Methods (2a), (3) and (4), we report the results computed by the Higgs@FC working group. For the leptonic colliders, the runs are considered in sequence. For the colliders with $\sqrt{s} \lesssim 400$ GeV, Methods (1) and (2.a) cannot be used, hence the dash signs in the corresponding cells. No sensitivity was computed along Method (2.a) for HE-LHC and CLIC₃₀₀₀ but our initial checks do not show any difference with the sensitivity obtained for Method (1). In the global analyses, Methods (2.a) and (4), we consider the flavour scenario of *Neutral Diagonality* (the results show little difference compared to the ones reported in the first version of this report within the *Neutral Diagonality* scenario). Due to the lack of results available for the ep cross section in SMEFT, we do not present any result for LHeC nor HE-LHeC, and only results with Method (1) for FCC-eh. For Method (3) results are shown with and without combination with HL-LHC for many of the colliders (in several cases, the fit for Method (4) does not converge for the standalone collider without HL-LHC input).

5 Rare Higgs boson decays

There are many reasons for the interest in rare Higgs boson decays. First, they provide access to Higgs couplings which are expected to be small in the SM and have not yet been directly probed. A leading example is the coupling to second and first generation fermions, whose determination would test the hypothesis that the same Higgs doublet is responsible for the mass generation of the lighter states of the SM. More specifically, the measurement of several Yukawa couplings will allow the comparison of ratios of couplings

Figure 11. Sensitivity at 68% probability on the Higgs cubic self-coupling at the various FCs. All values reported correspond to a simplified combination of the considered collider with HL-LHC. Only numbers for Method (1), i.e. “di-H excl.”, corresponding to the results given by the future collider collaborations, and for Method (4), i.e. “single-H glob.” are shown (the results for Method (3) are reported in parenthesis). For Method (4) we report the results computed by the Higgs@FC working group. For the leptonic colliders, the runs are considered in sequence. For the colliders with $\sqrt{s} \lesssim 400$ GeV, Method (1) cannot be used, hence the dash signs. Due to the lack of results available for the ep cross section in SMEFT, we do not present any result for LHeC nor HE-LHeC, and only results with Method (1) for FCC-eh. When uncertainties are asymmetric (CLIC and FCC-eh) or a range is given (HE-LHC) the mid value is displayed.

with ratios of masses on the one hand, and test constants of proportionality on the other. The second motivation is that processes which are predicted to be rare in the SM, offer enhanced sensitivity to new physics residing at high scales. A leading example is the search for flavour-changing neutral interactions, which are extremely suppressed in the SM and if detected would reliably point to the existence of new physics. Third, peculiar and rare final state signatures can have a special connection with BSM scenarios. One example is H decaying to invisible particles, which is used to constrain scenarios featuring DM candidates. In the SM, the Higgs boson can decay invisibly via $H \rightarrow 4\nu$ with a branching ratio of 0.11%. Finally, Yukawa interactions with first generation fermions are the cornerstone of the low-energy constraints on CP violation of the couplings on the third generation. The typical example here are limits obtained by the EDM’s on the CP -odd interaction of the third generation fermions (section 6).

The reach of various colliders for rare decays, depends in the first place on the available statistics of the Higgs bosons being produced. The expected rates are presented in the appendix B, table 18.

	HL-LHC	HL-LHC+						
		LHeC	HE-LHC	ILC ₅₀₀	CLIC ₃₀₀₀	CEPC	FCC-ee ₂₄₀	FCC-ee/eh/hh
κ_u	560.	320.	430.	330.	430.	290.	310.	280.
κ_d	260.	150.	200.	160.	200.	140.	140.	130.
κ_s	13.	7.3	9.9	7.5	9.9	6.7	7.	6.4
κ_c	1.2		0.87			measured directly		

Table 13. Upper bounds on the κ_i for u, d, s and c (at hadron colliders) at 95% CL, obtained from the upper bounds on BR_{unt} in the kappa-3 scenario.

In the following, we restrict ourselves to a summary of the prospects to bound or determine the size of the interactions of the Higgs to the other SM particles through decays. These can occur either directly, through a process which is proportional to a tree-level coupling squared, i.e. all decays $H \rightarrow \bar{f}f$, where f is any SM fermion of the first or second generation, or indirectly, i.e. through interfering amplitudes or loops, such as $H \rightarrow \gamma\gamma$ and $H \rightarrow \gamma Z$. We will also briefly present results on very rare exclusive decays, which could provide indirect information on the light-quark Yukawa couplings. We follow the notation introduced in the κ -framework and consider the rescaling factors $\kappa_i = y_i/y_i^{\text{SM}}$ introduced previously for the couplings to quarks $\kappa_u, \kappa_d, \kappa_c, \kappa_s$ and for κ_μ , and for the loop induced processes, κ_γ and $\kappa_{Z\gamma}$. The values of $\kappa_\mu, \kappa_\gamma, \kappa_{Z\gamma}, \kappa_c$ have been obtained from the kappa-3,-4 fits presented in section 3.2 and we do not reproduce them here, while the upper bounds on $\kappa_u, \kappa_d, \kappa_s$ (κ_c for hadron colliders) are obtained from the upper limits on BR_{unt} . Constraints on flavour-changing Higgs boson interactions are not reported here.

The constraints of the couplings to first and second generation quarks are given in table 13 and displayed in figure 12, based on the results on BR_{unt} . For κ_c the hadron colliders reach values of $\mathcal{O}(1)$, and lepton colliders and LHeC are expected to improve the precision by about two orders of magnitude, to a 1-2%. For the strange quarks the constraints are about 5-10 \times the SM value while for the first generation it ranges between 100-600 \times the SM value. For the latter, future colliders could improve the limits obtained at the HL-LHC by about a factor of two. For HL-LHC, HE-LHC and LHeC, the determination of BR_{unt} relies on assuming $\kappa_V \leq 1$. For $\kappa_\gamma, \kappa_{Z\gamma}$ and κ_μ the lepton colliders do not significantly improve the precision compared to HL-LHC but the higher energy hadron colliders, HE-LHC and FCC_{hh} , achieve improvements of factor of 2-3 and 5-10, respectively, in these couplings.

For the electron Yukawa coupling, the current limit $\kappa_e < 611$ [78] is based on the direct search for $H \rightarrow e^+e^-$. A preliminary study at the FCC-ee [79] has assessed the reach of a dedicated run at $\sqrt{s} = m_H$. At this energy the cross section for $e^+e^- \rightarrow H$ is 1.64 fb, which reduces to 0.3 with an energy spread equal to the SM Higgs width. According to the study, with 2 ab⁻¹ per year achievable with an energy spread of 6 MeV, a significance of 0.4 standard deviations could be achieved, equivalent to an upper limit of 2.5 times the SM value, while the SM sensitivity would be reached in a five year run.

While the limits quoted on κ_c from hadron colliders (see table 13) have been obtained indirectly, we mention that progress in inclusive direct searches for $H \rightarrow c\bar{c}$ at the LHC

Figure 12. Summary plot illustrating the limits that can be obtained from rare Higgs decays on the couplings.

Collider	95% CL upper bound on				
	BR _{inv} [%]			BR _{unt} [%]	
	Direct	kappa-3	BR _{inv} only	kappa-3	BR _{unt} only

Table 14. Expected upper limits on the invisible and untagged BRs of the Higgs boson. The SM decay, $H \rightarrow 4\nu$, has been subtracted as a background. Given are the values of the direct searches using missing (transverse) momentum searches, the constraint derived from the coupling fit (see table 5) in the kappa-3 scenario, and the result from a fit in the κ framework where only modifications of BR_{inv} are allowed. The last two columns show the corresponding information for untagged BR of the Higgs, BR_{unt}. For all fits the direct search for invisible decays is included.

has been reported from ATLAS together with a projection for the HL-LHC. Currently the upper bound on the charm coupling is $\kappa_c \lesssim 10$ [80]. With HL-LHC, it is expected to improve the sensitivity to values of $\kappa_c < 2.1$ (based on ref. [81]), while LHCb, with the foreseen detector improvement, could reach a sensitivity on κ_c of 2-3 [13].

Exclusive Higgs decays to a vector meson (V) and a photon, $H \rightarrow V\gamma$, $V = \rho, \omega, \phi, J/\psi, \Upsilon$ directly probe the Higgs bottom, charm strange, down and up quark Yukawas [82–84]. Within the LHC, the Higgs exclusive decays are the only direct probe of the u and d Yukawa couplings, while if s -tagging could be implemented at the LHC [84], then the strange Yukawa could be probed both inclusively and exclusively. On the experimental side, both ATLAS and CMS have reported upper bounds on $H \rightarrow J/\psi\gamma$ [85, 86], $H \rightarrow \phi\gamma$ and $h \rightarrow \rho\gamma$ [87, 88]. These processes receive contributions from two amplitudes, only one of which is proportional to the Yukawa coupling. Since the contribution proportional to the Yukawa is smaller, the largest sensitivity to the Higgs q -quark coupling is via the interference between the two diagrams. The prospects for probing light quark Yukawas within future LHC runs employing the direct probe from exclusive decays are not competitive with indirect limits that can be set from production or global fit or inclusive search for c -Yukawa [13, 81]. However, the information coming from exclusive decays will be relevant regardless of the global fit sensitivity. For example, a limit of $|y_s/y_b| \lesssim 50$ could be set HL-LHC [13] and $y_s/y_b \lesssim 25$ at FCC_{hh} [1].

The constraints on invisible and untagged BRs to new particles are reported in table 14. For the invisible decays the SM $H \rightarrow 4\nu$ process ($\text{BR}_{\text{inv}}^{\text{SM}} = \text{BR}(H \rightarrow 4\nu) = 0.11\%$) is treated as background. Shown are the estimated projections for direct searches for invisible decays using signatures of missing transverse or total energy, and the results from the kappa-3 fit presented earlier in table 5. Also shown is a kappa-fit where all SM BR values are fixed and only BR_{inv} is free in the fit. It is seen that the e^+e^- colliders generally improve the sensitivity by about a factor 10 compared to HL-LHC. FCC-hh improves it by another order of magnitude and will probe values below that of the SM. Comparing the three determinations of the BR_{inv} for the various colliders, it is seen that in most cases the difference is small, indicating that the BR_{inv} is mostly constrained by the direct search. An exception is LHeC where the kappa-fits improve the direct search result by a factor two.

Finally, comparing the bounds on the invisible and untagged BR one notices the latter are always weaker as the untagged BR is not constrained by any direct search here. For the untagged BR, the kappa-3 fit sensitivity is significantly worse than that obtained by fitting only BR_{unt} as the kappa-3 fit implicitly takes into account the experimental uncertainties on all other BR values.

6 Sensitivity to Higgs CP

Barring the strong-CP problem, in the SM the only source of CP violation stems from fermion mixing in the charged currents, while the Higgs boson is predicted to have CP-even, flavour-diagonal interactions. Detecting non-zero CP-odd components in the Higgs interactions with the SM particles, would therefore clearly point to physics beyond the Standard Model. Departures from the SM can be efficiently parametrised in terms of a

limited set of (flavour conserving) dimension-6 operators. Employing the Higgs basis, the (P-violating/C-conserving) CP-violating (CPV) HVV couplings are given by

$$\delta\mathcal{L}_{\text{CPV}}^{hVV} = \frac{h}{v} \left[\tilde{c}_{gg} \frac{g_s^2}{4} G_{\mu\nu}^a \tilde{G}_{\mu\nu}^a + \tilde{c}_{aa} \frac{e^2}{4} A_{\mu\nu} \tilde{A}_{\mu\nu} + \tilde{c}_{za} \frac{e\sqrt{g^2 + g'^2}}{2} Z_{\mu\nu} \tilde{A}_{\mu\nu} + \tilde{c}_{zz} \frac{g^2 + g'^2}{4} Z_{\mu\nu} \tilde{Z}_{\mu\nu} + \tilde{c}_{ww} \frac{g^2}{2} W_{\mu\nu}^+ \tilde{W}_{\mu\nu}^- \right], \quad (6.1)$$

where, g_s , g and g' are the $SU(3)$, $SU(2)_L$ and $U(1)_Y$ gauge coupling constants and $\tilde{V}_{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}V_{\rho\sigma}$. Out of the four electroweak parameters, only three are independent at this order in the EFT expansion. In particular,

$$\tilde{c}_{ww} = \tilde{c}_{zz} + 2\sin^2\theta_w \tilde{c}_{za} + \sin^4\theta_w \tilde{c}_{aa}. \quad (6.2)$$

The (P-violating/C-violating) CP-violating (yet flavour-diagonal) interactions of the Higgs boson with fermions can be parametrised as

$$\mathcal{L}_{\text{CPV}}^{hff} = -\bar{\kappa}_f m_f \frac{h}{v} \bar{\psi}_f (\cos\alpha + i\gamma_5 \sin\alpha) \psi_f, \quad (6.3)$$

where the angle α parametrizes the departure from the CP-even case. Another, equivalent parametrization employs $\kappa_f = \bar{\kappa}_f \cos\alpha$ and $\tilde{\kappa}_f = \bar{\kappa}_f \sin\alpha$, where $\kappa_f = 1 + \delta y_f$ in the notation used for the CP conserving cases in the κ -framework (with $\kappa > 0$). The pure scalar coupling corresponds to $\alpha = 0$ ($\tilde{\kappa}_f = 0$), a pure pseudoscalar coupling to $\alpha = 90^\circ$ ($\kappa_f = 0$), while CP violation occurs in all other intermediate cases.

Sensitivity to the CP-odd operators can arise from two distinct classes of observables. The first class includes CP-even observables, such as total cross sections or single particle inclusive distributions. In this case, CP-odd operators contribute in a way that is analogous to CP-even operators, i.e. affecting rates and shapes. The second class includes observables that are built to be directly sensitive to CP violation, i.e. they are zero (at the lowest order) if CP is conserved. Limits obtained from this second class are therefore automatically insensitive to the presence of higher-dimensional CP-conserving operators and deviations from zero would uniquely point to CP violation.

Sensitivity to the CP-odd hgg interaction comes from gluon fusion processes at the inclusive level, while direct sensitivity to CP violation can arise only starting from final states featuring at least two jets in the final state. Studies performed at the LHC exist, yet no dedicated investigation for future colliders has been documented. Sensitivity to the CP-odd hVV weak operators comes from Higgs-strahlung processes (WH and ZH), the vector boson fusion and the Higgs decay into four charged leptons ($H \rightarrow 4\ell$). Studies have been performed both at the level of rates/distributions and via CP-sensitive observables [13].

CP-violation effects in the couplings to fermions have been considered for the top quark and the tau lepton. Proposals to access information on CP violation in top quark interactions exist for both classes of observables, yet studies at future colliders have been mostly based on rates and distributions. These focus on ttH at hadron colliders and on ttH and tH final states at e^+e^- colliders and ep colliders, respectively, which are also sensitive

Name	α_τ	\tilde{c}_{zz}	Ref.

Table 15. Upper bounds on the CP phase α of the Yukawa coupling for τ leptons and the CP-violating coefficient \tilde{c}_{zz} entering the HZZ coupling. The result in parenthesis for the HL-LHC is obtained with the same method used for the CEPC study.

to the absolute signs of CP-even and CP-odd interactions through interference effects. For example, by studying distributions in ttH , the HL-LHC will be able to exclude a CP-odd Higgs at 95%CL with about 200 fb^{-1} of integrated luminosity. CLIC 1.5 TeV foresees to measure the mixing angle for the top quark, α_t in $t\bar{t}H$ to better than 15° . At LHeC, a Higgs interacting with the top quarks with a CP-odd coupling can be excluded at 3σ with 3 ab^{-1} . At FCC_{eh} a precision of 1.9% could be achieved on α_t .

The most promising direct probe of CP violation in fermionic Higgs decays is the $\tau^+\tau^-$ decay channel, which benefits from a relatively large branching fraction (6.3%). Accessing the CP violating phase requires a measurement of the linear polarisations of both τ leptons and the azimuthal angle between them. This can be done by analysing the angular distribution of the various components of the tau decay products and by building suitable CP sensitive quantities (such as triple products of three-vectors or acoplanarities). The estimated sensitivities for the CP-violating phases, α_τ of the τ Yukawa coupling and \tilde{c}_{zz} extracted from CP-sensitive variables are collected in table 15.

Before concluding this section, we recall that CP-violating Yukawa couplings are well constrained from bounds on the electric dipole moments (EDMs) [89–94] under the assumptions of i) no cancellation with other contributions to EDMs, ii) SM values for the CP-even part of the Yukawa couplings.

CP violation in the top quark sector can be constrained by the EDM of the electron, giving $\tilde{\kappa}_t < 0.001$ once the latest limits of the ACME collaboration are considered [95]. For the bottom and charm Yukawas the strongest limits come from the neutron EDM, $\tilde{\kappa}_b < 5$ and $\tilde{\kappa}_c < 21$ when theory errors are taken into account. For the light quark CPV Yukawas, measurements of the neutron EDM give a rather weak constraint on the strange quark Yukawa of $\tilde{\kappa}_s < 7.2$, while the bound on the mercury EDM translates into strong bounds on the up and down Yukawas of $\tilde{\kappa}_u < 0.11$ and $\tilde{\kappa}_d < 0.05$ (no theory errors, 90% CL). For the τ Yukawa coupling, using the latest ACME measurement gives $\tilde{\kappa}_\tau < 0.3$, while for the electron Yukawa, provides an upper bound of $\tilde{\kappa}_e < 1.9 \times 10^{-3}$.

Assuming a SM Yukawa coupling of the Higgs to the electron, one can easily compare the indirect limits from EDMs with the prospects for direct ones. Using the relations between $(\bar{\kappa}, \alpha)$ and $(\kappa, \tilde{\kappa})$ one can convert the results for both the top quark (given above) and for the τ lepton (collected in table 15). One finds that the direct top quark limits are not competitive with the indirect ones, while those on the τ lepton are comparable with the current indirect ones.

7 The Higgs boson mass and full width

The current best measurement of the Higgs boson mass, based on the ATLAS and CMS analyses of $H \rightarrow ZZ^*$ and $H \rightarrow \gamma\gamma$ events in the LHC Run-2 data is 125.18 ± 0.16 GeV [96]. Future accelerators are expected to substantially improve the precision of this mass measurement.

The mass measurements at lepton colliders in the centre-of-mass energy range 240-350 GeV analyse the recoil mass of the Higgs boson in $e^+e^- \rightarrow ZH$ events, with $Z \rightarrow e^+e^-, \mu^+\mu^-$. Only the statistical uncertainties on the mass measurements are shown, as systematic uncertainties in this recoil mass analysis are expected to be negligible. The CLIC mass measurements at higher centre-of-mass energies analyse the $H \rightarrow b\bar{b}$ invariant mass distribution in $e^+e^- \rightarrow H(\rightarrow b\bar{b})\nu\nu$ events. The quoted mass resolutions based on m_{bb} measurements account only for statistical uncertainties, but are sensitive to b -jet energy scale uncertainties. This systematic uncertainty can be constrained with a $e^+e^- \rightarrow Z(\rightarrow b\bar{b})\nu\nu$ calibration sample which is expected to yield comparable statistics to the Higgs sample. The mass measurement at HL-LHC is based on the analysis of $H \rightarrow Z(l^+l^-)Z(l^+l^-)$ events. While the calibration of lepton momentum scales has not been studied in detail, a resolution of 10-20 MeV is projected to be plausibly in reach with the assumption that the higher statistics can help to significantly improve muon p_T systematic uncertainties.

Table 16 summarizes the expected precision of Higgs boson mass measurements of future accelerators. Also shown is the impact of the m_H uncertainty on the $H \rightarrow ZZ^*$ partial decay width. Already with HL-LHC, it will be possible to reduce this impact to the level of about 0.2%. At this value, the parametric uncertainty on Higgs partial widths, (primarily on ZZ^*, WW^*) is much smaller than the expected precision at any hadron collider. For the e^+e^- colliders the precision on the W and Z couplings is of that order, so that the m_H precision needs to be further improved to about 10 MeV to avoid any limitations on the Higgs coupling extraction precision (assuming the uncertainty due to higher order processes gets improved in the future, see table 19).

In the SM, the width of a 125 GeV H boson is predicted to be around 4 MeV, i.e. three orders of magnitude smaller than that of the weak bosons and of the top quark. It is therefore very challenging to measure it directly. All methods considered so far at colliders are in fact indirect and model dependent to various degrees. Three methods have been proposed at the LHC, and are considered for future hadron colliders.

The most direct method involves the diphoton decay mode and it is based on the measurement of the shape of the invariant mass of the diphoton close to the Higgs boson mass. This observable has a dependence on the width from signal-background interference effects. The foreseen sensitivity, however, will not allow to probe values close to the SM predictions, and can provide constraints of about $8 - 22 \times \Gamma_{\text{SM}}$ [13].

A second method extracts the width indirectly from a global fit of the Higgs boson couplings by employing specific assumptions. For example, in the κ -framework, assuming $\kappa_Z \leq 1$ and $\text{BR}_{\text{unt}} = 0$ one can determine the width from the fit.¹⁹

¹⁹In fact, the width and the branching ratio to undetected final states are not independent observables. In the analysis presented in section 3.2 we opted to fit BR_{unt} and calculate Γ_H from eq. (3.4).

Collider	Strategy	δm_H (MeV)	Ref.	$\delta(\Gamma_{ZZ^*})$ [%]
LHC Run-2	$m(ZZ), m(\gamma\gamma)$	160	[96]	1.9
HL-LHC	$m(ZZ)$	10-20	[13]	0.12-0.24
ILC ₂₅₀	ZH recoil	14	[3]	0.17
CLIC ₃₈₀	ZH recoil	78	[98]	0.94
CLIC ₁₅₀₀	$m(bb)$ in $H\nu\nu$	30 ²⁰	[98]	0.36
CLIC ₃₀₀₀	$m(bb)$ in $H\nu\nu$	23	[98]	0.28
FCC-ee	ZH recoil	11	[99]	0.13
CEPC	ZH recoil	5.9	[2]	0.07

Table 16. Overview of expected precision of Higgs boson mass measurements for future accelerators scenarios. For the lepton colliders (ILC, CLIC, CEPC) the projected uncertainties listed are statistical only. The impact of δm_H on $\delta\Gamma_{ZZ^*}$ reported in this table is calculated as $1.2\% \cdot (\delta m_H / 100 \text{ MeV})$, following ref. [97].

A third method is based on the combination of two independent measurements in gluon fusion production of a H boson with subsequent decay into a ZZ final state: $gg \rightarrow H \rightarrow ZZ^*$, where the H boson is on shell (and at least one of the final state Z off shell) and $gg \rightarrow ZZ$ with two on-shell Z bosons, where the H boson contribution is off shell [100]. The ratio of the off-shell over the on-shell rate is directly proportional to the total width [101]. Even though in generic BSM scenarios including the EFT, the interpretation of the off-shell/on-shell ratio as an extraction of the width is model dependent, this ratio can provide useful information on other key aspects of the Higgs couplings, e.g. their energy dependence [102]. It is foreseen that, with the HL-LHC and improvements in the theoretical calculations, Γ_H can be measured with a precision of up to 20% using this method [13].

At lepton colliders, the mass recoil method allows to measure the inclusive cross section of the ZH process directly, without making any assumption about the Higgs BR's. This possibility is unique to lepton colliders as it relies on the precise knowledge of the total initial energy of the event. In combination with measurements of exclusive Higgs decay cross sections, it allows to extract the total width Γ_H with a mild model dependence. The simplest way is to consider the ratio of the ZH cross section (from the recoil method) with the $H \rightarrow ZZ$ branching ratio (extracted from the $ZH, H \rightarrow ZZ^*$ rate)

$$\frac{\sigma(e^+e^- \rightarrow ZH)}{\text{BR}(H \rightarrow ZZ^*)} = \frac{\sigma(e^+e^- \rightarrow ZH)}{\Gamma(H \rightarrow ZZ^*)/\Gamma_H} \simeq \left[\frac{\sigma(e^+e^- \rightarrow ZH)}{\Gamma(H \rightarrow ZZ^*)} \right]_{\text{SM}} \times \Gamma_H, \quad (7.1)$$

where the last approximate equality assumes a cancellation of new physics effects, which holds, for instance, in the κ -framework. This method is limited by the relatively poor statistical precision of the $H \rightarrow ZZ$ BR measurement. More in general, even in scenarios where such a cancellation does not hold, e.g. in an EFT, a global fit can be performed to extract information on the width, using other decays (particularly the bb and WW decays)

²⁰In ref. [98] the values are 36 MeV (for $\sqrt{s} = 1.5 \text{ TeV}$) and 28 MeV (for $\sqrt{s} = 3 \text{ TeV}$) are based on unpolarized beams. The values quoted here are for the default scenario of 80% electron polarisation assumed throughout.

Collider	$\delta\Gamma_H$ [%] from ref.	Extraction technique for standalone result	$\delta\Gamma_H$ [%] kappa-3 fit
ILC ₂₅₀	2.3	EFT fit [3, 4]	2.2
ILC ₅₀₀	1.6	EFT fit [3, 4, 14]	1.1
ILC ₁₀₀₀	1.4	EFT fit [4]	1.0
CLIC ₃₈₀	4.7	κ -framework [98]	2.5
CLIC ₁₅₀₀	2.6	κ -framework [98]	1.7
CLIC ₃₀₀₀	2.5	κ -framework [98]	1.6
CEPC	2.8	κ -framework [103, 104]	1.7
FCC-ee ₂₄₀	2.7	κ -framework [1]	1.8
FCC-ee ₃₆₅	1.3	κ -framework [1]	1.1

Table 17. Overview of expected precision of Higgs boson width measurements for future accelerator scenarios. The result given in the second column refers to the width extraction as performed by the future lepton colliders using the stated technique, and as provided in the references given. The last column of the table lists the width extracted from the kappa-3 scenario fit. It also includes the HL-LHC measurements (but excludes the constraint $\kappa_V < 1$ that is used in HL-LHC-only fits).

and channels ($e^+e^- \rightarrow H\nu\bar{\nu}$). This method is used for CEPC. For FCC-ee and CLIC the κ -formalism is used to extract the width, similar to what is done in this report for table 5. For ILC, the width reported here was extracted using an EFT formalism that does not assume that there is only one operator that governs the interactions between the Higgs boson and the Z boson (as is done implicitly in the κ -framework). In this determination of Γ_H , angular distributions and polarisation asymmetries are used to constrain the free parameters that result from relaxing this assumption [18], in addition to the parameters used by the κ -formalism for the other lepton colliders. This fit is different from the EFT fits performed in section 3.4.

Table 17 summarizes the expected relative precision that can be reached on the Higgs width at future lepton colliders, comparing the estimates of the standalone estimates of the future lepton colliders to the results of the kappa-3 scenario fits performed in this article (with HL-LHC data included). It is seen that the result obtained in the kappa-3 fit is generally more constraining than the results quoted in the references, primarily as this result also includes the constraint from the HL-LHC data, and, in some cases, uses a different approach to modelling changes to the total width. In both cases, the best precision is obtained for the ILC₅₀₀ and FCC-ee₃₆₅ scenarios.

8 Future studies of the Higgs sector, post-European Strategy

8.1 Higgs prospects at the muon collider

Electron-positron colliders offer a well-defined value of the collision energy of the hard-scattering process and a relatively clean event, as opposed to hadron collisions where the underlying event and the high-level of event pileup challenge the reconstruction of the hard scattering event and its measurement.

The main limitation to the collision energy of circular electron-positron colliders is due to the low mass of the electrons/positrons which leads to large fraction of their energy emitted as synchrotron radiation. The solutions pursued so far to reach high lepton collision energies are based on limiting the energy loss by synchrotron radiation by reducing the curvature either by increasing the radius of the circular colliders or by employing linear colliders. However, the beam acceleration does require a number of RF cavities imposing a machine of large dimensions.

With a mass of about two hundred times that of electrons, muons do not suffer significant energy losses due to synchrotron radiation (the loss goes as the inverse of the fourth power of the mass) and therefore could be accelerated up to multi-TeV collision energies. For example, if the LHC ring were used, with the proposed HE-LHC dipoles (Nb₃Sn, 16 T), muons would collide at an energy close to $\sqrt{s} = 14$ TeV, compared to the 0.2 to 0.4 TeV of an electron-positron collider.

Alternatively, a collider with $\sqrt{s} = 125$ GeV could be a very compact (diameter ~ 60 m) Higgs factory using s -channel production of Higgs bosons [105]. However, it should be noted that the expected rate of produced Higgs bosons by s -channel is small, given the instantaneous luminosity possible at this machine [106], and the limited production cross section (taking into account both the beam energy spread and the initial state radiation effects) [107–109]. Estimates of the achievable precision on Higgs couplings for such a machine are given in [110].

Muon production, cooling, lifetime and physics background [111] pose severe challenges to the accelerator and detector technologies. Although the study of a Muon Collider (machine and physics prospects) is not as mature as those of other future proposed colliders, its physics potential certainly merits consideration.

Currently, two different configurations have been proposed for the muon collider. In the first configuration, muons are produced by the decay of hadronically produced charged pions or kaons, and cooled before they undergo the acceleration [106]. In the second configuration, muons are produced at threshold (in the centre of mass frame) by high energy positron collisions with atomic electrons [112]. The first configuration has been originally proposed for $\mu^+\mu^-$ collision at the Higgs boson pole ($\sqrt{s} \sim 125$ GeV), while the second is mainly considered for very high energy collisions, in the range of $O(10)$ TeV.

At muon collision c.m. energies $\sqrt{s} \gtrsim 10$ TeV, assuming the *point cross section* $\sigma \simeq 4\pi\alpha^2/(3s) \simeq 1 \text{ fb} \cdot (10 \text{ TeV}/\sqrt{s})^2$, the requirement of a percent statistical precision in the measurement of heavy particle pair production would imply an integrated luminosity of the order $L \sim 10 \text{ ab}^{-1} (\sqrt{s}/10 \text{ TeV})^2$. This could correspond to a 10-year physics run with an instantaneous luminosity of the order $10^{35} (\sqrt{s}/10 \text{ TeV})^2 \text{ cm}^{-2} \text{ s}^{-1}$ [113]. At such large values of \sqrt{s} , both the single-Higgs and the multi-Higgs production mechanisms are dominated by vector-boson fusion (VBF) processes, which provides very large statistical Higgs samples [77]. As an example, at $\sqrt{s} \sim 14$ TeV, with 20 ab^{-1} , one would produce about 20 million single Higgs, 90,000 Higgs pairs, and 140 triple Higgs final states, with presumably quite moderate background. Although there is currently only preliminary analysis of the Higgs production in such an environment this would be a robust basis to considerably advance on the Higgs couplings determination. The Higgs self-coupling

sector might be explored with unprecedented precision. In particular, with the above Higgs production statistics, and no unexpectedly difficult background, an accuracy of few percent for the trilinear Higgs coupling, and a few tens of percent for the quadrilinear Higgs coupling might be reached at $\sqrt{s} \sim 14$ TeV, with 20 ab^{-1} , assuming all the remaining Higgs and EW parameters at their SM value. Many other investigations of the Higgs properties might significantly benefit from such collider configuration [77, 113].

8.2 Higgs physics at multi-TeV electron-positron colliders

The length of linear accelerators proposed today, is largely determined by the electric field gradients that can be achieved with RF cavities. For the superconducting RF technology used by ILC the limit is about 35 MV/m while for the drive-beam technology, envisaged for CLIC, it is about 100 MV/m.

Much higher gradients (up to 1000 times more acceleration compared to RF) can be achieved using plasma-wakefield acceleration, where laser pulses [114–117], electron [118, 119] or proton [120] bunches (called drivers) can excite ultra-high fields in plasma devices. Thus this is a very promising technique for future high energy e^+e^- and $\gamma\gamma$ colliders.²¹ The ALEGRO Collaboration [9] has been formed with the goal of designing an Advanced Linear Collider (ALIC) based on this technology. A summary of the facilities operating today and planned for the future, as well as the R&D needed, are given in [9]. The physics opportunities of an e^+e^- collider with \sqrt{s} up to 100 TeV are also discussed there.

The minimum instantaneous luminosity that needs to be achieved for probing cross sections of new particles interacting weakly at energies in the 10 – 100 TeV is found to be $10^{36} \text{ cm}^{-2}\text{s}^{-1}$. With such a collider, an integrated luminosity of 30 ab^{-1} could be collected within a few years. With this dataset, the Higgs physics programme is similar to that of a Multi-TeV muon collider outlined above. It is also being considered to have such a collider at lower collision energies, in the range between m_Z and 3 TeV. Here, it would have the same physics programme as the other proposed colliders, assuming that comparable luminosity values can be achieved and background conditions are similar.

The proposed ALIC collider [9] would achieve $\sqrt{s} = 30$ TeV with a peak luminosity of $10^{36} \text{ cm}^{-2}\text{s}^{-1}$ in a tunnel of 9 km length. While the principle of acceleration has been proven, there are many issues that need to be resolved before a collider based on plasma-technology can be achieved, but none are considered to be show-stoppers at present. The primary focus of the R&D programme is the beam quality which is addressed at lower-energy applications (e.g. free-electron lasers, fixed target experiments) and will benefit the development of a collider based on this technology.

8.3 What and why: Higgs prospect studies beyond this report

The purpose of this subsection is to place the Higgs coupling measurements in perspective with other new physics studies performed at future colliders with the aim of providing answers to the following two questions: *What are we going to learn?*, *What can we possibly*

²¹For $\gamma\gamma$ colliders it is sufficient to accelerate two e^- beams which is technically less demanding than accelerating positrons.

discover? The unknown territory of energy and precision to be explored may have different discoveries in store, including unexpected ones. Given the scope of this document, a discussion of the various options would hardly be self-contained, and would miss, by definition, the most exciting case of unexpected discoveries. On the other hand, by focusing on some open problems in particle physics, it is possible to structure a self-contained discussion at least around the first question. The hierarchy problem (HP), dark matter (DM) and the electroweak phase transition (EW Φ T) are issues on which we shall definitely make progress. Flavour could also be added to this list, but mostly in the measure in which it is connected to the HP.

In view of its centrality, and of the controversial regard in which it is sometimes held, a succinct but modern appraisal of the HP is needed. The HP is a paradox challenging the modern effective field theory (EFT) view of particle physics. The challenge is presented by the clash between infrared (IR) Simplicity and Naturalness. IR Simplicity is an unavoidable feature of any EFT when making observations at energies much below its fundamental scale Λ_{UV} . In practice that is due to the decoupling of the infinite (complicated) set of non-renormalizable couplings in favor of the finite (simple) set of renormalizable ones. Naturalness instead arises by viewing EFT parameters as functions of more fundamental ones: in this point of view it is expected that any specific structure, like the presence of a very small parameter, should be accounted for by symmetries and selection rules rather than by accidents. Now, the structure of the SM is such that several crucial experimental facts like approximate baryon and lepton numbers, lightness of neutrinos, GIM suppression of FCNC, custodial symmetry *all* remarkably and beautifully follow from IR Simplification. That is by assuming $\Lambda_{UV} \gg m_{weak}$. However when considering the Higgs mass parameter, one famously finds that $\Lambda_{UV} \gg m_H$ is inconsistent with the predicate of Naturalness. In the SM, IR Simplicity can thus only be obtained at the price of un-Naturalness. But this is only half of the problem. The other half is that models realizing Naturalness, like supersymmetry (SUSY) or Composite Higgs (CH), invariably sacrifice Simplicity. Indeed all these natural extensions have concrete structural difficulties in reproducing the observed simplicity in flavour, CP violating and electroweak observables. In order to meet the corresponding experimental constraints, these scenarios must rely on *clever* constructions mostly associated with *ad hoc* symmetries, like flavour symmetries or custodial symmetry, which in the SM are either not needed or automatic. The paradoxical tension between Simplicity and Naturalness is what defines the hierarchy problem: no win-win scenario seems to be available.

The paradox could already be formulated before LEP, and gained in importance with more and more precise flavour and electroweak data that demands a more elaborate structure in natural models. Furthermore, the ever stronger bounds from direct searches for ‘Natural’ agents at Tevatron and LHC imply the need for some amount of un-Naturalness, or fine tuning, even in models like SUSY or CH that aimed at full Naturalness. Depending on the scenario, the finesse of the cancellation in the Higgs mass parameter needed to lift new physics out of LHC reach can be quantified to roughly range from 1/10 to 1/10³.

The test of Naturalness vs. Simplicity offers one concrete criterion to compare future machines across their reach in three different sets of measurements: direct searches, Higgs couplings, EW precision tests (EWPT).

- *Direct searches*: natural models all possess computational control over the Higgs squared mass. The result varies in a finite range, and a small or vanishing result can only be achieved by tuning different contributions against one another. Indicating by Δm_H^2 the most sizeable contribution, the tuning is simply measured by

$$\epsilon \equiv m_H^2 / \Delta m_H^2, \tag{8.1}$$

with m_H the observed Higgs mass. Because of its large Yukawa coupling, the most sizeable effects come from coloured states associated with the top, the so-called top-partners. Models can be broadly classified into three classes according to the dependence of Δm_H^2 on the top partner mass m_T :

- *Soft*: $\Delta m_H^2 \sim m_T^2$. This situation is realized in SUSY with soft terms generated at a high scale. In the absence of any tuning $m_T \sim m_H \sim 100$ GeV, within the energy range of LEP and Tevatron.
- *SuperSoft*: $\Delta m_H^2 \sim (3y_t^2)/(4\pi^2) m_T^2$. This situation is realized in SUSY with low scale mediation and in CH. Without any tuning one expects $m_T \sim m_H / \sqrt{3y_t^2/4\pi^2} \sim 450$ GeV, within the reach of the LHC.
- *HyperSoft*: $\Delta m_H^2 \sim (3\lambda_h)/(16\pi^2) m_T^2$. The mechanism of Neutral Naturalness is a prime example. The top partner mass is naturally pushed around 1.5 TeV.

A ~ 10 TeV reach on m_T like offered by FCC-hh or muon-collider (the top partners have often EW quantum numbers) will thus probe Naturalness down to $\epsilon = 10^{-4}, 10^{-3}, 10^{-2}$ in respectively Soft, SuperSoft and HyperSoft scenarios.

- *Higgs couplings*: the deviations δg_h from the SM in single and multi-Higgs couplings satisfy

$$\delta g_H / g_H^{\text{SM}} \sim c \epsilon, \tag{8.2}$$

with c a coupling-dependent coefficient, and ϵ the Higgs mass correction defined in (8.1). In basically all models, there always exists a set of couplings where $c \sim O(1)$. The only exception is strictly supersoft SUSY, where one can cleverly go down to $c \sim 0.1$. Not surprisingly full Naturalness basically mandates $O(1)$ deviations in Higgs couplings.

The best measurements that will be carried out at future machines aim at 10^{-3} precision on some of the Higgs couplings, in particular g_{HWW} and g_{HZZ} . This should be compared to the reach in ϵ in direct searches. In particular, Higgs couplings probe less than direct searches in the simplest high scale SUSY models. But one must not forget that these models admit countless variants, with additional states, in particular SM singlets, and with a spread spectra. So one cannot completely discount the relevance of Higgs couplings to probe these models. In any case, one should not underestimate the value of Higgs precision programme that can measure the Higgs couplings with a 10^{-3} precision. The equal relevance of Higgs studies and direct searches for CH models seems robust.

In view of parametric uncertainties, 10^{-3} seems like a limiting (or at least a critical) sensitivity to BSM deviations in single Higgs production near threshold. However these deviations are all associated with operators of dimension ≥ 6 , whose effects grow with energy when considering processes with a sufficient number of legs, like $gg \rightarrow HH, hV_L$ or $VV \rightarrow HH, V_L V_L$. And one must then consider the possibility of obtaining a better sensitivity by measuring such processes. For instance, FCC-hh can probe $gg \rightarrow HV_L$ and $VV \rightarrow VV$ up to $\epsilon \sim 1\%$ [79]. Lepton machines might compete better: while CLIC can reach a sensitivity to $\epsilon \sim 10^{-2}$ in $VV \rightarrow HH$ [121], still one order of magnitude poorer than single Higgs measurements, a recent analysis [77] of a muon collider shows the $\epsilon = 10^{-3}$ wall is beaten for a CM energy of 10 TeV. A μ -dream machine running at 30 TeV could go down to $\epsilon = 2 \times 10^{-4}$ [77], which competes well even with the reach on top partners (~ 14 TeV) for such a machine.

- *EWPT*: while Higgs couplings are prime sensors of Naturalness, EWPT sense the dynamics of EWSB indirectly, via loops. To make this concrete, consider the \hat{S} parameter, defined with the normalization of [48]. For all models, encompassing supersymmetry, CH or technicolor one can write a parametric formula

$$\hat{S} \sim \frac{\alpha_W}{4\pi} \frac{g_*^2 v^2}{m_*^2} N \lesssim \frac{m_W^2}{m_*^2}, \tag{8.3}$$

where m_*, g_* indicate overall mass and coupling of the new dynamics (the most obvious expectation being $m_* \sim m_T$), while N measures the number of new degrees of freedom. Theoretical considerations set the upper bound $g_* \sqrt{N} \lesssim 4\pi$, which is saturated in CH and technicolor where $\hat{S} \sim m_W^2/m_*^2$. In these models a measurement of \hat{S} translates into an indirect measurement of the scale m_* . In the case of CH, one obtains $\hat{S} \equiv 3 \times 10^{-2} \epsilon$, indicating that a sensitivity to $\hat{S} \sim \text{few} \times 10^{-5}$ corresponds to 10^{-3} sensitivity in Higgs couplings/fine tuning. Supersymmetric models are instead well below the saturation of the upper bound, as in that case the g_* is of the order of SM couplings, principally g_W and y_t , while the multiplicity N is $O(1)$ [122]. One can then very roughly write $\hat{S} \sim (\alpha_W/4\pi)(m_{weak}^2/m_*^2)$ implying $m_* \gtrsim 1$ TeV is enough to make $\hat{S} \lesssim 10^{-5}$, below the wildest dreams of an FCC-ee.

Very much like for Higgs couplings, we can consider the sensitivity to the same class of dim-6 operators contributing to \hat{S} in processes with more legs, where the growth with energy can be exploited. A crucial comparison here is that between the reach of a Z -pole machine like the FCC-ee and CLIC which can study processes such as $e^+e^- \rightarrow hZ, h\gamma, WW$ at higher energies.²² The available CLIC studies estimate its reach as $\hat{S} \simeq 0.5 \times 10^{-5}$. This should be compared to the estimated reach of 5×10^{-5} at FCC-ee. Again the systematics of the two measures would be drastically different, with CLIC dominated by statistics and with FCC-ee dominated by parametric and intrinsic systematics.

²²The latter processes are sensitive to slightly different combinations of operator coefficients than \hat{S} at low energy, but in well motivated models like CH, this difference is often subdominant, and at worse they represent equally interesting but different combinations.

The above analysis also offers the starting point for the consideration of other motivations and other viewpoints. As we mentioned at the beginning the EW phase transition and DM offer alternative motivations. We will discuss them briefly in what follows.

The interest in the order of the EW phase transition is largely related to baryogenesis. A strongly first order transition with sizeable sources of CP violation from BSM dynamics could generate the observed cosmological baryon asymmetry. The corresponding new physics would impact both future colliders and precision low energy studies. In particular a first order phase transition implies a $O(1)$ change in the Higgs potential at finite temperature, indicating the possibility for important effects also at zero temperature, the regime we can test at colliders. The connection between $T \neq 0$ and $T = 0$ is however model dependent and one can broadly distinguish two scenarios. In the absence of new symmetries $T \neq 0$ and $T = 0$ are directly connected and the Higgs trilinear is expected to be $O(1)$ off its SM prediction (see e.g. [123]). On the other hand in the presence of extra symmetries [124] there could be a further phase separation between $T \neq 0$ and $T = 0$ in which case deviations can be smaller but hardly smaller than a few % [125]. The low energy implications of EW baryogenesis concern electric dipole moments (edms) from new sources of CP violation. Here it must be noticed that the present bound $d_e < 10^{-29}$ e-cm on the electron edm is already very strongly constraining many scenarios. Moreover there are serious plans to improve the sensitivity on d_e by a few orders of magnitude in the future. A thorough analysis is not available to our knowledge, but it would be interesting in order to better appreciate the impact of such improved measurements on the space of possibilities, as that conditions the importance of Higgs trilinear studies. It should however be kept in mind that the EW Φ T could be viewed as interesting *per se*, regardless of baryogenesis, as it is an essential part of the history of our Universe. It also offers a new bridge between Higgs physics and gravitational physics: in case of a strong first order phase transition, the EW Φ T would be the source of a stochastic gravitational wave (GW) background and future GW experiments like LISA could proffer complementary probes of the Higgs potential [126].

The search for Dark Matter (DM) at future colliders is a broad field whose implications cannot be even partially described here. One crucial strength of a machine with a reach in the multi-TeV range is that it should be able to discover the minimal incarnation of DM, the one which arises from the purely radiatively split EW multiplets. Amazingly, this simple and well motivated class of models is hardly directly detectable in view of its loop suppressed spin independent cross section (see table 1 in [127]). Focussing on Higgs studies the basic question is: to what extent can an invisible Higgs width be associated with DM? The answer is given in figure 4 of ref. [128]: considering all present constraints there remains a very small region around $m_{DM} = m_H/2$, and part of this region will be explored, by direct DM detection experiments a long time before the future precision Higgs studies. The chance that DM sits in this region seems slim but a discovery in direct detection would certainly add to the Higgs programme. One should also keep in mind that the Higgs boson can decay invisibly to new particles that are not by themselves stable with the right relic abundance, but that would be part of a more complex DM sector whose abundance would not set by its interactions with the Higgs but rather by its own internal

dynamics. Twin sectors of Mirror Twin Higgs models [129] and strongly coupled dark sectors [130] are examples of this type and they offer a motivation to search for invisible decays of the Higgs.

9 Summary

The precision study of the Higgs boson will be the primary guaranteed deliverable of any future collider facility. The apparent uniqueness of the Higgs boson, as the only fundamental scalar boson thus far discovered, justifies the importance which it is accorded in planning for future facilities.

Several future colliders have been proposed in the context of the update of the European Strategy for Particle Physics. The potential of these machines for Higgs boson physics has been intensely studied by the proponents of these machines. The purpose of the Higgs@FutureCollider Working Group (Higgs@FC WG) and this report is to provide a coherent comparison of the reach of these machines in the exploration of the Higgs sector. We have assumed the baseline provided by the approved programme of the HL-LHC and quantified the additional information that would be provided by each of the future facilities.

Taking into account the inputs submitted to the strategy process and our dedicated discussions with proponents of future colliders, we provide this report on the comparisons achieved, using both the simplified kappa framework and an alternative EFT framework. The comparisons are made in reasonable frameworks developed based on current knowledge, with the prime objective to allow a clear and coherent comparison. Where relevant we note the potential caveats in the approaches taken. We have also reported on the rare decays of the Higgs boson, on measurements of its mass and width, and on the expectations for CP violation studies.

Acknowledgments

We would like to express our appreciation to the numerous colleagues who have presented and discussed material to our working group, and in addition for the valuable comments made on a draft of this report by representatives of the future collider projects.

We wish to express special thanks to J. Gu for discussions, for providing some of the inputs for the EFT studies in this report, and for his help in producing some of the results presented in section 4. We are also very grateful to J. Tian for his cross-checks of the EFT fit results and to J. Reuter for his results on the double Higgs cross-sections at lepton colliders.

We thank S. Heinemeyer and collaborators for kindly sharing an updated version of their study of the theory uncertainties in electroweak and Higgs precision observables, whose results were also include in this report. We also benefited from helpful discussions with R. Contino, G. Durieux, G.F. Giudice, M. Kumar, M. Mangano, M. McCullough, G. Panico, A. Paul, M.E. Peskin, A. Pomarol, J. Reuter, F. Riva, A. Shivaji, Y. Soreq, E. Vryonidou, A. Wulzer and X. Zhao.

The work of CG and BH was in part funded by the Deutsche Forschungsgemeinschaft under Germany’s Excellence Strategy-EXC 2121 “Quantum Universe” — 390833306. The work of JDH and FM was partly supported by F.R.S.-FNRS under the “Excellence of Science — EOS” — be.h project n. 30820817.

A Mandate agreed by RECFA in consultation with the PPG “Higgs physics with future colliders in parallel and beyond the HL-LHC”

In the context of exploring the Higgs sector, provide a coherent comparison of the reach with all future collider programmes proposed for the European Strategy update, and to project the information on a timeline.

- For the benefit of the comparison, motivate the choice for an adequate interpretation framework (e.g. EFT, κ , ...) and apply it, and map the potential prerequisites related to the validity and use of such framework(s).
- For at least the following aspects, where achievable, comparisons should be aim for:
 - Precision on couplings and self-couplings (through direct and indirect methods);
 - Sensitivities to anomalous and rare Higgs decays (SM and BSM), and precision on the total width;
 - Sensitivity to new high-scale physics through loop corrections;
 - Sensitivities to flavour violation and CP violating effects.
- In all cases the future collider information is to be combined with the expected HL-LHC reach, and the combined extended reach is to be compared with the baseline reach of the HL-LHC.
- In April 2019, provide a comprehensive and public report to inform the community.
- ECFA helps in the creation of a working group relevant for the Strategy process, especially for the Physics Preparatory Group (PPG).
- Towards the Open Symposium the working group will work together with the PPG to provide a comprehensive and public report to inform the community, i.e. this is not an ECFA report.
- The working group has a scientific nature, i.e. not a strategic nature; it uses the input submitted to the Strategy process to map the landscape of Higgs physics at future colliders.
- The convenors in the PPG who are connected to this specific topic (Beate Heinemann and Keith Ellis) and the ECFA chair will be included as *ex-officio* observers.

Table 19. Partial decay widths for the Higgs boson to specific final states and the uncertainties in their calculation [97]. The uncertainties arise either from intrinsic limitations in the theoretical calculation (Th_{Intr}) and parametric uncertainties (Th_{Par}). The parametric uncertainties are due to the finite precision on the quark masses, $\text{Th}_{\text{Par}}(m_q)$, on the strong coupling constant, $\text{Th}_{\text{Par}}(\alpha_s)$, and on the Higgs boson mass, $\text{Th}_{\text{Par}}(M_H)$. The columns labelled “partial width” and “current uncertainty” and refer to the current precision [97], while the predictions for the future are taken from ref. [131]. For the future uncertainties, the parametric uncertainties assume a precision of $\delta m_b = 13$ MeV, $\delta m_c = 7$ MeV, $\delta m_t = 50$ MeV, $\delta\alpha_s = 0.0002$ and $\delta M_H = 10$ MeV.

C Inputs

In this section we report some information relative to the inputs to the strategy process. Figure 13 shows the start date and extent of the runs of proposed future projects, using the earliest start time provided in the submitted documentation.

Figure 13. Sketch of timeline of various collider projects starting at the “earliest start time” stated in the respective documents. For FCC-eh/hh this figure assumes that it is not preceded by FCC-ee. If it comes after FCC-ee it would start in the early 2060s. Only scenarios as submitted to the European Strategy by Dec. 2018 are displayed. Additional scenarios considered in this report (e.g. Giga-Z at ILC/CLIC, ILC at 1 TeV, LE-FCC) are not shown.

C.1 Inputs for Higgs studies

The uncertainties on inputs for all the colliders used in our analysis are listed in tables 20–26. In all cases the relative uncertainty on the measurement is given corresponding to a Gaussian $1\text{-}\sigma$ uncertainty.

C.2 Inputs for electroweak precision observables

The uncertainties on several electroweak precision observables related to the properties (masses and couplings) of the electroweak vector bosons are presented in table 27. We also report the expected uncertainties on the top-quark mass, which enters in the analysis as an input of the global electroweak fit.

For the extraction of m_{top} from a $t\bar{t}$ scan threshold at e^+e^- colliders the current theoretical uncertainty is ~ 40 MeV [132]. As it was done for the other intrinsic theory uncertainties, this is expected to improve in the future and is neglected in the baseline fits. We therefore use a common statistical uncertainty of ~ 20 MeV for all lepton colliders running at the $t\bar{t}$ threshold.

For the circular colliders, the asymmetries A_f and partial-width ratios R_f are not given for $\sqrt{s} \gg 90$ GeV as the statistical precision is much higher at the Z pole, and the Z -pole run is part of the default programme. For the linear colliders a Giga- Z run is not part of the running plan submitted to the EPPSU, but it is used in some of the results presented in this report to illustrate the impact of such a run in the EW and Higgs programmes. For the ILC and CLIC Giga- Z option, an integrated luminosity of 100 fb^{-1} is assumed, and polarisations as stated in table 1. Note that the asymmetry parameters A_f can be extracted in different ways depending on the access of polarization of the initial and/or final states. For instance, at linear colliders with polarized beams A_b can be directly extracted from a left-right forward-backward asymmetry. Without polarized beams, circular colliders can access that quantify via a forward-backward asymmetry $A_{FB}^b = \frac{3}{4}A_e A_b$, but it requires to know A_e . On the other hand, both circular and linear colliders could access A_e and A_τ separately, measuring the polarization of the final states in $e^+e^- \rightarrow \tau^+\tau^-$. We refer to the discussion in section 3.4.1 for the assumptions adopted in the treatment of systematic uncertainties for the heavy flavor observables included the fits.

For ILC all values are taken from ref. [4]. For CLIC all values are taken from refs. [5, 11]. For CEPC they are taken from either ref. [2] or from ref. [133]. For FCC-ee they are taken from refs. [79, 134–136].

Table 27. Uncertainty on several observables related to the properties of the electroweak vector bosons. We also list the uncertainty on the top mass. For dimensionful quantities the absolute uncertainty is given, while relative errors are listed for dimensionless quantities. A few comments on some particular numbers are in order: a) For hadron colliders the top mass is not the pole mass. b) For the top mass all lepton colliders require a dedicated top threshold scan to achieve the uncertainty given here. (For ILC the quoted value comes from a dedicated run at 350 GeV.) c) From direct reconstruction in the ZH run 2-3 MeV can be achieved [2]. d) In a 4-year dedicated run 2 MeV can be achieved by ILC [137]. e) From τ polarization measurements. f) At circular colliders, for A_b and A_c previous measurement uncertainties were dominated by the physics modelling [138] and the systematic uncertainty arising from this was only estimated by FCC-ee [135]. When these systematics are set to zero in the measurements of A_{FB}^b and A_{FB}^c the uncertainty in A_b and A_c is controlled by the statistical errors plus the uncertainty on A_e . This is the setup used for the baseline fits. See discussion in section 3.4.1 for details. g) $R_\nu \equiv \Gamma_{Z \rightarrow \text{inv}}/\Gamma_{Z \rightarrow \text{had}}$ and $R_{\text{inv}} \equiv \Gamma_{Z \rightarrow \text{inv}}/\Gamma_{Z \rightarrow \ell\ell}$.

D Correlation matrices

The correlations of three of the lepton collider kappa-3 fits, discussed in section 3.2, are shown in figure 14.

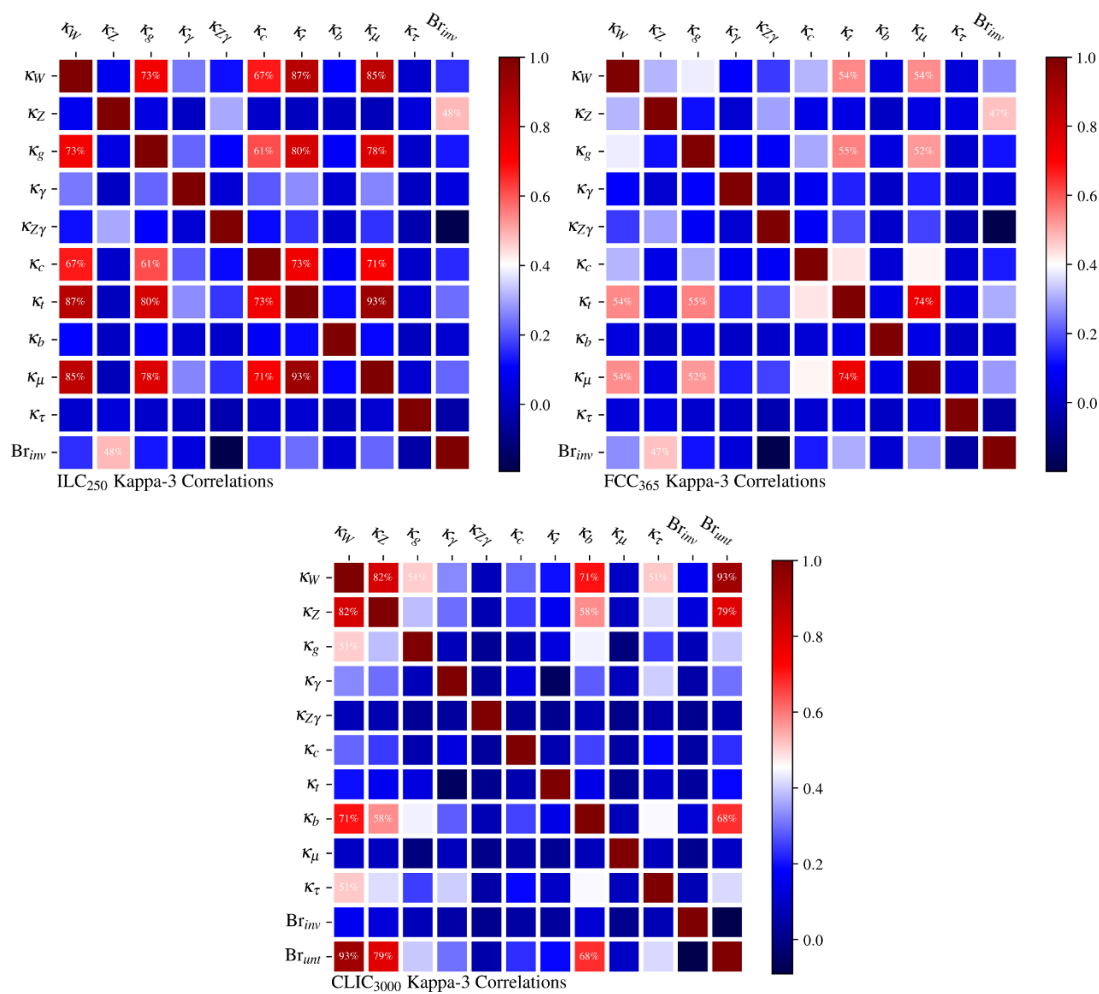

Figure 14. Correlation seen in the kappa-3 scenario fit for three future colliders as discussed in section 3.2. Top left: ILC₂₅₀. Top right: FCC₃₆₅. Bottom: CLIC₃₀₀₀.

E Additional Kappa scenario fits

This appendix contains additional kappa scenarios to complement the results shown in section 3.2. Tables 28 and 29 present the results of the different colliders in the kappa-2 scenario, in which BSM decays are allowed and future colliders are considered independently and not fitted together with the HL-LHC prospects.

kappa-2	HL-LHC	LHeC	HE-LHC (S2)	HE-LHC (S2')
$1 \geq \kappa_W > (68\%)$	0.985	0.994	0.988	0.992
$1 \geq \kappa_Z > (68\%)$	0.987	0.988	0.990	0.990
κ_g [%]	$\pm 2.$	± 3.9	± 1.6	± 1.1
κ_γ [%]	± 1.6	± 7.8	± 1.3	± 0.96
$\kappa_{Z\gamma}$ [%]	$\pm 10.$	–	± 5.6	± 3.8
κ_c [%]	–	± 4.3	–	–
κ_t [%]	± 3.2	–	± 2.6	± 1.6
κ_b [%]	± 2.5	± 2.3	± 2.0	± 1.5
κ_μ [%]	± 4.4	–	± 2.3	± 1.5
κ_τ [%]	± 1.6	± 3.6	± 1.2	± 0.85
$\text{BR}_{\text{inv}} (<\%)$	1.9	2.2	3.2★	2.4★
$\text{BR}_{\text{unt}} (<\%)$	inferred using constraint $ \kappa_V \leq 1$			
	4.	2.2	3.2	2.1

Table 28. Expected relative precision (%) of the κ parameters in the kappa-2 (standalone) scenario described in section 2 for the HL-LHC, LHeC, and HE-LHC. A bound on $|\kappa_V| \leq 1$ is applied since no direct access to the Higgs width is possible, thus the uncertainty on κ_W and κ_Z is one-sided. For the remaining kappa parameters one standard deviation is provided in \pm . The corresponding 95%CL upper limit on BR_{inv} is also given. In this scenario BR_{unt} is a floating parameter in the fit, to propagate the effect of an assumed uncertain total width on the measurement of the other κ_i . Based on this constraint the reported values on BR_{unt} are inferred. The 95% CL upper limits are given for these. Cases in which a particular parameter has been fixed to the SM value due to lack of sensitivity are shown with a dash (–). In the case of κ_t sensitivity at the LHeC, note that the framework relies as input on μ_{ttH} , and does not take into consideration μ_{tH} . A star (★) indicates the cases in which a parameter has been left free in the fit due to lack of input in the reference documentation. The integrated luminosity and running conditions considered for each collider in this comparison are described in table 1.

kappa-2	ILC	ILC	ILC	CLIC	CLIC	CLIC	CEPC	FCC-ee	FCC-ee	FCC

Table 29. Expected relative precision (%) of the κ parameters in the kappa-2 (standalone collider) scenario described in section 2 for future accelerators beyond the LHC era. The corresponding 95%CL upper limits on BR_{unt} and BR_{inv} and the derived constraint on the Higgs width (in %) are also given. Cases in which a particular parameter has been fixed to the SM value due to lack of sensitivity are shown with a dash (-). An asterisk (*) indicates the cases in which a parameter has been left free in the fit due to lack of input in the reference documentation. The integrated luminosity and running conditions considered for each collider in this comparison are described in table 1. FCC-ee/eh/hh corresponds to the combined performance of FCC-ee₂₄₀+FCC-ee₃₆₅, FCC-eh and FCC-hh.

F Additional comparisons

In this section additional potential scenarios for accelerators are compared. The inputs for these were mostly provided after the European Strategy meeting in Granada.

Table 30 and figure 15 show the results of the kappa-0-HL fit for various FCC scenarios. This fit is a replica of the already described kappa-0 one, which does not allow any BSM decay of the Higgs, but incorporating the HL-LHC information in a combined fit for completeness. With 4 instead of 2 IPs the uncertainties reduce by a factor of up to 1.4 due to the increased statistics. With the FCC-hh only, the uncertainties all increase by factors of 2-5. When omitting FCC-eh, the uncertainty on κ_W increases by a factor of two and that on κ_b increases by 20%, the others are mostly unaffected. When omitting FCC-ee, most uncertainties increase by about 20% and that on κ_Z increases by more than a factor of two.

Another interesting questions is what uncertainties are obtained when combining any of the lower energy stages of e^+e^- colliders with the FCC-hh. This is shown in table 31 for the kappa-0-HL fit and in table 32 for the EFT fit. The results for the various 1st-stage e^+e^- colliders are comparable within a factor of about two for the Higgs couplings in the kappa-fits. Figure 16 shows this comparison graphically. For the EFT framework, the differences are a bit larger, in particular for the aTGC values, see table 32.

Table 31. Results for the kappa-0-HL fit for FCC-hh combined with any of the four e^+e^- colliders proposed.

Figure 16. Combination of the different future ee colliders with FCC-hh and HL-LHC, in an extension of the kappa-0-HL scenario. Note that ILC₂₅₀ and CLIC₃₈₀ (first stages) are shown in comparison with CEPC (240) and FCC-ee₃₆₅.

The ILC and CLIC documents submitted to the European Strategy did not contain any explicit analysis related to the Z boson properties. In the meantime, it was explored what can be done either using radiative Z boson events during the standard running or by a dedicated running at $\sqrt{s} \approx M_Z$ for a period of 1-3 years, collecting 100 fb^{-1} . The results shown in the main body of this paper now include the radiative return analysis. Here, we present the additional improvement which can be made when a dedicated Z running period is considered. Table 33 shows the effective Higgs boson couplings with and without Giga- Z running for the ILC and CLIC. It is seen that for ILC₂₅₀ a Giga- Z running improves the H couplings to vector bosons by about 30%, and for other couplings the improvement

is much smaller. For ILC₅₀₀ and CLIC₃₈₀ the impact of dedicated Giga-Z running is low, except for the precision on the TGC parameter $\delta\kappa_\gamma$.

Table 34 shows the impact of the Giga-Z running on the precision on the effective couplings of the Z boson to fermions. In many cases, the impact is significant, improving the precision by up to a factor of ~ 4 . Also shown are the results expected for CEPC

Table 36. Expected relative precision (%) of the κ parameters in the kappa-0-HL scenario described in section 2 for future lepton colliders combined with the HL-LHC and the FCC-hh_{37.5} (top part) and with HL-LHC and FCC-hh (bottom part). No BSM width is allowed in the fit: both BR_{unt} and BR_{inv} are set to 0.

and FCC-ee. In most cases, CEPC and FCC-ee achieve the highest precision. A notable exception is the top quark coupling which is best constrained by the ILC₅₀₀.

It is also interesting to compare the highest energy options closely. This is done in table 35. In all cases, it is assumed that the colliders also include a Giga-Z run of 1-3 years [4, 11].

After the Granada meeting, it was also studied what could be achieved with a hadron-hadron collider with $\sqrt{s} = 37.5$ TeV and $\mathcal{L} = 15 \text{ ab}^{-1}$, in conjunction with one of the e^+e^- colliders [10]. This is shown in table 36 compared to the nominal FCC-hh in combination with the various e^+e^- colliders. For most coupling parameters the sensitivity of the 37.5 TeV collider is degraded by about a factor 1.5 – 2 w.r.t. the 100 TeV collider, except for $Z\gamma$ where it is a factor of 5. For κ_Z and κ_c there is no difference as both are very much dominated by the lepton collider sensitivity.

G Electroweak precision constraints on oblique parameters

In this section we will focus on the constraints on heavy new physics that can be obtained by precise measurement of the on-shell W and Z properties. We will focus on universal effects that can be fully encapsulated in the vector boson propagators, with no direct correction to the interaction vertices with fermions. This assumption allows on the one hand to limit the analysis to a few parameters. On the other hand, it should be noted, motivated models, like the minimal composite Higgs, often satisfy this assumption to a very good approximation. When considering universal deviations from the SM one must distinguish between the number of on-shell Z and W observables and the total number of parameters, which corresponds to the total number of on- and off-shell observables.

Under the assumption of universality, the relevant on-shell observables of W and Z physics reduce to three quantities: the relative normalization of charged and neutral currents (or the Z 's axial coupling), and the two relative differences among the three possible definitions of the Weinberg angle (from $\alpha(M_Z)$, G_F , M_Z , from the Z 's vector coupling, and from M_W/M_Z). These can be nicely encapsulated in the ϵ 's of Altarelli and Barbieri [140]:

$$\begin{aligned}\epsilon_1 &= \Delta\rho, \\ \epsilon_2 &= \cos^2\theta_w\Delta\rho + \frac{\sin^2\theta_w}{\cos^2\theta_w - \sin^2\theta_w}\Delta r_W - 2s_0^2\Delta\kappa, \\ \epsilon_3 &= \cos^2\theta_w\Delta\rho + (\cos^2\theta_w - \sin^2\theta_w)\Delta\kappa.\end{aligned}\tag{G.1}$$

where we define the weak angle from $\sin^2\theta_w \cos^2\theta_w \equiv \frac{\pi\alpha(M_Z)}{\sqrt{2}G_F M_Z^2}$ and the Δr_W , $\Delta\rho$ and $\Delta\kappa$ parameters are defined from the masses and effective vector and axial couplings of the electroweak bosons:

$$\begin{aligned}\frac{M_W^2}{M_Z^2} &= \frac{1}{2}\sqrt{1 + \sqrt{1 - \frac{4\pi\alpha(M_Z)}{\sqrt{2}G_F M_Z^2}(1 - \Delta r_W)}}, \\ g_V^f &= \sqrt{1 + \Delta\rho}(T_3^f - 2Q_f(1 + \Delta\kappa)\sin^2\theta_w), \\ g_A^f &= \sqrt{1 + \Delta\rho}T_3^f.\end{aligned}\tag{G.2}$$

(T_3^f and Q_f are weak isospin and charge of the corresponding fermion.) Notice that ϵ_2 relies on the measurement of the W mass while $\epsilon_{1,3}$ do not.

The number of parameters describing universal new physics in the W, Z channel on- and off-shell is instead four.²³ They correspond to the leading effects in a derivative expansion of the vector boson self-energies, $\Pi_{VV'}(q^2)$. More precisely they correspond to the

²³For a good part of the history of EW precision tests, the community has mostly relied on a set of three quantities, S, T, U . These are however inadequate in any realistic new physics scenario: they are always either redundant or incomplete. Indeed in technicolor models, it was understood that U is negligible and the set is redundant in that case [141–144]. On the other hand S, T, U are insufficient to describe even the simplest sequential Z' models that fall into the class of universal theories. That the relevant set should be consist of 4 quantities was first realized in [145] in the context of linearly realized EW symmetry, i.e. SMEFT. The generality of this counting, and therefore its validity also in technicolor/HEFT scenarios, has been clarified in [48].

Table 37. Comparison of the sensitivity at 68% probability to new physics contributions to EWPO in the form of the oblique S and T parameters, under different assumptions for the SM theory uncertainties. We express the results in terms of the usually normalised parameters: $S = 4 \sin^2 \theta_w \hat{S}/\alpha$ and $T = \hat{T}/\alpha$.

leading effects in each independent channel (with the channels characterized by the relevant quantum numbers: electric charge, electroweak and custodial symmetry). Considering the vector boson self-energies, using the constraints from $U(1)_{\text{EM}}$ unbroken gauge invariance (massless photon), and subtracting the quantities that play the role of SM inputs (v, g, g'), one is left with these four leading quantities

$$\begin{aligned}
 \hat{S} &= g^2 \Pi'_{W_3 B}(0), \\
 \hat{T} &= \frac{g^2}{M_W^2} (\Pi_{W_3 W_3}(0) - \Pi_{W^+ W^-}(0)), \\
 W &= \frac{1}{2} g^2 M_W^2 \Pi''_{W_3 W_3}(0), \\
 Y &= \frac{1}{2} g'^2 M_W^2 \Pi''_{BB}(0),
 \end{aligned} \tag{G.3}$$

which can be mapped to four linear combinations of operators in the SMEFT Lagrangian. Finally, considering their effect on W, Z on-shell propagation, one finds, writing $\epsilon_i = \epsilon_{i,\text{SM}} + \delta\epsilon_i$,

$$\begin{aligned}
 \delta\epsilon_1 &= \hat{T} - W - Y \tan^2 \theta_w, \\
 \delta\epsilon_2 &= -W, \\
 \delta\epsilon_3 &= \hat{S} - W - Y.
 \end{aligned} \tag{G.4}$$

Strongly coupled models come with a parametric enhancement of \hat{S}, \hat{T} over W, Y , such that in the class of models, one can simplify further the analysis of EW data and perform a two-dimensional fit.

The results of this fit setup are presented in table 37 and figure 17, for the different future lepton-collider options, where the largest improvement in terms of measurements of the EW precision observables (EWPO) is expected. In the table and figures we also show the impact of the SM theory uncertainties in the results. The results are presented assuming the projected future improvements in SM theory calculations (*Full Th_{Intr} Unc.*), neglecting the intrinsic theory uncertainties associated to such calculations (*No Th_{Intr} Unc.*) and,

Figure 17. (Left) $2\text{-}\sigma$ regions in the $S - T$ plane at the different future colliders, combined with the HL-LHC (including also the LEP/SLD EWPO programme). We express the results in terms of the usually normalised parameters: $S = 4 \sin^2 \theta_w \hat{S}/\alpha$ and $T = \hat{T}/\alpha$. The results include the future projected parametric uncertainties in the SM predictions of the different EWPO, but not the intrinsic ones. (Right) The same illustrating the impact of neglecting such intrinsic theory errors. For each project (including the Giga-Z option for linear colliders) the solid regions show the results in the left panel, to be compared with the regions bounded by the dashed lines, which include the full projected theory uncertainty.

finally, also assuming that parametric uncertainties become subdominant (*No $Th_{\text{par+Intr}} \text{Unc.}$*). Since several of the SM EW inputs are to be measured at the future collider under consideration, the latter scenario goes beyond the physics potential of these machines. This scenario is presented only to illustrate whether the precision of the measurements of such inputs can become a limiting factor in terms of the reach of \hat{S} and \hat{T} . This seems to be the case for the circular colliders and, to a less extent, the linear collider Giga-Z options.

H Consistency of electroweak precision data

Before the discovery of a Higgs boson, the consistency of the SM has often been illustrated by comparing the direct measurement of m_W and m_{top} with the indirect constraints derived from precision measurement at the Z -pole and at low-energy experiments. Figure 18 for the future e^+e^- colliders.

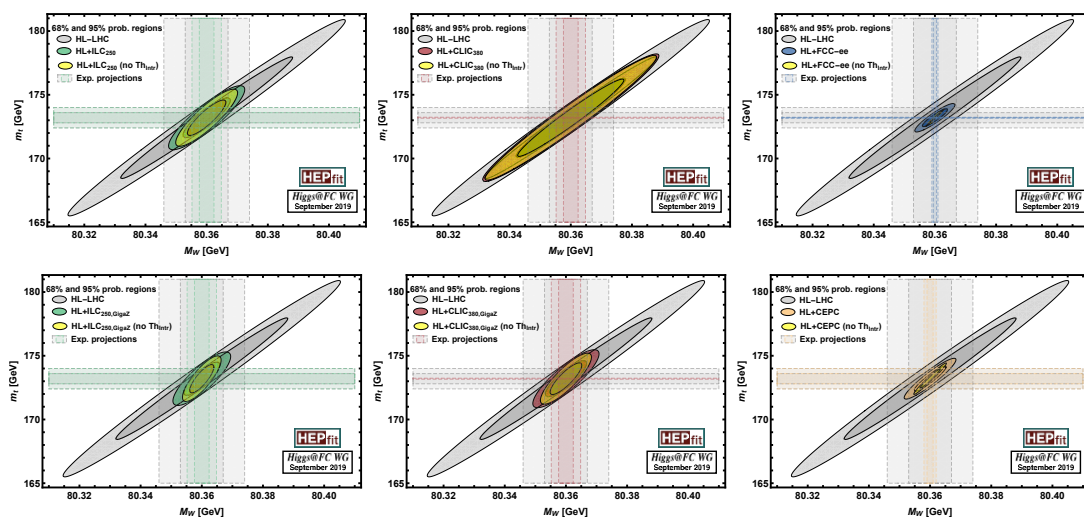

Figure 18. Constraints on m_W and m_{top} from direct measurements (horizontal and vertical lines) and indirect constraints (ellipses). In all cases the constraints from current data plus HL-LHC are compared to the ones expected for the e^+e^- collider. For ILC and CLIC the result is shown without (top row) and with a Giga-Z (bottom row) run.

I Improvement with respect to HL-LHC

Figures 19 and 20 give a graphic comparison of the improvement with respect to HL-LHC in the Kappa-3 and SMEFT-ND frameworks. This improvement is shown as the ratio of the precision at the HL-LHC over the precision at the future collider, with more darker colors corresponding to larger improvement factors. The kappa-3 result shows large improvements, up to an order of magnitude, for all future ee colliders for the measurement of the couplings to Z, W and b and the limits on the invisible branching ratio, and an ‘infinite’ improvement in the case of the coupling to charm, immeasurable at the HL-LHC. Rare, statistically dominated, couplings, as well as the coupling to the top quark are shown to be markedly improved with respect to HL-LHC only with FCC-hh. The more complete SMEFT-ND fit highlights more clearly the improvement in precision, with improvements of the order of an order of magnitude in the measurement of Z, W and b couplings for all future ee colliders. The aTGC results show an even more dramatic improvement, with factors over 100 and 1000 for the last stages of the linear colliders.

Figure 19. Graphic comparison of the improvement with respect to HL-LHC in the Kappa-3 framework.

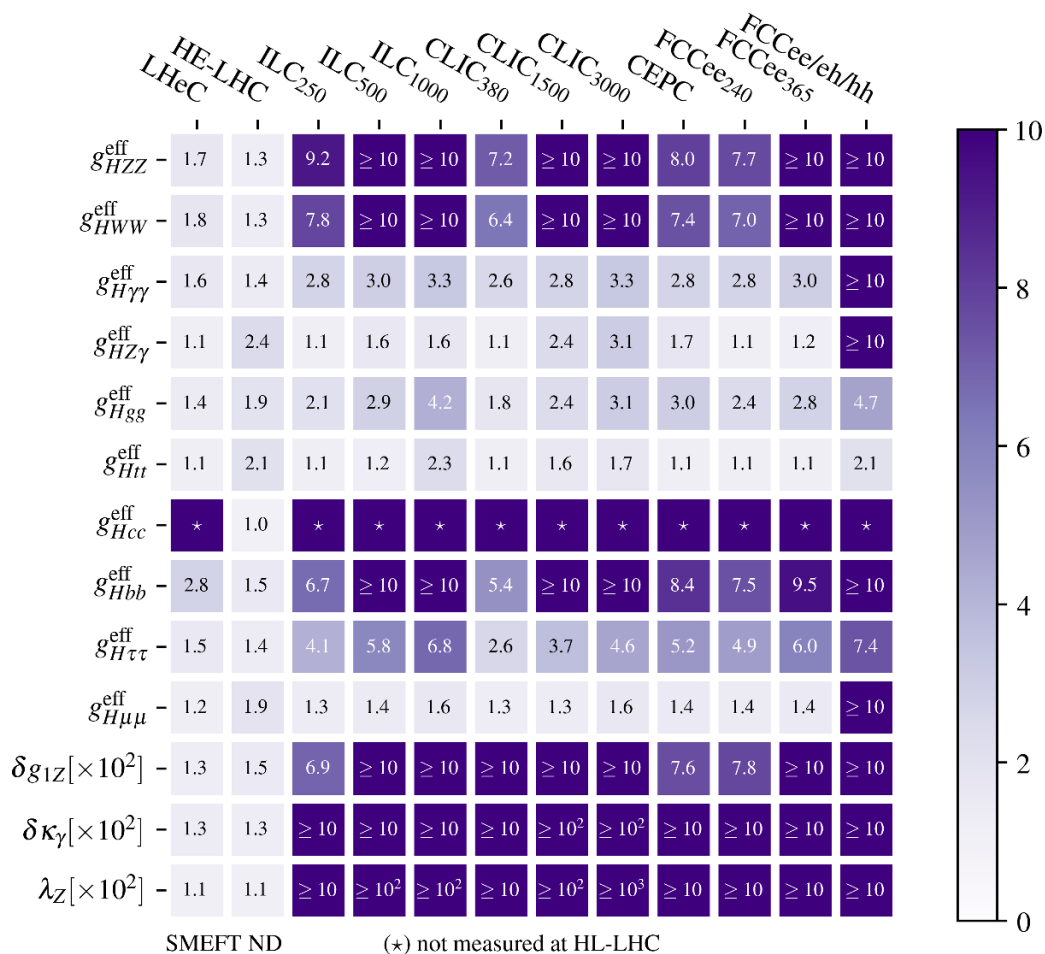

Figure 20. Graphic comparison of the improvement with respect to HL-LHC in the SMEFT-ND framework.

Measurement of the top quark mass using proton-proton data at $\sqrt{s} = 7$ and 8 TeV

V. Khachatryan *et al.**

(CMS Collaboration)

(Received 14 September 2015; published 7 April 2016)

A new set of measurements of the top quark mass are presented, based on the proton-proton data recorded by the CMS experiment at the LHC at $\sqrt{s} = 8$ TeV corresponding to a luminosity of 19.7 fb^{-1} . The top quark mass is measured using the lepton + jets, all-jets and dilepton decay channels, giving values of $172.35 \pm 0.16(\text{stat}) \pm 0.48(\text{syst})$ GeV, $172.32 \pm 0.25(\text{stat}) \pm 0.59(\text{syst})$ GeV, and $172.82 \pm 0.19(\text{stat}) \pm 1.22(\text{syst})$ GeV, respectively. When combined with the published CMS results at $\sqrt{s} = 7$ TeV, they provide a top quark mass measurement of $172.44 \pm 0.13(\text{stat}) \pm 0.47(\text{syst})$ GeV. The top quark mass is also studied as a function of the event kinematical properties in the lepton + jets decay channel. No indications of a kinematic bias are observed and the collision data are consistent with a range of predictions from current theoretical models of $t\bar{t}$ production.

DOI: [10.1103/PhysRevD.93.072004](https://doi.org/10.1103/PhysRevD.93.072004)

I. INTRODUCTION

The mass of the top quark (m_t) is one of the fundamental parameters of the standard model (SM). A precise measurement of its value provides a key input to global electroweak fits and to tests of the internal consistency of the SM [1,2]. Its value leads to constraints on the stability of the electroweak vacuum [3,4] and affects models with broader cosmological implications [5,6].

The most precise measurements of m_t have been derived from combinations of the results from the CDF and D0 experiments at the Tevatron, and ATLAS and CMS at the CERN LHC. The current combination from the four experiments gives a top quark mass of 173.34 ± 0.76 GeV [7], while the latest combination from the Tevatron experiments gives a mass of 174.34 ± 0.64 GeV [8]. The Tevatron combination is currently the most precise measurement and it includes all of the current Tevatron measurements. In contrast, the current four experiment combination has not been updated since 2013 and does not include the latest Tevatron and LHC measurements, in particular the measurement from ATLAS using a combination of the lepton + jets and dilepton channels [9].

Beyond the leading order (LO) in quantum chromodynamics (QCD), the numerical value of m_t depends on the renormalization scheme [10,11]. The available Monte Carlo (MC) generators contain matrix elements at LO or next-to-leading order (NLO), while higher orders are approximated by applying parton showering. Each of the

measurements used in the combinations has been calibrated against the mass implemented in a MC program. Given the precision of the experimental results, a detailed understanding of the relationship between the measurements and the value of m_t in different theoretical schemes is needed. Current indications are that the present measurements based on the kinematic reconstruction of the top quark mass correspond approximately to the pole (“on-shell”) mass to within a precision of about 1 GeV [12].

At the LHC, top quarks are predominantly produced in quark-antiquark pairs ($t\bar{t}$) and top quark events are characterized by the decays of the daughter W bosons. This leads to experimental signatures with two jets associated with the hadronization of the bottom quarks and either a single lepton (e, μ), one undetected neutrino and two light quark jets (lepton + jets channel), or four light quark jets (all-jets channel), or two leptons ($ee, e\mu, \mu\mu$) and two undetected neutrinos (dilepton channel). While the events which contain leptonic τ decays are included in the analysis samples, they contribute very little to the mass measurements as their yields are negligible. The results presented in this paper focus on the analysis of data in these three channels recorded by the CMS experiment in the 2012 part of what is commonly referred to as Run 1 of the LHC.

The paper is organized as follows. The main features of the detector and the data are discussed in Secs. II and III. Section IV is a discussion of the analysis techniques, which lead to the measurements of Sec. V. The categorization of the systematic uncertainties is presented in Sec. VI, followed by the full results for the three decay channels in Sec. VII. Section VIII presents a study of m_t as a function of the kinematical properties of the $t\bar{t}$ system in the lepton + jets channel. This is followed in Secs. IX and X, which discuss the combination of the measurements and the final result for m_t , respectively.

II. THE CMS DETECTOR

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter, providing a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL), each composed of a barrel and two endcap sections. The tracker has a track-finding efficiency of more than 99% for muons with transverse momentum $p_T > 1$ GeV and pseudorapidity $|\eta| < 2.5$. The ECAL is a fine-grained hermetic calorimeter with quasiprojective geometry, and is distributed in the barrel region of $|\eta| < 1.48$ and in two endcaps that extend up to $|\eta| < 3.0$. The HCAL barrel and endcaps similarly cover the region $|\eta| < 3.0$. In addition to the barrel and endcap detectors, CMS has extensive forward calorimetry. Muons are measured in gas-ionization detectors, which are embedded in the steel flux-return yoke outside of the solenoid. A more detailed description of the CMS detector, together with a definition of the coordinate system used, and the relevant kinematic variables can be found in Ref. [13].

III. DATA SETS

The measurements presented in this paper are based on the data recorded at a center-of-mass energy of 8 TeV during 2012, and correspond to an integrated luminosity of 19.7 fb^{-1} .

A. Event simulation and reconstruction

Simulated $t\bar{t}$ signal events are generated with the MADGRAPH 5.1.5.11 LO matrix element generator with up to three additional partons [14]. MADSPIN [15] is used for the decay of heavy resonances, PYTHIA 6.426 for parton showering [16] using the Z2* tune, and TAUOLA [17] for decays of τ leptons. The most recent PYTHIA Z2* tune is derived from the Z1 tune [18], which uses the CTEQ5L parton distribution function (PDF) set, whereas Z2* uses CTEQ6L [19]. A full simulation of the CMS detector based on GEANT4 [20] is used. The $t\bar{t}$ signal events are generated for seven different values of m_t ranging from 166.5 to 178.5 GeV. The W/Z + jets background events are generated with MADGRAPH 5.1.3.30. The diboson background (WW , WZ , ZZ) is simulated using PYTHIA 6.426 using the Z2* tune. The single top quark background is simulated using POWHEG 1.380 [21–25], assuming an m_t of 172.5 GeV. The $t\bar{t}$, W/Z + jets, and single top quark samples are normalized to the theoretical predictions described in Refs. [26–30]. The simulation includes the effects of additional proton-proton collisions (pileup) by overlapping minimum bias events with the same multiplicity distribution and location as in data.

Events are reconstructed using a particle-flow (PF) algorithm [31,32]. This proceeds by reconstructing and

identifying each final-state particle using an optimized combination of all of the subdetector information. Each event is required to have at least one reconstructed collision vertex. The primary vertex is chosen as the vertex with the largest value of $\sum p_T^2$ of the tracks associated with that vertex. Additional criteria are applied to each event to reject events with features consistent with detector noise and beam-gas interactions.

The energy of electrons is determined from a combination of the track momentum at the primary vertex, the corresponding ECAL energy cluster, and the sum of the reconstructed bremsstrahlung photons associated with the track [33]. The momentum of muons is obtained from the track momentum determined in a combined fit to information from the silicon trackers and the muon detectors [34]. The energy of charged hadrons is determined from a combination of the track momentum and the corresponding ECAL and HCAL energies, corrected for the suppression of small signals and calibrated for the nonlinear response of the calorimeters. Finally, the energy of the neutral hadrons is obtained from remaining calibrated HCAL and ECAL energies. As the charged leptons originating from top quark decays are typically isolated from other particles, a relative isolation variable (I_{rel}) is constructed to select lepton candidates. This is defined as the scalar sum of the p_T values of the additional particles reconstructed within an angle $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ of the lepton direction, divided by the p_T of the lepton. Here $\Delta\eta$ and $\Delta\phi$ are the differences in the pseudorapidity and azimuthal angles between the lepton direction and other tracks and energy depositions. A muon candidate is rejected if $I_{\text{rel}} \geq 0.12$ for $\Delta R = 0.4$, and an electron candidate is rejected if $I_{\text{rel}} \geq 0.10$ for $\Delta R = 0.3$.

Jets are clustered from the reconstructed PF candidates using the anti- k_T algorithm [35] with a distance parameter of 0.5, as implemented in the FASTJET package [36]. The jet momentum is determined from the vector sum of the momenta of the particles in each jet, and is found in simulation to be within 5% to 10% of the jet momentum at hadron level for the full p_T range [37]. Corrections to the jet energy scale (JES) and the jet energy resolution (JER) are obtained from the simulation and through *in situ* measurements of the energy balance of exclusive dijet, photon + jet, and Z + jet events. Muons, electrons, and charged hadrons originating from pileup interactions are not included in the jet reconstruction. Missing transverse energy (E_T^{miss}) is defined as the magnitude of the negative vector p_T sum of all selected PF candidates in the event. Charged hadrons originating from pileup interactions are not included in the calculation of E_T^{miss} . Jets are classified as b jets through their probability of originating from the hadronization of bottom quarks, using the combined secondary vertex (CSV) b tagging algorithm, which combines information from the significance of the track impact parameters, the kinematical properties of the jets, and the

presence of tracks that form vertices within the jet. Three different minimum thresholds are used for the CSV discriminator to define the loose (CSVL), medium (CSVM), and tight (CSVT) working points. These have b tagging efficiencies of approximately 85%, 67%, and 50%, and misidentification probabilities for light-parton jets of 10%, 1%, and 0.1%, respectively [38].

B. Event selection

For the lepton + jets channel we use the data collected using a single-muon or single-electron trigger with a minimum trigger p_T threshold for an isolated muon (electron) of 24 GeV (27 GeV), corresponding to an integrated luminosity of 19.7 fb^{-1} . We then select events

that have exactly one isolated muon or electron, with $p_T > 33 \text{ GeV}$ and $|\eta| < 2.1$. In addition, at least four jets with $p_T > 30 \text{ GeV}$ and $|\eta| < 2.4$ are required. Jets originating from b quarks (denoted as b jets) are identified using the CSV algorithm at the medium working point [38]. With the requirement of exactly two b -tagged jets among the four jets with the highest p_T , 104 746 $t\bar{t}$ candidate events are selected in data. From simulation, the sample composition is expected to be 93% $t\bar{t}$, 4% single top quark, 2% W + jets, and 1% other processes. Figure 1 shows the comparison of the data and simulation for the selected events in some representative distributions. The simulation shown is not corrected for the uncertainty in the shape of the top quark p_T distribution [39], which accounts for almost all of the

FIG. 1. Distributions for the lepton + jets channel of (upper left) lepton p_T , (upper right) missing transverse energy, (lower left) leading jet p_T , (lower right) second-leading jet p_T for data and simulation, summed over all channels and normalized by luminosity. The vertical bars show the statistical uncertainty and the hatched bands show the statistical and systematic uncertainties added in quadrature. The lower portion of each panel shows the ratio of the yields between the collision data and the simulation.

FIG. 2. Distributions for the dilepton channel: (upper left) leading lepton p_T , (upper right) second-leading lepton p_T , (lower left) leading jet p_T , (lower right) second-leading jet p_T for data and simulation, summed over all channels and normalized by luminosity. The vertical bars show the statistical uncertainty and the hatched bands show the statistical and systematic uncertainties added in quadrature. The lower portion of each panel shows the ratio of the yields between the collision data and the simulation.

slope visible in the data/MC ratio plots. However, even without making a correction, the data and simulation are consistent within the quoted uncertainties.

For the all-jets channel we use the data collected using a multijet trigger, corresponding to an integrated luminosity of 18.2 fb^{-1} . The trigger requires the presence of at least four jets, reconstructed from the energies deposited in the calorimeters, with transverse momenta $p_T > 50 \text{ GeV}$. Since fully hadronically decaying top quark pairs lead to six partons in the final state, events are required to have at least four jets with $p_T > 60 \text{ GeV}$ and a fifth and sixth jet with $p_T > 30 \text{ GeV}$. Jets originating from b quarks are identified using the CSV b algorithm at the tight working point [38]. With the requirement of exactly two b -tagged jets among the six leading ones, 356 231 candidate events are selected. From simulation, the sample is expected to be dominated by the QCD multijet background and to have a signal fraction of about 13%. The QCD multijet background cannot be reliably simulated and we determine its kinematic dependence from a control sample in the data. The background normalization is determined as a part of the fit process, which is discussed in Sec. V B.

For the dilepton channel, events are required to pass the triggers appropriate for each of the three channels. The $e\mu$ channel uses a logical OR of two triggers that require a muon of $p_T > 17$ (or 8) GeV and an isolated electron of 8 (or 17) GeV. Dimuon events must pass a trigger which requires a $p_T > 17 \text{ GeV}$ for the muon with the highest (“leading”) p_T and 8 GeV for the second-leading muon. Similarly, dielectron events must satisfy a trigger with a threshold of $p_T > 17 \text{ GeV}$ for the leading electron and 8 GeV for the second-leading electron. In this case both electrons are required to be isolated. In all three cases the amount of data corresponds to a luminosity of 19.7 fb^{-1} . We select events for analysis if they have two isolated opposite-sign leptons with $p_T > 20 \text{ GeV}$ and $|\eta| < 2.4$ (2.5) for muons (electrons). Jets originating from b quarks are identified with the CSV algorithm at the loose working point [38]. Events are retained if they have at least two b -tagged jets. Background contamination from low-mass resonances is reduced by demanding a dilepton pair invariant mass, $m_{\ell\ell}$, of at least 10 GeV. To suppress the background from Z boson decays, events with $e\bar{e}$ and $\mu\bar{\mu}$ signatures are required to have $E_T^{\text{miss}} > 40 \text{ GeV}$, and to fall outside of the dilepton invariant mass window $76 < m_{\ell\ell} < 106 \text{ GeV}$. The remaining Drell–Yan background is estimated from the data using the ratio of the event yield inside vs outside the invariant mass window [38]. After all of the requirements, we find 41 125 candidate events in data for which the sample compositions is expected to be 95% $t\bar{t}$, 3% single top quark, 2% Drell–Yan, and $< 0.3\%$ other processes. Figure 2 shows a comparison of the data and simulation for events with at least one b jet for some representative distributions. As with the lepton + jets plot (Fig. 1) the simulation is not corrected for the

discrepancy in the top quark p_T distribution, leading to the slopes visible in the data/MC plots.

IV. ANALYSIS TECHNIQUES

The measurements discussed in the following sections use analysis techniques in which either m_t alone is determined or m_t and the overall jet energy scale factor (JSF) are determined simultaneously. For the lepton + jets and the all-jets channels we use analyses based on the ideogram technique (Sec. IV A). While the ideogram technique provides the most precise measurements, it is not suitable for dilepton events where the presence of more than one neutrino introduces uncertainties in the use of the measured E_T^{miss} . Instead, for the dilepton channel, we use the analytical matrix weighting technique (AMWT) method (Sec. IV B).

A. One- and two-dimensional ideogram analyses

The ideogram method is a joint maximum likelihood fit that determines m_t and, optionally, the JSF from a sample of selected $t\bar{t}$ candidate events in the lepton + jets or all-jets channels. The observable used for measuring m_t is the mass m_t^{fit} estimated by a kinematic fit [40]. The kinematic fit constrains the candidates for the $t\bar{t}$ decay products to the hypothesis of the production of two heavy particles of equal masses, each one decaying to a W boson and a bottom quark, where the W boson invariant mass is constrained to 80.4 GeV [41]. The JSF is defined as a multiplicative factor to be applied in addition to the standard jet energy corrections (JEC) [37] to the four-momenta of the jets. The JSF is determined from the invariant masses of the jet pairs, m_W^{reco} , associated with the W bosons before the jet momenta are constrained by the kinematic fit. For the case of a simultaneous fit to both m_t and the JSF (2D approach), no prior knowledge of the JSF is assumed. If only m_t is fitted (1D approach), the jet energy scale determined from the JEC is taken as the JSF prior, fixing it to unity. A third category of fits (hybrid approach) incorporates the prior knowledge about the jet energy scale by using a Gaussian constraint, $P(\text{JSF})$, centered at 1 with a variance depending on the total JEC uncertainty. For the hybrid analysis in the lepton + jets channel, the JSF determined from the W boson decays and the jet energy scale from the JEC are given equal weight in the fit. In contrast, for the hybrid fit in the all-jets channel, the jet energy scale from the JEC contributes 80% of the information, because of the larger uncertainty on the JSF from the 2D fit.

The distributions of m_t^{fit} and m_W^{reco} are obtained from simulation for three to seven different m_t and three to five different JSF values for the $t\bar{t}$ signal, and from simulated background events (lepton + jets) or the control sample for the multijet background (all-jets). From these distributions, probability density functions are derived separately for different cases of jet-parton assignments for the signal, and

for the background contribution. The signal functions depend on m_t and JSF, and are labeled $P(m_t^{\text{fit}}|m_t, \text{JSF})$ and $P(m_W^{\text{reco}}|m_t, \text{JSF})$, respectively, for an event in the final likelihood.

The likelihood for measuring m_t and the JSF in an observed data sample can be expressed as

$$\mathcal{L}(\text{sample}|m_t, \text{JSF}) = \prod_{\text{events}} \mathcal{L}(\text{event}|m_t, \text{JSF})^{w_{\text{event}}}, \quad (1)$$

where the event weight $w_{\text{event}} = c \sum_{i=1}^n P_{\text{gof}}(i)$ is used in the lepton + jets analysis to reduce the impact of events for which the chosen permutation of the jets is incorrect. Here, c is a normalization constant and the remaining quantities are defined as in Eq. (2). For the all-jets channel, $w_{\text{event}} = 1$ is used. The event likelihoods (or *ideograms*) are given by

$$\begin{aligned} \mathcal{L}(\text{event}|m_t, \text{JSF}) &= \sum_{i=1}^n P_{\text{gof}}(i) \{f_{\text{sig}} P_{\text{sig}}(m_{t,i}^{\text{fit}}, m_{W,i}^{\text{reco}}|m_t, \text{JSF}) \\ &+ (1 - f_{\text{sig}}) P_{\text{bkg}}(m_{t,i}^{\text{fit}}, m_{W,i}^{\text{reco}})\}, \end{aligned} \quad (2)$$

where the index i runs over the n selected permutations of an event that each have a goodness-of-fit probability P_{gof} assigned from the kinematic fit. The signal fraction f_{sig} is assumed to be 1 for the lepton + jets channel and is left as a free parameter of the fit for the all-jets channel. The background term P_{bkg} is independent of both m_t and the JSF for backgrounds determined from the collision data.

As the W boson mass is fixed to 80.4 GeV in the fit, the observables m_t^{fit} and m_W^{reco} have a low correlation coefficient (less than 5%) and the probability density P can be factorized into one-dimensional expressions,

$$\begin{aligned} P(m_t^{\text{fit}}, m_W^{\text{reco}}|m_t, \text{JSF}) &= \sum_j f_j P_j(m_t^{\text{fit}}|m_t, \text{JSF}) \\ &\times P_j(m_W^{\text{reco}}|m_t, \text{JSF}), \end{aligned} \quad (3)$$

where the index j denotes the different jet-parton permutation classes defined for the measurement. Their relative fraction f_j is either determined from the simulated sample with $m_{t,\text{gen}} = 172.5$ GeV or by the fit.

The most likely m_t and JSF values are obtained by minimizing $-2 \ln \mathcal{L}(\text{sample}|m_t, \text{JSF})$ for the 2D and hybrid analyses. For the 1D analyses only m_t is determined and the JSF is set to unity during the minimization.

B. Analytical matrix weighting technique

The measurement of m_t for the dileptonic $t\bar{t}$ decays is performed using the AMWT. This is based on a matrix weighting technique used by the D0 Collaboration [42], combined with an analytical algorithm to find solutions of the kinematic equations [43]. The method allows the

determination of m_t with the assumption of JSF = 1, and in this sense, the results are comparable to the 1D fits performed in either the lepton + jets or all-jets channels (see Sec. IV A).

In dileptonic $t\bar{t}$ decays, the final state consists of two charged leptons, two neutrinos, and two b quarks, resulting in 18 unknowns: three momentum components for each of the six final state particles. Of these, we observe the momenta of the two charged leptons, the momenta of the two jets, and the momenta of all of the other charged particles and jets. If there are more than two jets in an event we have to select the jets to assign to the b quarks from the decay of the top quark pair. We preferentially assign b -tagged jets to these. Hence, after physics object reconstruction, we measure the following observables for each event:

- (i) the momenta \vec{p}_{ℓ^+} and \vec{p}_{ℓ^-} of the charged leptons from the W^+ and W^- decays,
- (ii) the momenta \vec{p}_b and $\vec{p}_{\bar{b}}$ of the b and \bar{b} quarks produced by the t and \bar{t} quark decays,
- (iii) the total transverse momentum $\vec{p}_T^{\ell\ell}$ of the $t\bar{t}$ pair.

This leaves four unknowns that must be solved analytically. Conservation of four-momentum provides the following four constraints on the kinematics, if a hypothetical value for the top-quark mass is assumed:

- (i) the masses $m_{\ell^+\nu}$ and $m_{\ell^-\bar{\nu}}$ of the lepton-neutrino pairs from the W^+ and W^- decays are constrained to be 80.4 GeV [41],
- (ii) the masses of the systems of particles from the t and \bar{t} decays must equal the hypothesized mass of the top quark.

Hence, the system of equations is appropriately constrained. However, there is not a unique solution, because the equations are nonlinear. For a given assignment of reconstructed momenta to final-state particles there can be up to four solutions for the neutrino momenta such that the event satisfies all of the constraints. There is a twofold ambiguity of assigning jet momenta to the b and \bar{b} jets, which doubles this to eight possible solutions. We follow the algorithm given in Refs. [44,45] to find these solutions. In rare cases, a latent singularity in the equations used to find these solutions can prohibit the calculation of the longitudinal momenta. In such events, a numerical method is employed to find the incalculable variables [44].

For each event, we find all solutions of neutrino momenta for hypothesized top quark masses between 100 and 600 GeV, in 1 GeV increments. In general, we expect solutions to be found for a large range of mass hypotheses. To each solution we assign a weight w given by [46]

$$\begin{aligned} w(\vec{X}|m_t) &= \left[\sum_{\text{initial partons}} F(x_1)F(x_2) \right] \\ &\times p(E_{\ell^+}|m_t)p(E_{\ell^-}|m_t), \end{aligned} \quad (4)$$

where \vec{X} represents the momentum vectors of the final state particles as obtained from the solutions of the kinematic equations. We sum the parton distribution functions $F(x)$, evaluated at $Q^2 = m_t^2$, over the possible LO initial parton states ($u\bar{u}$, $\bar{u}u$, $d\bar{d}$, $\bar{d}d$, and gg); x_1 and x_2 are the Bjorken x values for the initial-state partons which can be computed from the momenta of the final-state particles. The function $p(E|m_t)$ is the probability density of observing a charged lepton of energy E in the rest frame of a top quark of mass m_t , given by [46]

$$p(E|m_t) = \frac{4m_t E(m_t^2 - m_b^2 - 2m_t E)}{(m_t^2 - m_b^2)^2 + M_W^2(m_t^2 - m_b^2) - 2M_W^4}, \quad (5)$$

where the b quark mass, m_b , is set to 4.8 GeV, and the W boson mass, M_W , to 80.4 GeV. For each m_t hypothesis, we find an overall weight by summing the weights of all solutions found. To compensate for mismeasurements of the momenta due to finite detector resolution or the loss of correlation between the jet and quark momentum because of hard-gluon radiation, we account for the jet energy resolution during reconstruction. Every event in both the collision and simulated data is reconstructed 500 times, each time with jet momenta drawn randomly from a Gaussian distribution of widths given by the detector resolution and with means given by the measured momenta. After this randomization procedure, approximately 96% of all events in both the collision and simulated data have at least one solution, and hence a top quark mass estimator. The final weight curve of each event is given by the average of the weight distributions from each of the 500 randomizations, after excluding the cases for which there is no valid solution. This distribution serves as a measure of the relative probability that the observed event occurs for any given value of m_t .

The estimator for m_t is then the hypothesized mass with the highest average sum weight for each event, called the AMWT mass, m_t^{AMWT} .

V. MASS MEASUREMENTS

A. The lepton + jets channel

To check the compatibility of an event with the $t\bar{t}$ hypothesis and improve the resolution of the reconstructed quantities, a kinematic fit [40] is applied to the events. For each event, the inputs to the fitter are the four-momenta of the lepton and the four leading jets, the missing transverse energy, and their respective resolutions. The fit constrains these to the hypothesis of the production of two heavy particles of equal mass, each one decaying to a W boson with an invariant mass of 80.4 GeV [41] and a bottom quark. It minimizes $\chi^2 = (\mathbf{x} - \mathbf{x}^m)^T \mathbf{E}^{-1} (\mathbf{x} - \mathbf{x}^m)$ where \mathbf{x}^m is the vector of measured observables, \mathbf{x} is the vector of fitted observables, and \mathbf{E}^{-1} is the inverse error matrix which is given by the resolutions of the observables. The two b -tagged jets are candidates for the bottom quarks in the

$t\bar{t}$ hypothesis, while the two untagged jets serve as candidates for the light quarks for one of the W boson decays. This leads to two possible parton-jet assignments per event and two solutions for the z component of the neutrino momentum.

For simulated $t\bar{t}$ events, the parton-jet assignments are classified as *correct permutations*, *wrong permutations*, and *unmatched permutations*. The correct permutation class includes those events for which all of the quarks from the $t\bar{t}$ decay (after initial-state parton shower) are correctly matched to the selected jets within a distance $\Delta R < 0.3$. The wrong permutations class covers the events for which the jets from the $t\bar{t}$ decay are correctly matched to the selected jets, but where two or more of the jets are interchanged. Lastly, the unmatched permutations class includes the events for which at least one quark from the $t\bar{t}$ decay is not matched unambiguously to any of the four selected jets. To increase the fraction of correct permutations, we require $P_{\text{gof}} > 0.2$ for the kinematic fit with 2 degrees of freedom. This selects 28 295 events for the mass measurement, with an estimated composition of 96.3% $t\bar{t}$ signal and 3.7% non- $t\bar{t}$ background, which is dominated by single top quark events. In the mass extraction, the permutations are weighted by their P_{gof} values, and the effective fraction of correct permutations among the $t\bar{t}$ signal improves from 13% to 44%, while the fractions of wrong and unmatched permutations change from 16% to 21% and 71% to 35%, respectively, determined in simulation.

Figure 3 shows the distributions before and after the kinematic fit and P_{gof} selection of the reconstructed mass m_W^{reco} of the W boson decaying to a $q\bar{q}$ pair and the mass m_t^{reco} of the corresponding top quark for all possible permutations.

The ideogram method (Sec. IV A) is calibrated for each combination of the top quark mass hypothesis, m_t^{gen} and JSF values by conducting 10 000 pseudoexperiments, separately for the muon and electron channels, using simulated $t\bar{t}$ and background events. The average deviations between extracted mass and JSF and their input values are obtained as a function of m_t^{gen} and the bias is fit with a linear function for each generated JSF value. From these fits, additional small corrections for calibrating the top quark mass and the jet energy scale are derived as linear functions of both the extracted top quark mass and JSF. The corrections are approximately -0.2 GeV for m_t and -0.4% for the JSF. The statistical uncertainties of the method are also corrected by factors of approximately 1.04 that are derived from the widths of the corresponding pull distributions.

The 2D ideogram fit to the combined electron and muon channels yields

$$m_t^{2D} = 172.14 \pm 0.19(\text{stat} + \text{JSF}) \text{ GeV},$$

$$\text{JSF}^{2D} = 1.005 \pm 0.002(\text{stat}).$$

As m_t and the JSF are measured simultaneously, the statistical uncertainty in m_t combines the statistical

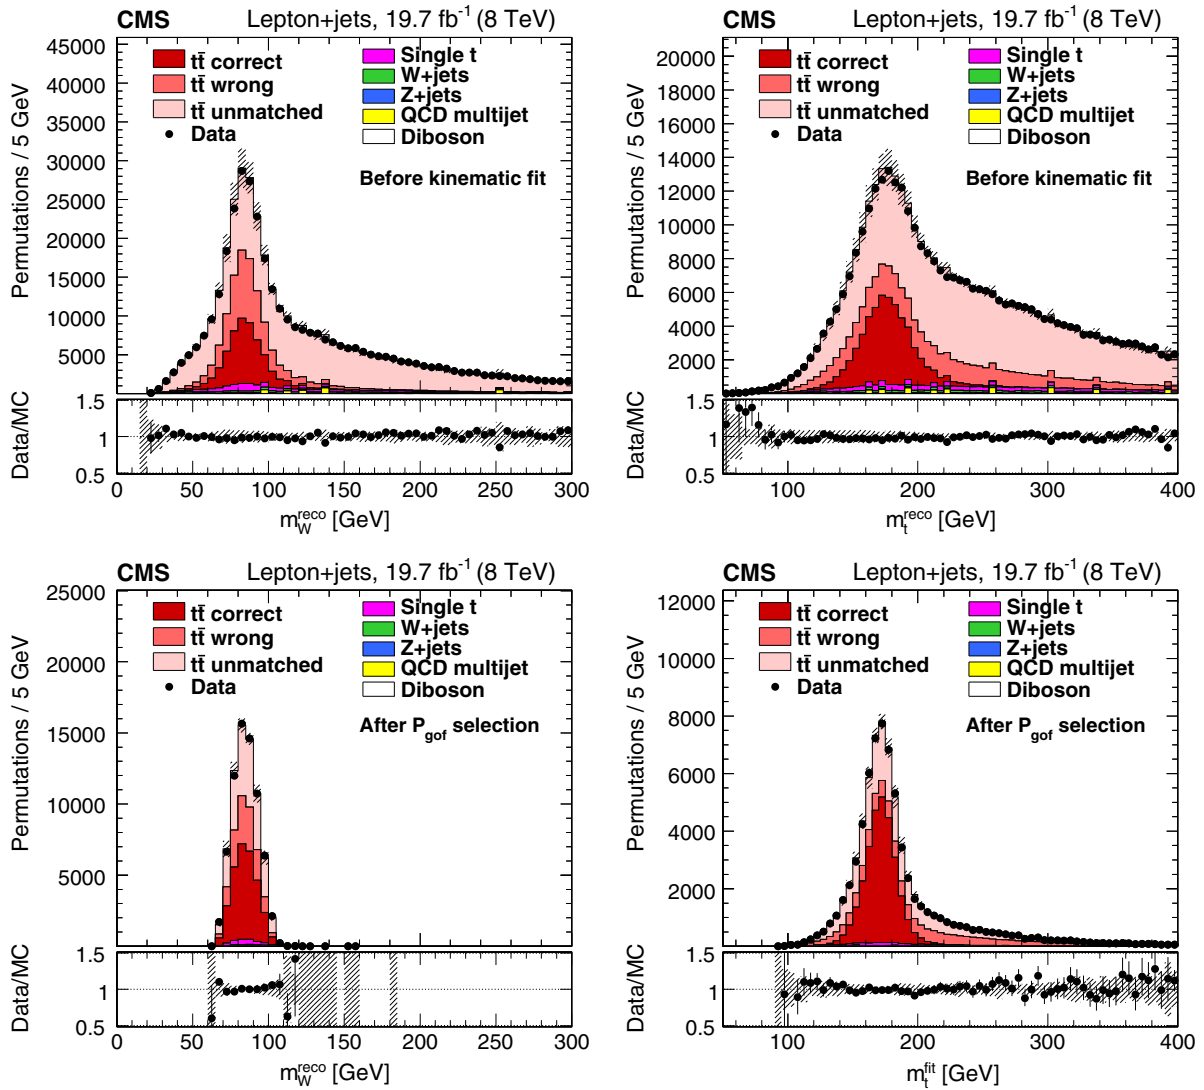

FIG. 3. Reconstructed masses of (upper left) the W bosons decaying to $q\bar{q}$ pairs and (upper right) the corresponding top quarks, prior to the kinematic fitting to the $t\bar{t}$ hypothesis. Panels (lower left) and (lower right) show, respectively, the reconstructed W boson masses and the fitted top quark masses after the goodness-of-fit selection. The total number of permutations found in simulation is normalized to be the same as the total number of permutations observed in data. The vertical bars show the statistical uncertainty and the hatched bands show the statistical and systematic uncertainties added in quadrature. The lower portion of each panel shown the ratio of the yields between the collision data and the simulation.

uncertainty arising from both components of the measurement. The uncertainty of the measurement agrees with the expected precision obtained by performing pseudoexperiments.

The results in the individual muon and electron channels are compatible within their statistical uncertainties:

$$\begin{aligned} \mu + \text{jets: } m_t^{2D} &= 172.03 \pm 0.27(\text{stat} + \text{JSF}) \text{ GeV,} \\ \text{JSF}^{2D} &= 1.007 \pm 0.003(\text{stat}), \\ e + \text{jets: } m_t^{2D} &= 172.26 \pm 0.28(\text{stat} + \text{JSF}) \text{ GeV,} \\ \text{JSF}^{2D} &= 1.003 \pm 0.003(\text{stat}). \end{aligned}$$

The 1D and hybrid analyses give results of

$$\begin{aligned} m_t^{1D} &= 172.56 \pm 0.12(\text{stat}) \text{ GeV,} \\ m_t^{\text{hyb}} &= 172.35 \pm 0.16(\text{stat} + \text{JSF}) \text{ GeV,} \\ \text{JSF}^{\text{hyb}} &= 1.002 \pm 0.001(\text{stat}), \end{aligned}$$

respectively. Both the 2D and hybrid results for the JSF (JSF^{2D} and JSF^{hyb}) are within 0.5% of one. The results for m_t and the JSF are compared in Fig. 4, which shows the two-dimensional statistical likelihoods obtained from data in the 2D and hybrid cases and m_t from the 1D analysis.

FIG. 4. The two-dimensional likelihood ($-2\Delta \log(\mathcal{L})$) for the lepton + jets channel for the 2D, hybrid, and 1D fits. The thick (thin) ellipses correspond to contours of $-2\Delta \log(\mathcal{L}) = 1(4)$ allowing the construction of the one (two) σ statistical intervals of m_t . For the 1D fit, the thick and thin lines correspond to the one and two σ statistical uncertainties, respectively.

B. The all-jets channel

As in the lepton + jets channel, a kinematic fit [47] is used to improve the resolution of the reconstructed quantities and to check the compatibility of an event with the $t\bar{t}$ hypothesis. For each event, the inputs to the fit are the four-momenta of the six leading jets. The fit constrains these to the hypothesis of the production of two heavy particles of equal masses, each one decaying to a W boson with its invariant mass constrained to 80.4 GeV [41] and a bottom quark. The two b -tagged jets are candidates for the bottom quarks in the $t\bar{t}$ hypothesis, while the four untagged jets serve as candidates for the light quarks of the W boson decays. This leads to six possible parton-jet assignments per event and the assignment that fits best to the $t\bar{t}$ hypothesis based on the χ^2 of the kinematic fit is chosen. As final selection criteria, we require $P_{\text{gof}} > 0.1$ for the kinematic fit with 3 degrees of freedom, and the two b quark jets be separated in η - ϕ space by $\Delta R_{b\bar{b}} > 2.0$. These requirements select 7049 events for the mass measurement in data and the fraction of signal events f_{sig} increases from 14% to 61% based on the simulation.

For simulated $t\bar{t}$ events, the parton-jet assignments are classified as *correct permutations* and *wrong permutations*. The correct permutation class is defined in the same way as for the lepton + jets channel (Sec. VA). The wrong permutations class consists of permutations where at least one quark from the $t\bar{t}$ decay is not unambiguously matched with a distance of $\Delta R < 0.3$ to any of the six selected jets. For correct permutations, which compose 42% of the

selected $t\bar{t}$ events, the kinematic fit improves the resolution of the fitted values of m_t from 13.8 to 7.5 GeV.

The multijet background from QCD is modeled using a control sample that is obtained from data with the same event selection but without the b tagging requirement. While this sample has a small contamination of a few percent coming from signal events, these have no influence on the results for the background model. For each event, the kinematic selection is applied to all possible assignments of the six jets to the six quarks from the $t\bar{t}$ hypothesis. The best fitting assignment is chosen and the event is used to model the background if it fulfills the P_{gof} and $\Delta R_{b\bar{b}}$ criteria. The modeled background is compared to the background predicted by an event mixing technique [48]. Both predictions are found to agree within their uncertainties that are derived from the validation of the methods on simulated multijet events.

Figure 5 compares data to the expectation from simulated $t\bar{t}$ signal and background estimate from the data for m_t^{fit} , m_W^{reco} , P_{gof} , and $\Delta R_{b\bar{b}}$.

The ideogram method is calibrated for each combination of the m_t^{en} and JSF values by conducting 10 000 pseudoexperiments. The average deviations between extracted mass and JSF and their input values are obtained as a function of m_t^{en} and the bias is fit with a linear function for each generated JSF value. From these fits, additional small corrections for calibrating the top quark mass and the jet energy scale are derived as linear functions of both the extracted top quark mass and JSF. The corrections are approximately -0.6 GeV for m_t and $+1.0\%$ for the JSF. The statistical uncertainties of the method are corrected by factors of approximately 1.005 using values derived from the widths of the corresponding pull distributions.

Applying the ideogram method on data with no prior knowledge on the JSF (2D), yields the results:

$$m_t^{2D} = 171.64 \pm 0.32(\text{stat} + \text{JSF}) \text{ GeV},$$

$$\text{JSF}^{2D} = 1.011 \pm 0.003(\text{stat}).$$

As m_t and the JSF are measured simultaneously, the statistical uncertainty in m_t combines the statistical uncertainty arising from both components of the measurement. The two additional free parameters in the fit, the signal fraction f_{sig} and the fraction of correct permutations f_{cp} , are in agreement with the expectation from simulation.

Using the JEC determined from γ/Z + jet events in combination with the JSF prior from the 2D fit yields the results in the 1D and hybrid approaches of

$$m_t^{1D} = 172.46 \pm 0.23(\text{stat}) \text{ GeV},$$

$$m_t^{\text{hyb}} = 172.32 \pm 0.25(\text{stat} + \text{JSF}) \text{ GeV},$$

$$\text{JSF}^{\text{hyb}} = 1.002 \pm 0.001(\text{stat}).$$

For the all-jets channel, the fitted results for the JSF (JSF^{2D} and JSF^{hyb}) are both within 1.1% of one. While the

FIG. 5. Distributions of (upper left) the reconstructed top quark mass from the kinematic fit, (upper right) the average reconstructed W boson mass, (lower left) the goodness-of-fit probability, and (lower right) the separation of the two b quark jets for the all-jets channel. The simulated $t\bar{t}$ signal and the background from the control sample are normalized to data. The value of m_t used in the simulation is 172.5 GeV and the nominal jet energy scale is applied. The vertical bars show the statistical uncertainty and the hatched bands show the statistical and systematic uncertainties added in quadrature. The lower portion of each panel shows the ratio of the yields between the collision data and the simulation.

JSF results from the 2D analyses in the lepton + jets and all-jets channels differ by 0.6%, the results from the hybrid analyses agree to within 0.2%. The all-jets results for m_t and the JSF are compared in Fig. 6 which shows the two-dimensional statistical likelihoods obtained from data in the 2D and hybrid cases and m_t from the 1D analysis.

C. The dilepton channel

Figure 7 shows the distribution of m_t^{AMWT} in data compared to a simulation with $m_t = 172.5$ GeV for events containing at least one b jet. This channel is very clean with a negligible background from non- $t\bar{t}$ sources and the collision and simulated events are in good agreement.

AMWT masses are computed for all events in both the data and the simulations. The m_t^{AMWT} distributions computed for each of the seven simulated $t\bar{t}$ mass samples are added to the distributions from the background samples, and these are treated as templates in a binned likelihood fit. To minimize the effects of any bias from the poorly populated tails of the distribution, we only examine events with m_t^{AMWT} between 100 and 400 GeV. For each of the seven mass templates, a maximum likelihood fit is performed to the data distribution. A parabola is fit to the negative logarithms of the maximum likelihoods returned by the fits, and the minimum of the parabola is taken as the measured mass value.

FIG. 6. The two-dimensional likelihood $[-2\Delta \log(\mathcal{L})]$ for the all-jets channel for the 2D, hybrid, and 1D fits. The thick (thin) ellipses correspond to contours of $-2\Delta \log(\mathcal{L}) = 1(4)$ allowing the construction of the one (two) σ statistical intervals of m_t . For the 1D fit, the thick and thin lines correspond to the one and two σ statistical uncertainties, respectively.

FIG. 7. Distribution of m_t^{AMWT} for the collision and simulated data with $m_t = 172.5$ GeV. The vertical bars show the statistical uncertainty and the hatched bands show the statistical and systematic uncertainties added in quadrature. The lower section of the plot shows the ratio of the yields between the collision data and the simulation.

FIG. 8. Plot of the negative log likelihood for data for the dilepton analysis. The continuous line represents a parabolic fit to the points.

The fit is calibrated to correct for any biases induced by the reconstruction using pseudodata. The calibration is performed by means of a test using the simulated templates for the top quark masses between 169.5 and 175.5 GeV. We randomly draw 1000 samples of events, each selected such that the total number of events is the same as in the full data sample. For each template, the 1000 measured masses are averaged together and subtracted from the input mass to obtain a numerical value for the bias induced by the fit. The bias is then parametrized as a linear dependence on the generated value of m_t , and the resulting calibration curve is used to correct for biases in the final result.

The likelihoods obtained from a fit of each of the seven simulated templates to data, as well as a second-order polynomial fit to these values, are shown in Fig. 8. This yields an uncalibrated measured mass of $m_t = 172.77 \pm 0.19(\text{stat})$ GeV. After correcting for the fit bias, the result for the top quark mass is found to be $m_t = 172.82 \pm 0.19(\text{stat})$ GeV.

The analysis was optimized with the value of m_t blinded. The optimization of the event selection was done by minimizing the total expected (statistical + systematic) uncertainty. This resulted in the restriction of the analysis to events containing only two b jets, rather than the requirement of at least one b jet which was used initially.

VI. SYSTEMATIC UNCERTAINTIES

The systematic uncertainties affecting each of the measurements can be grouped into four distinct categories: one experimental category and three theoretical categories that describe the modeling uncertainties. The experimental

classification covers the uncertainties that arise from the precision of the calibration and resolution of the CMS detector and the effects coming from the backgrounds and pileup. The other three categories cover the modeling of the hard scattering process and the associated radiation; non-perturbative QCD effects, such as the simulation of the underlying event and color reconnection; and the modeling of the light- and b -quark hadronization. Each of these is broken down into subcategories leading to a total of 24 distinct systematic uncertainties. In each case the uncertainty is evaluated in terms of the largest shift that is observed in the value of m_t that occurs when the parameter is varied by $\pm 1\sigma$, where σ is the uncertainty assigned to that quantity. The only exception to this is if the statistical uncertainty in the observed shift is larger than the value of the calculated shift. In this case the statistical uncertainty is taken as the best estimate of the uncertainty in the parameter.

A. Experimental effects

- (i) Intercalibration jet energy correction: This is the part of the JES uncertainty originating from modeling of the radiation in the relative (p_T —and η -dependent) intercalibration procedure.
- (ii) *In situ* jet energy calibration: This is the part of the JES uncertainty coming from the uncertainties affecting the absolute JES determination using $\gamma/Z + \text{jets}$ events.
- (iii) Uncorrelated jet energy correction: This is the uncertainty source coming from the statistical uncertainty in the *in situ* jet energy calibration, the contributions stemming from the jet energy correction due to pileup effects, the uncertainties due to the variations in the calorimeter response versus time, and some detector specific effects. To give a clear indication of the contribution to the JES uncertainty coming from pileup, we have subdivided this uncertainty into nonpileup and pileup contributions.
- (iv) Lepton energy scale (LES): Analogous to the JES, the energy scale of the leptons may also induce a systematic bias. A typical variation of 0.6% is taken for electrons in the barrel region and 1.5% in the detector endcaps. For the muons, the uncertainty is negligible.
- (v) E_T^{miss} scale: Measurement of the E_T^{miss} is affected by the variation in LES and JES and by the uncertainty in scale of the unclustered energy. The unclustered energy scale is varied independently of LES and JES to obtain the E_T^{miss} uncertainty.
- (vi) Jet energy resolution: The systematic uncertainty associated with the JER in the simulation is determined by increasing or decreasing the JER by 1σ .
- (vii) b tagging: The uncertainty in the b tagging efficiency and misidentification probability of non- b jets may lead to varying background and signal

levels. This uncertainty is estimated by varying the b tagging discriminator requirements in simulations. In the lepton + jets analysis, for example, the changes in the CSVM discriminator leads to an uncertainty in the b tagging efficiency of 1.2% and the false tagging rate of 15%, both of which correspond to a 1σ variation in the value of the b tagging scale factor. The all-jets and dilepton uncertainties are computed in a similar manner for the CSVT and CSVL discriminators, respectively. Propagating the tagging efficiency uncertainty to the values of m_t leads to the systematic uncertainty.

- (viii) Trigger: This systematic uncertainty captures the uncertainties related to the modeling of the trigger efficiency, and is only significant for the all-jets measurement.
- (ix) Pileup: During the data taking period, the instantaneous luminosity increased dramatically during the year, leading to an increased number of simultaneous proton-proton interactions overlapping with the primary hard scattering (in-time pileup) and possible effects due to the detector response to previous collision events (out-of-time pileup). These effects are evaluated by using pseudoexperiments in which the average number of pileup events was varied by $\pm 5\%$.
- (x) Backgrounds: The background contamination expected from simulation is $< 5\%$ in the lepton + jets and dilepton channels. The effect of the background modeling on m_t is estimated by varying the shape and normalization for each background within their uncertainty. Uncertainties from simulated backgrounds are taken to be correlated across all the measurements. The only channel for which there is a significant non- $t\bar{t}$ background in the final fit sample is the all-jets channel. For this, the shape of the QCD multijet background is estimated from a control sample in the data. The method is validated using simulated QCD multijet events and with an alternative approach using event mixing in the data. The predicted background shapes are varied to cover the residual differences found in the validation. The uncertainties from the background estimation from control samples in the data are assumed to be uncorrelated.
- (xi) Fit calibration: For the calibration of the fits, the simulated samples are statistically limited. The uncertainty quoted is the statistical uncertainty in the residual bias in the fit calibration.

B. Theoretical and modeling uncertainties

1. Hard scattering and radiation

- (i) Parton distribution functions: PDFs are used in modeling the hard scattering in proton-proton

collisions in the simulations. The uncertainties in the PDFs and their effect on the measured value of m_t are studied by reweighting a $t\bar{t}$ sample with different PDF eigenvectors using the PDF4LHC prescription [49]. The reweighted events are used to generate pseudoexperiments and the variation in the fitted mass is quoted as the uncertainty [37].

- (ii) Renormalization and factorization scales: This uncertainty is estimated using the simultaneous

variation of the renormalization and factorization scales by factors of 2 and 0.5 in the matrix element calculation and the initial-state parton shower of the signal and the $W + \text{jets}$ background.

- (iii) ME-PS matching threshold: In the $t\bar{t}$ simulation, the matching thresholds used for interfacing the matrix elements (ME) generated with MADGRAPH to the PYTHIA parton showers (PS) are varied from the default of 40 GeV down to 30 GeV and up to 60 GeV

TABLE I. Category breakdown of the systematic uncertainties for the 2D, 1D, and hybrid measurements in the lepton + jets channel. Each term has been estimated using the procedures described in Sec. VI. The uncertainties are expressed in GeV and the signs are taken from the $+1\sigma$ shift in the value of the quantity. Thus a positive sign indicates an increase in the value of m_t or the JSF and a negative sign indicates a decrease. For uncertainties determined on independent simulated samples the statistical precision of the shift is displayed. With the exception of the flavor-dependent JEC terms (see Sec. VI), the total systematic uncertainty is obtained from the sum in quadrature of the individual systematic uncertainties.

and the uncertainty is taken as the maximal difference in m_t induced by this variation.

- (iv) ME generator: The sensitivity to the parton-level modeling is estimated by comparing the reference samples (MADGRAPH and PYTHIA) to samples produced using POWHEG and PYTHIA. The difference between the values of m_t obtained with the two samples is taken as the uncertainty.

- (v) Top quark p_T uncertainty: This term represents the uncertainty coming from the modeling of the top quark p_T distribution in the ME generator. The uncertainty is estimated by taking the difference in shape between the parton level p_T spectrum from the ME generator and the unfolded p_T spectrum determined from the data [39]. The uncertainty is considered fully correlated across the measurements.

2. Nonperturbative QCD

- (i) Underlying event: This represents the uncertainty in modeling the soft underlying hadronic activity in the event, which affects the simulation of both signal and background. The uncertainty is estimated by comparing PYTHIA tunes with increased and decreased underlying event activity relative to a central tune. For this we compare the results for the Perugia 2011 tune to the results obtained using the Perugia 2011 mpiHi and the Perugia 2011 Tevatron tunes [50].
- (ii) Color reconnection: The effects of possible mis-modeling of color reconnection are estimated by comparing the mass calculated using underlying event tunes with and without the inclusion of these effects. For these simulations the Perugia 2011 and Perugia 2011 no CR tunes are used [50]. The uncertainty is taken as the difference between the two computed values of m_t .

3. Hadronization

- (i) Flavor-dependent hadronization uncertainty: This is the part of the JES uncertainty that comes from differences in the energy response for different jet flavors and flavor mixtures with respect to those used in the calibration procedures. Four uncertainties are quoted that correspond to the uncertainties for light quarks (u , d , s), charm quarks, bottom quarks and gluons. These are evaluated by comparing Lund string fragmentation (PYTHIA 6 [16]) and cluster fragmentation (HERWIG++ [51]) for each category of jets. The models in PYTHIA and HERWIG allow for the differences between the jet types, and the uncertainty is determined by varying the jet energies within their respective flavor-dependent uncertainties. The full flavor-dependent uncertainty is obtained by taking a signed linear sum of these four contributions. For this we perform $\pm 1\sigma$ shifts for each of the contributions and compute the total uncertainty from the sum of the $+1\sigma$ and -1σ shifts separately. As these are symmetric, we quote the $+1\sigma$ shifts for the values of the uncertainties in Tables I–III.
- (ii) b quark fragmentation and b hadron branching fraction uncertainties: This term provides a description of the residual uncertainties not covered by the flavor-dependent hadronization term. It has two components: the uncertainty in the modeling of the b quark fragmentation function and the uncertainty from the measured b hadron semileptonic branching fractions. The b quark fragmentation function in PYTHIA is modeled using a Bowler-Lund model for the fragmentation into b hadrons. The fragmentation uncertainty is determined from the difference between a version tuned to ALEPH [52]

TABLE III. Category breakdown of the systematic uncertainties for the AMWT measurement in the dilepton channel. Each term has been estimated using the procedures described in Sec. VI. The uncertainties are expressed in GeV and the signs are taken from the $+1\sigma$ shift in the value of the quantity. Thus a positive sign indicates an increase in the value of m_t and a negative sign indicates a decrease. For uncertainties determined on independent simulated samples the statistical precision of the shift is displayed. With the exception of the flavor-dependent JEC terms (see Sec. VI), the total systematic uncertainty is obtained from the sum in quadrature of the individual systematic uncertainties.

and DELPHI [53] data and the PYTHIA Z2* tune. Lastly, the uncertainty from the semileptonic b hadron branching fraction is obtained by varying by -0.45% and $+0.77\%$, which is the range of the measurements from B^0/B^+ decays and their uncertainties [41].

VII. INDIVIDUAL CHANNEL RESULTS

A. The lepton + jets channel

After estimating the systematic uncertainties for the lepton + jets channel, the measurement of m_t and the JSF from the 2D analysis gives

$$m_t^{2D} = 172.14 \pm 0.19(\text{stat} + \text{JSF}) \pm 0.59(\text{syst}) \text{ GeV},$$

$$\text{JSF}^{2D} = 1.005 \pm 0.002(\text{stat}) \pm 0.007(\text{syst}).$$

The overall uncertainty in m_t is 0.62 GeV and the measured JSF is compatible with the one obtained from events with Z bosons and photons [37] within the systematic uncertainties.

The measurements from the 1D and hybrid analyses are

$$m_t^{1D} = 172.56 \pm 0.12(\text{stat}) \pm 0.62(\text{syst}) \text{ GeV},$$

$$m_t^{\text{hyb}} = 172.35 \pm 0.16(\text{stat} + \text{JSF}) \pm 0.48(\text{syst}) \text{ GeV}.$$

Thus the hybrid approach delivers the most precise measurement of the methods studied for the lepton + jets channel with a total uncertainty of 0.51 GeV.

The breakdown of the systematic uncertainties for the three fits is shown in Table I. In the lepton + jets and all-jets measurements several uncertainty sources yield opposite signs in the 1D and 2D approaches. This arises because the untagged jets used for m_W^{reco} have a softer p_T spectrum and larger gluon contamination compared to the b jets. As a consequence, the measurement of the JSF in the 2D measurement is more sensitive to low- p_T effects and radiation uncertainties than the 1D measurement where the light-jet energies are bound to fulfill the W mass constraint. The net effect, when using a flat JSF, is that the uncertainties can be overcorrected in the 2D fit and thus their signs reverse. The hybrid fit makes optimal use of the available information and leads to partial cancelation of these uncertainties, resulting in the observed improvement of the precision of the mass measurement.

B. The all-jets channel

The 2D analysis in the all-jets channel yields a measurement of

$$m_t^{2D} = 171.64 \pm 0.32(\text{stat} + \text{JSF}) \pm 0.95(\text{syst}) \text{ GeV},$$

$$\text{JSF}^{2D} = 1.011 \pm 0.003(\text{stat}) \pm 0.011(\text{syst}),$$

giving an overall uncertainty in the mass of 1.00 GeV.

The measurements from the 1D and hybrid analyses are

$$m_t^{1D} = 172.46 \pm 0.23(\text{stat}) \pm 0.62(\text{syst}) \text{ GeV},$$

$$m_t^{\text{hyb}} = 172.32 \pm 0.25(\text{stat} + \text{JSF}) \pm 0.59(\text{syst}) \text{ GeV},$$

with overall uncertainties of 0.66 and 0.64 GeV for the 1D and hybrid fits, respectively.

The breakdown of the systematic uncertainties for the three fits is shown in Table II.

C. The dilepton channel

For the dilepton channel the systematic uncertainties are defined as the difference between measurements of m_t from pseudodata events, selected at random from the MC events in the $m_t = 172.5$ GeV template. For each category of systematic uncertainty, modified templates were produced with a given systematic variable shifted, generically by $\pm 1\sigma$. The fit is repeated using the modified pseudodata and the respective mean is subtracted from the mean of the default $t\bar{t}$ MC simulation to calculate the final systematic uncertainty for each category. This yields a final mass measurement of

$$m_t = 172.82 \pm 0.19(\text{stat}) \pm 1.22(\text{syst}) \text{ GeV}.$$

The breakdown of the systematic uncertainty for the dilepton mass measurement is shown in Table III. In comparison with the lepton + jets (Table I) and the all-jets (Table II) channels, the systematic uncertainties are similar in size with the exception of the factorization and renormalization, and b fragmentation terms, both of which are significantly larger. Studies of these indicate that this is probably the result of an increased boost of the visible decay products, coupled to the weak constraint of the E_T^{miss} on the energies of the two neutrinos.

D. The 2010 and 2011 measurements

The published CMS measurements are based on $\sqrt{s} = 7$ TeV data recorded during 2010 and 2011. Although much less precise than the new measurements, they come

TABLE IV. CMS measurements of the top quark mass using the data recorded at $\sqrt{s} = 7$ TeV.

Analysis	Reference	m_t (GeV)	Statistical uncertainty (GeV)	Systematic uncertainty (GeV)
2010 dilepton (AMWT)	[54]	175.50	4.60	4.52
2011 lepton + jets (2D)	[55]	173.49	0.27	1.03
2011 all-jets (1D)	[48]	173.49	0.69	1.23
2011 dilepton (AMWT)	[43]	172.50	0.43	1.46

from independent data sets and have different sensitivities to the various systematic uncertainties. These are included in the combined mass analysis, which is discussed in Sec. IX. For completeness we summarize these measurements in Table IV below. The analysis techniques used for each of these are very similar to those used for the 2012 analyses. The dilepton results both use the AMWT method, which is described in Sec. IV B, and the lepton + jets (all-jets) result comes from the 2D (1D) ideogram technique, which is described in Sec. IV A.

VIII. MEASURED TOP QUARK MASS AS A FUNCTION OF KINEMATIC OBSERVABLES

To search for possible biases in our measurements and the potential limitations of current event generators, a series of differential measurements of m_t as a function of the kinematic properties of the $t\bar{t}$ system is performed. To maximize the accuracy of the results, the study is performed in the lepton + jets channel using the hybrid fit technique. The variables are chosen to probe potential effects from color reconnection, initial- and final-state

FIG. 9. Measurements of m_t as a function of the transverse momentum of the hadronically decaying top quark ($p_T^{t, \text{had}}$), the invariant mass of the $t\bar{t}$ system ($m_{t\bar{t}}$), the transverse momentum of the $t\bar{t}$ system ($p_T^{t\bar{t}}$), and the number of jets with $p_T > 30$ GeV. The filled circles represent the data, and the other symbols are for the simulations. For reasons of clarity the horizontal error bars are shown only for the data points and each of the simulations is shown as a single offset point with a vertical error bar representing its statistical uncertainty. The statistical uncertainty of the data is displayed by the inner error bars. For the outer error bars, the systematic uncertainties are added in quadrature. The open circles correspond to MADGRAPH with the PYTHIA Z2* tune, the open squares correspond to MADGRAPH with the PYTHIA Perugia 2011 tune, and the open triangles represent MADGRAPH with the PYTHIA Perugia 2011 noCR tune. The open diamonds correspond to POWHEG with the PYTHIA Z2* tune and the open crosses correspond to POWHEG with HERWIG 6. The filled stars are for MC@NLO with HERWIG 6 and the open stars are for SHERPA.

radiation, and the kinematics of the jets coming from the top quark decays.

For each measurement, the hybrid analysis method is applied to subsets of events defined according to the value of a given kinematic event observable after the kinematic fit. The contribution of the external JSF constraint is fixed to 50% to ensure consistency of all bins with the inclusive result. Constant shifts in the measured m_t values may arise due to the systematic uncertainties of the inclusive measurement or from the use of different m_t values in data and

simulations. To search for kinematics-dependent biases the value of the mean measured top quark mass is subtracted and the results are expressed in the form $m_t - \langle m_t \rangle$, where the mean comes from the inclusive measurement on the specific sample. In each case, the event sample is divided into 3 to 5 bins as a function of the value of the kinematic observable and we populate each bin using all permutations which lie within the bin boundaries. As some observables depend on the jet-quark assignment that cannot be resolved unambiguously, such as the p_T of a reconstructed top

FIG. 10. Measurements of m_t as a function of the p_T of the b jet assigned to the hadronic decay branch ($p_T^{b, had}$), the pseudorapidity of the b jet assigned to the hadronic decay branch ($|\eta^{b, had}|$), the ΔR between the b jets (ΔR_{bb}), and the ΔR between the light-quark jets ($\Delta R_{q\bar{q}}$). The filled circles represent the data, and the other symbols are for the simulations. For reasons of clarity the horizontal error bars are shown only for the data points and each of the simulations is shown as a single offset point with a vertical error bar representing its statistical uncertainty. The statistical uncertainty of the data is displayed by the inner error bars. For the outer error bars, the systematic uncertainties are added in quadrature. The open circles correspond to MADGRAPH with the PYTHIA Z2* tune, the open squares to MADGRAPH with the PYTHIA Perugia 2011 tune, and the open triangles represent MADGRAPH with the PYTHIA Perugia 2011 noCR tune. The open diamonds correspond to POWHEG with the PYTHIA Z2* tune and the open crosses correspond to POWHEG with HERWIG 6. The filled stars are for MC@NLO with HERWIG 6 and the open stars are for SHERPA.

quark, a single event is allowed to contribute to multiple bins.

To aid in the interpretation of a difference between the value of $m_t - \langle m_t \rangle$ and the prediction from a simulation in the same bin, a bin-by-bin calibration of the results is performed using the MADGRAPH+PYTHIA simulation. This is performed using the same technique as for the inclusive measurement [55] except that it is performed on each bin separately. Thus, after calibration the value in each bin can be interpreted in terms of its agreement with respect to the inclusive measurement.

For eight kinematic variables the results for the calibrated mass difference, $m_t - \langle m_t \rangle$, are shown as a function of the chosen variable, and we compare the results to the predictions of seven different simulations. For each plotted point the statistical uncertainty and the dominant systematic uncertainties are combined in quadrature, where the latter include the JES (p_T -, η - and flavor-dependent), JER, pileup, b fragmentation, renormalization and factorization scales, and ME-PS matching threshold. The systematic uncertainties are assumed to be correlated among all bins, so that any constant shift is removed by subtracting $\langle m_t \rangle$. We note that this approximation may underestimate the uncertainties from the p_T/η -dependent JES.

For each plot we compare the data to simulations based on LO (MADGRAPH and SHERPA) and NLO (POWHEG and MC@NLO) matrix element calculations with both string (PYTHIA) and cluster (HERWIG) models for fragmentation. We also vary the choice of underlying event tune from Z2* to Perugia 2011 both with and without color reconnections, and the AUET2 tune. With the exception of the MC@NLO and SHERPA simulations, which are only used for this study, these are the same simulation as those discussed in Sec. III A. The simulations used for this study are

- (i) MADGRAPH with the PYTHIA Z2* tune, which is the simulation used in the mass determinations [14–16,56];
- (ii) MADGRAPH with the PYTHIA Perugia 2011 tune [14,16,50];
- (iii) MADGRAPH with the PYTHIA Perugia 2011 noCR tune [14,16,50];
- (iv) SHERPA 1.4.0 with up to 4 additional jets from the LO matrix element [57,58];
- (v) POWHEG with the PYTHIA Z2* tune [16,21–25,56];
- (vi) POWHEG with the HERWIG 6.520 AUET2 tune [21–25,59];
- (vii) MC@NLO 3.41 with the HERWIG 6.520 default tune [59–61].

The variables were chosen for their potential sensitivity to modeling the kinematics of top quark production (Fig. 9) and decay (Fig. 10). No significant deviation in the value of the measured m_t is observed, indicating that within the current precision, there is no evidence for a bias in the measurements. The agreement between the data and each of the simulations is quantified in Table V. Here we show

TABLE V. Comparison of different simulations and the data. The summed χ^2 values and number of standard deviations are computed for the 27 points entering Figs. 9 and 10 assuming two-sided Gaussian statistics.

Simulation	χ^2	Standard deviations
MG + PYTHIA 6 Z2*	17.55	0.10
MG + PYTHIA 6 P11	37.68	1.73
MG + PYTHIA 6 P11noCR	31.57	1.15
POWHEG + PYTHIA 6 Z2*	19.70	0.20
POWHEG + HERWIG 6	76.48	4.84
MC@NLO + HERWIG 6	20.47	0.24
SHERPA	46.79	2.56

the cumulative χ^2 for the 27 degrees of freedom represented by the eight distributions studied (Figs. 9 and 10) and the corresponding number of standard deviations between the data and the simulation, where we have assumed two-sided Gaussian confidence intervals for each simulation. In all cases, with the possible exception of POWHEG+HERWIG 6 simulation, the data is well described by the models.

IX. COMBINING THE MASS MEASUREMENTS

In this section, results for the combined top quark mass measurement are presented. As inputs we use the new results presented in this paper and the published CMS measurements from the 2010 [54] and 2011 [43,48,55] analyses. To combine the results, the best linear unbiased estimate method (BLUE) [62] is used. This determines a linear combination of the input measurements which takes into account statistical and systematic uncertainties by minimizing the total uncertainty of the combined result. The procedure takes account of the correlations that exist between the different uncertainty sources through the use of correlation coefficients. These are chosen to reflect the current knowledge of the uncertainties for both the correlations between measurements in a given decay channel from different years (ρ_{chan}) and between the measurements in different decay channels from the same year (ρ_{year}). The nominal values are set to either zero for uncorrelated or unity for fully correlated (see Table VI). Because the measurements from the 2012 analyses are significantly more precise, both statistically and systematically, than those from the 2010 and 2011 analyses, the use of unity coefficients for ρ_{chan} and ρ_{year} is problematic. To mitigate this, we have chosen to perform combinations in which the correlation coefficients are limited to value of less than unity. This has been done by setting the correlation coefficients for each pair of measurements in the fully correlated cases to $\rho = \sigma_i/\sigma_j$, where σ_i and σ_j are the uncorrelated components of the uncertainties in measurements i and j , respectively, and $\sigma_i < \sigma_j$. For all of the measurements, the statistical uncertainties are assumed to be uncorrelated.

TABLE VI. Nominal correlation coefficients for the systematic uncertainties, The term ρ_{chan} is the correlation factor for measurements in the same top quark decay channel, but different years and the term ρ_{year} is the correlation between measurements in different channels from the same year.

A. Measurement permutations

The precision of any combination of the measurements will be dominated by the set of new measurements, derived from the 2012 data. To investigate the effect of

TABLE VII. Combination results for the permutations of the 2D, 1D, and hybrid measurements. The permutation order is defined to be lepton + jets:all-jets:dilepton, thus 211 corresponds to the 2D lepton + jets:1D all-jets:AMWT dilepton combination.

Combination	m_t (GeV)	Stat + JSF uncertainty (GeV)	Syst uncertainty (GeV)
211	172.40	0.13	0.54
121	172.61	0.11	0.57
221	172.30	0.15	0.58
111	172.66	0.12	0.56

hh1	172.44	0.13	0.47
2h1	172.35	0.14	0.53

the choice of fit method on the result, we perform a series of combinations in which the 2012 inputs from the lepton + jets and all-jets decay channels are varied. For simplicity of discussion, these are classified according to the type of fit used for each channel. They are labeled as follows: 2 for a 2D fit, 1 for a 1D or AMWT fit, and h for a

FIG. 11. Systematic uncertainty correlations for mass measurements in the lepton + jets and all-jets channels. Each point represents a single systematic uncertainty taken from Tables I and II. Top: for the 2D lepton + jets and 1D all-jets measurements; bottom: for the hybrid lepton + jets and the 1D all-jets measurements. The filled circles correspond to the systematic uncertainties which show a positive correlation between the two fit methods and the open circles to the systematic terms which show a negative correlation. The points shown as filled squares are those for which the systematic estimation is dominated by a statistical uncertainty, so no clear categorization is possible. The vertical and horizontal error bars correspond to the statistical uncertainties in the systematic uncertainties.

FIG. 12. Summary of the CMS m_t measurements and their combination. The thick error bars show the statistical uncertainty and the thin error bars show the total uncertainty. Also shown are the current Tevatron [8] and world average [7] combinations.

hybrid fit. Thus a lepton + jets:all-jets:dilepton fit is denoted 211 in the case of a 2D fit for the lepton + jets channel a 1D fit for the all-jets channel and the AMWT fit in the dilepton channel.

The most precise set of nonhybrid measurements corresponds to the set 211, which gives a result of

$$m_t = 172.40 \pm 0.13(\text{stat} + \text{JSF}) \\ \pm 0.54(\text{syst}) \text{ GeV (211 combination).}$$

To verify that this gives the most precise combination, combinations are performed using the other permutations of the 2012 measurements. The results, listed in Table VII,

are in good agreement with the 211 result but have less precision, as expected.

For the hybrid results, the effect of constraining the JSF factor in the mass fits can be examined. There are three significant new permutations to consider, the h11, hh1, and 2h1 combinations. The results, shown in Table VII, are in good agreement with the 211 result, with the h11 and hh1 combinations giving the most precise measurements, as expected. For these the results are

$$m_t = 172.45 \pm 0.13(\text{stat} + \text{JSF}) \\ \pm 0.47(\text{syst}) \text{ GeV (h11 combination),}$$

$$m_t = 172.44 \pm 0.13(\text{stat} + \text{JSF}) \\ \pm 0.47(\text{syst}) \text{ GeV (hh1 combination),}$$

both with an overall improvement in precision of 0.07 GeV with respect to the 211 analysis, and a total uncertainty of 0.48 GeV.

B. Anticorrelation effects

For the results presented here, the signs of most of the uncertainty contributions are well defined (i.e. for a 1σ shift in a given quantity, the statistical component of the estimated systematic uncertainty is significantly smaller than the value of the uncertainty). This allows a comparison of the signs of the systematic uncertainties for the different channels and for the different fitting techniques. An anticorrelation (i.e. opposite signs) is observed between several of the terms when comparing the results from a 2D and a 1D (or AMWT) fit. However, if the 2D fit is replaced by the corresponding hybrid result, the anticorrelations are removed. This is illustrated in Fig. 11, which shows the uncertainty correlations between the lepton + jets and all-jets channels for the 2D vs 1D and the hybrid vs 1D cases. In the 2D vs 1D plot (Fig. 11 left) we observe a significant number of anticorrelated terms (coming primarily from the JES and pileup terms), whereas in the hybrid vs 1D plot (Fig. 11 right) we see no significant anticorrelations. Given the uncertainty terms that vary between the 2D and hybrid treatments, it is believed that the observed effect arises from

TABLE VIII. Correlations between input measurements. The elements in the table are labeled according to the analysis they correspond to (rows and columns read as 2010, 2011, 2012 followed by the $t\bar{t}$ decay channel name).

		2010		2011		2012		
		dilepton	dilepton	lepton + jets	all-jets	dilepton	lepton + jets	all-jets
2010	dilepton	1.00						
	dilepton	0.15	1.00					
2011	lepton + jets	0.09	0.37	1.00				
	all-jets	0.10	0.62	0.31	1.00			
	dilepton	0.09	0.26	0.17	0.17	1.00		
2012	lepton + jets	0.05	0.21	0.30	0.26	0.26	1.00	
	all-jets	0.06	0.20	0.27	0.28	0.32	0.61	1.00

the variation in the JSF factors between the 2D, 1D, and hybrid results (Secs. VA and VB).

These effects are not considered in the standard 211 combination as the input correlation coefficients are positive for all of the correlated cases (see Table VI). To estimate the effect of including anticorrelations, the correlation coefficients are set to negative values for the cases where an anticorrelation (opposite sign) is observed and positive values where a positive (same sign) or neutral (statistically limited) correlation is observed and the 211 combination analysis is repeated. This gives a result of $172.40 \pm 0.13(\text{stat} + \text{JSF}) \pm 0.47(\text{syst})$ GeV. Thus, while the result for the mass is unchanged, the systematic uncertainty is decreased and becomes comparable to that achieved in the hybrid combinations.

X. RESULTS

Based on the expected uncertainties for each of the individual measurements (Tables I–III) and the consistency of the hybrid and 1D results for the JSF (Secs. VA, VB), the hh1 combination is chosen as the preferred result. Combining the seven input measurements (four from $\sqrt{s} = 7$ TeV and three from this analysis) gives a combined top quark mass measurement of

$$m_t = 172.44 \pm 0.13(\text{stat} + \text{JSF}) \pm 0.47(\text{syst}) \text{ GeV},$$

for which the combination χ^2 is 2.5 for 6 degrees of freedom, corresponding to a probability of 87%. This is compared to the full set of Run 1 measurements in Fig. 12 where the current world average [7] and Tevatron [8] combinations are also shown. The result is consistent with all of the published LHC measurements and is the most precise measurement to date with a precision of 0.3%.

The correlations between each of the measurements is shown in Table VIII. Figure 13 shows the combination coefficients and pulls, where the pull is defined as $(m_{\text{top}}^{\text{comb}} - m_{\text{top}}^{\text{meas}}) / \sqrt{\sigma_{\text{meas}}^2 - \sigma_{\text{comb}}^2}$ where $m_{\text{top}}^{\text{comb}}$ and $m_{\text{top}}^{\text{meas}}$ are the combined and the individual measurements of m_t , respectively, and σ_{comb} and σ_{meas} are the corresponding total uncertainties. The 2010 measurement contributes very little to the overall result. As the treatment of the systematic uncertainty for this analysis is the least sophisticated of the seven measurements, the final combination is repeated to verify that it does not influence the final result. Excluding this measurement produces negligible changes in the values of m_t or its total uncertainty, δm_t . For the combination of the remaining six measurements the χ^2 is 2.3 for 5 degrees of freedom, corresponding to a probability of 80%.

The breakdown of the systematic uncertainties for the combination is shown in Table IX. The dominant uncertainty in the measurement arises from the modeling of the hadronization, with 0.33 GeV coming from the flavor-dependent jet energy corrections and a further 0.14 GeV

FIG. 13. Results of the BLUE combining procedure on the CMS measurements showing (left) the combination coefficients, and (right) the pulls for each contribution.

coming from the b jets. There are a further six terms with uncertainties in the range of 0.11–0.12 GeV. Of these, four are coming from theory and only two, the JEC *in situ* (0.12 GeV) and the JEC uncorrelated nonpileup (0.10 GeV) are experimental. The theoretical uncertainties

are computed using the same models so they should be fully correlated. For the two experimental terms, the strength of the assumed correlations is varied by 50% of their nominal values to check the sensitivity to the assumed correlation strength. In both cases this produces changes of less than 0.01 GeV in m_t and δm_t . We therefore conclude that the result is quite stable against reasonable changes in the assumed correlation strength.

Although we do not believe that the use of 100% correlation strengths is appropriate to use for the correlated systematic uncertainties, for completeness we have rerun the final combination without the constraint on the correlation strengths. In this case we observe shifts of -0.28 GeV in m_t and -0.03 GeV in δm_t . For this combination, four of the seven measurements have negative combination coefficients and the central mass lies outside of the boundaries of the measurements. This corresponds to the result obtained using the standard BLUE method.

Figure 14 shows the mass values obtained from each of the three channels separately. These correspond to

FIG. 14. The combined $\sqrt{s} = 7$ and 8 TeV measurements of m_t for each of the $t\bar{t}$ decay channels.

combinations h2 (2012, 2011) for the lepton + jets channel, h11 (2012, 2011, 2010) for the dilepton channel, and h1 (2012, 2011) for the all-jets channel, respectively. The results are all in good agreement with the combined measurement.

XI. SUMMARY

A new set of measurements of the top quark mass has been presented, based on the data recorded by the CMS experiment at the LHC at $\sqrt{s} = 8$ TeV during 2012, and corresponding to a luminosity of 19.7 fb^{-1} . The top quark mass has been measured in the lepton + jets, all-jets and dilepton decay channels, giving values of $172.35 \pm 0.16(\text{stat}) \pm 0.48(\text{syst}) \text{ GeV}$, $172.32 \pm 0.25(\text{stat}) \pm 0.59(\text{syst}) \text{ GeV}$, and $172.82 \pm 0.19(\text{stat}) \pm 1.22(\text{syst}) \text{ GeV}$, respectively. Individually, these constitute the most precise measurements in each of the decay channels studied. When combined with the published CMS results at $\sqrt{s} = 7$ TeV, a top quark mass measurement of $172.44 \pm 0.13(\text{stat}) \pm 0.47(\text{syst}) \text{ GeV}$ is obtained. This is the most precise measurement of m_t to date, with a total uncertainty of 0.48 GeV, and it supersedes all of the previous CMS measurements of the top quark mass.

The top quark mass has also been studied as a function of the event kinematical properties in the lepton + jets channel. No indications of a kinematical bias in the measurements is observed and the data are consistent with a range of predictions from current theoretical models of $t\bar{t}$ production.

ACKNOWLEDGMENTS

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules/CNRS, and Commissariat à l'Énergie Atomique et aux Énergies Alternatives/CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Scientific Research Foundation, and National Innovation Office, Hungary; the Department of Atomic Energy and the Department of Science and Technology, India; the Institute for Studies in Theoretical Physics and Mathematics, Iran; the Science Foundation, Ireland; the Istituto Nazionale di Fisica Nucleare, Italy; the Ministry of Science, ICT and Future Planning, and National Research Foundation (NRF), Republic of Korea; the Lithuanian Academy of Sciences; the Ministry of Education, and University of Malaya (Malaysia); the Mexican Funding Agencies (CINVESTAV, CONACYT, SEP, and UASLP-FAI); the Ministry of Business, Innovation and

Employment, New Zealand; the Pakistan Atomic Energy Commission; the Ministry of Science and Higher Education and the National Science Centre, Poland; the Fundação para a Ciência e a Tecnologia, Portugal; JINR, Dubna; the Ministry of Education and Science of the Russian Federation, the Federal Agency of Atomic Energy of the Russian Federation, Russian Academy of Sciences, and the Russian Foundation for Basic Research; the Ministry of Education, Science and Technological Development of Serbia; the Secretaría de Estado de Investigación, Desarrollo e Innovación and Programa Consolider-Ingenio 2010, Spain; the Swiss Funding Agencies (ETH Board, ETH Zurich, PSI, SNF, UniZH, Canton Zurich, and SER); the Ministry of Science and Technology, Taipei; the Thailand Center of Excellence in Physics, the Institute for the Promotion of Teaching Science and Technology of Thailand, Special Task Force for Activating Research and the National Science and Technology Development Agency of Thailand; the Scientific and Technical Research Council of Turkey, and Turkish Atomic Energy Authority; the National Academy of Sciences of Ukraine, and State Fund for Fundamental Researches, Ukraine; the Science and Technology Facilities Council, UK; the U.S. Department of Energy, and the U.S. National Science Foundation. Individuals have received support from the Marie-Curie program and the European Research Council and EPLANET (European Union); the Leventis Foundation; the A. P. Sloan Foundation; the Alexander von Humboldt Foundation; the Belgian Federal Science Policy Office; the Fonds pour la Formation à la Recherche dans l'Industrie et dans l'Agriculture (FRIA-Belgium); the Agentschap voor Innovatie door Wetenschap en Technologie (IWT-Belgium); the Ministry of Education, Youth and Sports (MEYS) of the Czech Republic; the Council of Science and Industrial Research, India; the HOMING PLUS program of the Foundation for Polish Science, cofinanced from European Union, Regional Development Fund; the OPUS program of the National Science Center (Poland); the Compagnia di San Paolo (Torino); the Consorzio per la Fisica (Trieste); MIUR project 20108T4XTM (Italy); the Thalís and Aristeia programs cofinanced by EU-ESF and the Greek NSRF; the National Priorities Research Program by Qatar National Research Fund; the Rachadapisek SomWetenschappelijk Onderzopot Fund for Postdoctoral Fellowship, Chulalongkorn University (Thailand); and the Welch Foundation, Contract No. C-1845.

Observation of $t\bar{t}H$ Production

A. M. Sirunyan *et al.**
(CMS Collaboration)

 (Received 8 April 2018; revised manuscript received 1 May 2018; published 4 June 2018)

The observation of Higgs boson production in association with a top quark-antiquark pair is reported, based on a combined analysis of proton-proton collision data at center-of-mass energies of $\sqrt{s} = 7, 8,$ and 13 TeV, corresponding to integrated luminosities of up to $5.1, 19.7,$ and 35.9 fb $^{-1}$, respectively. The data were collected with the CMS detector at the CERN LHC. The results of statistically independent searches for Higgs bosons produced in conjunction with a top quark-antiquark pair and decaying to pairs of W bosons, Z bosons, photons, τ leptons, or bottom quark jets are combined to maximize sensitivity. An excess of events is observed, with a significance of 5.2 standard deviations, over the expectation from the background-only hypothesis. The corresponding expected significance from the standard model for a Higgs boson mass of 125.09 GeV is 4.2 standard deviations. The combined best fit signal strength normalized to the standard model prediction is $1.26^{+0.31}_{-0.26}$.

DOI: [10.1103/PhysRevLett.120.231801](https://doi.org/10.1103/PhysRevLett.120.231801)

Proton-proton (pp) collisions at the CERN LHC, at the center-of-mass (c.m.) energies of $\sqrt{s} = 7, 8,$ and 13 TeV, have allowed direct measurements of the properties of the Higgs boson [1–3]. In particular, the 13 TeV data collected so far by the ATLAS [4] and CMS [5] experiments have led to improved constraints on the couplings of the Higgs boson compared to those performed at the lower energies [6], permitting more precise consistency checks with the predictions of the standard model (SM) of particle physics [7–9]. Nonetheless, not all properties of the Higgs boson have been established, in part because of insufficiently large data sets. The lack of statistical precision can be partially overcome by combining the results of searches in different decay channels of the Higgs boson and at different c.m. energies. Among the properties that are not yet well established is the tree-level coupling of Higgs bosons to top quarks.

In this Letter, we present a combination of searches for the Higgs boson (H) produced in association with a top quark-antiquark pair ($t\bar{t}$), based on data collected with the CMS detector. Results from data collected at $\sqrt{s} = 13$ TeV [10–14] are combined with analogous results from $\sqrt{s} = 7$ and 8 TeV [15]. As a result of this combination, we establish the observation of $t\bar{t}H$ production. This constitutes the first confirmation of the tree-level coupling of the Higgs boson to top quarks.

A top quark decays almost exclusively to a bottom quark and a W boson, with the W boson subsequently decaying either to a quark and an antiquark or to a charged lepton and its associated neutrino. The Higgs boson exhibits a rich spectrum of decay modes that includes the decay to a bottom quark-antiquark pair, a $\tau^+\tau^-$ lepton pair, a photon pair, and combinations of quarks and leptons from the decay of intermediate on- or off-shell W and Z bosons. Thus, $t\bar{t}H$ production gives rise to a wide variety of final-state event topologies, which we consider in our analyses and in the combination of results presented below.

In the SM, the masses of elementary fermions are accounted for by introducing a minimal set of Yukawa interactions, compatible with gauge invariance, between the Higgs and fermion fields. Following the spontaneous breaking of electroweak symmetry [16–21], charged fermions of flavor f couple to H with a strength y_f proportional to the mass m_f of those fermions, namely $y_f = m_f/v$, where $v \approx 246$ GeV is the vacuum expectation value of the Higgs field. Measurements of the Higgs boson decay rates to down-type fermions (τ leptons and bottom quarks) agree with the SM predictions within their uncertainties [22,23]. However, the top quark Yukawa coupling (y_t) cannot be similarly tested from the measurement of a decay rate since on-shell top quarks are too heavy to be produced in Higgs boson decay. Instead, constraints on y_t can be obtained through the measurement of the $pp \rightarrow t\bar{t}H$ production process. Example tree-level Feynman diagrams for this process are shown in Fig. 1. To date, $t\bar{t}H$ production has eluded definite observation, although first evidence has been recently reported by the ATLAS [24] and CMS [10] Collaborations.

The overall agreement observed between the SM predictions and data for the rate of Higgs boson production

FIG. 1. Example tree-level Feynman diagrams for the $pp \rightarrow t\bar{t}H$ production process, with g a gluon, q a quark, t a top quark, and H a Higgs boson. For the present study, we consider Higgs boson decays to a pair of W bosons, Z bosons, photons, τ leptons, or bottom quark jets.

through gluon-gluon fusion and for the $H \rightarrow \gamma\gamma$ decay mode [6] suggests that the Higgs boson coupling to top quarks is SM-like, since the quantum loops in these processes include top quarks. However, non-SM particles in the loops could introduce terms that compensate for, and thus mask, other deviations from the SM. A measurement of the production rate of the tree-level $t\bar{t}H$ process can provide evidence for, or against, such new-physics contributions.

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter, providing a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter, and a brass and scintillator hadron calorimeter, each composed of a barrel and two end cap sections. Forward calorimeters extend the pseudorapidity coverage provided by the barrel and end cap detectors. Muons are detected in gas-ionization chambers embedded in the steel flux-return yoke outside the solenoid. A detailed description of the CMS detector can be found in Ref. [5].

Events of interest are selected using a two-tiered trigger system [25] based on custom hardware processors and a farm of commercial processors running a version of the full reconstruction software optimized for speed. Offline, a particle-flow algorithm [26] is used to reconstruct and identify each particle in an event based on a combination of information from the various CMS subdetectors. Additional identification criteria are employed to improve

purities and define the final samples of candidate electrons, muons, hadronically decaying τ leptons (τ_h) [27,28], and photons. Jets are reconstructed from particle-flow candidates using the anti- k_T clustering algorithm [29] implemented in the FASTJET package [30]. Multivariate algorithms [31,32] are used to identify (tag) jets arising from the hadronization of bottom quarks (b jets) and discriminate against gluon and light flavor quark jets. The algorithms utilize observables related to the long lifetimes of hadrons containing b quarks and the relatively larger particle multiplicity and mass of b jets compared to light flavor quark jets. The τ_h identification is based on the reconstruction of the hadronic τ decay modes $\tau^- \rightarrow h^- \nu_\tau$, $h^- \pi^0 \nu_\tau$, $h^- \pi^0 \pi^0 \nu_\tau$, and $h^- h^+ h^- \nu_\tau$ (plus the charge conjugate reactions), where h^\pm denotes either a charged pion or kaon. More details about the reconstruction procedures are given in Refs. [10–15].

The 13 TeV data employed for the current study were collected in 2016 and correspond to an integrated luminosity of up to 35.9 fb^{-1} [33]. The 7 and 8 TeV data, collected in 2011 and 2012, correspond to integrated luminosities of up to 5.1 and 19.7 fb^{-1} [34], respectively. The 13 TeV analyses are improved relative to the 7 and 8 TeV studies in that they employ triggers with higher efficiencies, contain improvements in the reconstruction and background-rejection methods, and use more precise theory calculations to describe the signal and the background processes. For the 7, 8, and 13 TeV data, the theoretical calculations of Ref. [35] for Higgs boson production cross sections and branching fractions are used to normalize the expected signal yields.

The event samples are divided into exclusive categories depending on the multiplicity and kinematic properties of reconstructed electrons, muons, τ_h candidates, photons, jets, and tagged b jets in an event. Samples of simulated events based on Monte Carlo event generators, with simulation of the detector response based on the GEANT4 [36] suite of programs, are used to evaluate the detector acceptance and optimize the event selection for each category. In the analysis of data, the background is, in general, evaluated from data control regions. When this is not feasible, either because the background process has a very small cross section or a control region depleted of signal events cannot be identified, the background is evaluated from simulation with a systematic uncertainty assigned to account for the known model dependence. Multivariate algorithms [37–41] based on deep neural networks, boosted decision trees, and matrix element calculations are used to reduce backgrounds.

At 13 TeV, we search for $t\bar{t}H$ production in the $H \rightarrow b\bar{b}$ decay mode by selecting events with at least three tagged b jets and with zero leptons [11], one lepton [12], or an opposite-sign lepton pair [12], where “lepton” refers to an electron or muon candidate. A search for $t\bar{t}H$ production in the $H \rightarrow \gamma\gamma$ decay mode is performed in events with two

FIG. 2. Best fit value of the $t\bar{t}H$ signal strength modifier $\mu_{t\bar{t}H}$, with its 1 and 2 standard deviation confidence intervals (σ), for (upper section) the five individual decay channels considered, (middle section) the combined result for 7 + 8 TeV alone and for 13 TeV alone, and (lower section) the overall combined result. The Higgs boson mass is taken to be 125.09 GeV. For the $H \rightarrow ZZ^*$ decay mode, $\mu_{t\bar{t}H}$ is constrained to be positive to prevent the corresponding event yield from becoming negative. The SM expectation is shown as a dashed vertical line.

reconstructed photons in combination with reconstructed electrons or muons, jets, and tagged b jets [13]. The signal yield is extracted from a fit to the diphoton invariant mass spectrum. Events with combinations of jets and tagged b jets and with two same-sign leptons, three leptons, or four leptons are used to search for $t\bar{t}H$ production in the $H \rightarrow \tau^+\tau^-$, WW^* , or ZZ^* decay modes [10,14], where in this case “lepton” refers to an electron, muon, or τ_h candidate (the asterisk denotes an off-shell particle). The searches in the different decay channels are statistically independent from each other. Analogous searches have been performed with the 7 and 8 TeV data [15].

The presence of a $t\bar{t}H$ signal is assessed by performing a simultaneous fit to the data from the different decay modes and also from the different c.m. energies as described below. A detailed description of the statistical methods can be found in Ref. [42]. The test statistic q is defined as the negative of twice the logarithm of the profile likelihood ratio [42]. Systematic uncertainties are incorporated through the use of nuisance parameters treated according to the frequentist paradigm. The ratio between the normalization of the $t\bar{t}H$ production process and its SM expectation [35], defined as the signal strength modifier $\mu_{t\bar{t}H}$, is a freely floating parameter in the fit. The SM expectation is evaluated assuming the combined ATLAS

and CMS value for the mass of the Higgs boson, which is 125.09 GeV [43]. We consider the five Higgs boson decay modes with the largest expected event yields, namely, $H \rightarrow WW^*$, ZZ^* , $\gamma\gamma$, $\tau^+\tau^-$, and $b\bar{b}$. Other Higgs boson decay modes and production processes, including $pp \rightarrow tH + X$ (or $\bar{t}H + X$), with X a light flavor quark or W boson, are treated as backgrounds and normalized using the predicted SM cross sections, subject to the corresponding uncertainties.

The measured values of the five independent signal strength modifiers, corresponding to the five decay channels considered, are shown in the upper section of Fig. 2 along with their 1 and 2 standard deviation confidence intervals obtained in the asymptotic approximation [44]. Numerical values are given in Table I. The individual measurements are seen to be consistent with each other within the uncertainties.

We also perform a combined fit, using a single signal strength modifier $\mu_{t\bar{t}H}$, that simultaneously scales the $t\bar{t}H$ production cross sections of the five decay channels considered, with all Higgs boson branching fractions fixed to their SM values [35]. Besides the five decay modes

TABLE I. Best fit value, with its uncertainty, of the $t\bar{t}H$ signal strength modifier $\mu_{t\bar{t}H}$, for the five individual decay channels considered, the combined result for 7 + 8 TeV alone and for 13 TeV alone, and the overall combined result. The total uncertainties are decomposed into their statistical, experimental systematic, background theory systematic, and signal theory components. The numbers in parentheses are those expected for $\mu_{t\bar{t}H} = 1$.

considered, the signal normalizations for the Higgs boson decay modes to gluons, charm quarks, and $Z\gamma$, which are subleading and cannot be constrained with existing data, are scaled by $\mu_{\tilde{t}\tilde{t}H}$. The results combining the decay modes at 7 + 8 TeV, and separately at 13 TeV, are shown in the middle section of Fig. 2. The overall result, combining all decay modes and all c.m. energies, is shown in the lower section, with numerical values given in Table I. Table I includes a breakdown of the total uncertainties into their statistical and systematic components. The overall result is $\mu_{\tilde{t}\tilde{t}H} = 1.26^{+0.31}_{-0.26}$, which agrees with the SM expectation $\mu_{\tilde{t}\tilde{t}H} = 1$ within 1 standard deviation.

The principal sources of experimental systematic uncertainty in the overall result for $\mu_{\tilde{t}\tilde{t}H}$ stem from the uncertainty in the lepton and b jet identification efficiencies and in the τ_h and jet energy scales. The background theory systematic uncertainty is dominated by modeling uncertainties in $\tilde{t}\tilde{t}$ production in association with a W boson, a Z boson, or a pair of b or c quark jets. The dominant contribution to the signal theory systematic uncertainty arises from the finite accuracy in the SM prediction for the $\tilde{t}\tilde{t}H$ cross section because of missing higher order terms and uncertainties in the proton parton density functions [35].

To highlight the excess of data over the expectation from the background-only hypothesis, we classify each event

FIG. 3. Distribution of events as a function of the decimal logarithm of S/B , where S and B are the expected postfit signal (with $\mu_{\tilde{t}\tilde{t}H} = 1$) and background yields, respectively, in each bin of the distributions considered in this combination. The shaded histogram shows the expected background distribution. The two hatched histograms, each stacked on top of the background histogram, show the signal expectation for the SM ($\mu_{\tilde{t}\tilde{t}H} = 1$) and the observed ($\mu_{\tilde{t}\tilde{t}H} = 1.26$) signal strengths. The lower panel shows the ratios of the expected signal and observed results relative to the expected background.

that enters the combined fit by the ratio S/B , where S and B are the expected postfit signal (with $\mu_{\tilde{t}\tilde{t}H} = 1$) and background yields, respectively, in each bin of the distributions considered in the combination. The distribution of $\log_{10}(S/B)$ is shown in Fig. 3. The main sensitivity at high values of S/B is given by events selected in the $H \rightarrow \gamma\gamma$ analysis with a diphoton mass around 125 GeV and by events selected in the $H \rightarrow \tau^+\tau^-$, $H \rightarrow WW^*$, and $H \rightarrow b\bar{b}$ analyses with high values of the multivariate discriminating variables used for the signal extraction. A broad excess of events in the rightmost bins of this distribution is observed, consistent with the expectation for $\tilde{t}\tilde{t}H$ production with a SM-like cross section.

The value of the test statistic q as a function of $\mu_{\tilde{t}\tilde{t}H}$ is shown in Fig. 4, with $\mu_{\tilde{t}\tilde{t}H}$ based on the combination of decay modes described above for the combined fit. The results are shown for the combination of all decay modes at 7 + 8 TeV and at 13 TeV, separately, and for all decay modes at all c.m. energies. To quantify the significance of the measured $\tilde{t}\tilde{t}H$ yield, we compute the probability of the background-only hypothesis (p value) as the tail integral of the test statistic using the overall combination evaluated at $\mu_{\tilde{t}\tilde{t}H} = 0$ under the asymptotic approximation [45]. This corresponds to a significance of 5.2 standard deviations for a one-tailed Gaussian distribution. The expected significance for a SM Higgs boson with a mass of 125.09 GeV, evaluated through use of an Asimov data set [45], is 4.2 standard deviations.

In summary, we have reported the observation of $\tilde{t}\tilde{t}H$ production with a significance of 5.2 standard deviations

FIG. 4. Test statistic q , described in the text, as a function of $\mu_{\tilde{t}\tilde{t}H}$ for all decay modes at 7 + 8 TeV and at 13 TeV, separately, and for all decay modes at all c.m. energies. The expected SM result for the overall combination is also shown. The horizontal dashed lines indicate the p values for the background-only hypothesis obtained from the asymptotic distribution of q , expressed in units of the number of standard deviations.

above the background-only hypothesis, at a Higgs boson mass of 125.09 GeV. The measured production rate is consistent with the standard model prediction within one standard deviation. In addition to comprising the first observation of a new Higgs boson production mechanism, this measurement establishes the tree-level coupling of the Higgs boson to the top quark, and hence to an up-type quark.

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMFWF and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES and CSF (Croatia); RPF (Cyprus); SENESCYT (Ecuador); MoER, ERC IUT, and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); OTKA and NIH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); MSIP and NRF (Republic of Korea); LAS (Lithuania); MOE and UM (Malaysia); BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI (Mexico); MBIE (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Dubna); MON, RosAtom, RAS, RFBR and RAEP (Russia); MESTD (Serbia); SEIDI, CPAN, PCTI and FEDER (Spain); Swiss Funding Agencies (Switzerland); MST (Taipei); ThEPCenter, IPST, STAR, and NSTDA (Thailand); TUBITAK and TAEK (Turkey); NASU and SFFR (Ukraine); STFC (United Kingdom); DOE and NSF (USA).

Identification of heavy-flavour jets with the CMS detector in pp collisions at 13 TeV

The CMS collaboration

E-mail: cms-publication-committee-chair@cern.ch

ABSTRACT: Many measurements and searches for physics beyond the standard model at the LHC rely on the efficient identification of heavy-flavour jets, i.e. jets originating from bottom or charm quarks. In this paper, the discriminating variables and the algorithms used for heavy-flavour jet identification during the first years of operation of the CMS experiment in proton-proton collisions at a centre-of-mass energy of 13 TeV, are presented. Heavy-flavour jet identification algorithms have been improved compared to those used previously at centre-of-mass energies of 7 and 8 TeV. For jets with transverse momenta in the range expected in simulated $t\bar{t}$ events, these new developments result in an efficiency of 68% for the correct identification of a b jet for a probability of 1% of misidentifying a light-flavour jet. The improvement in relative efficiency at this misidentification probability is about 15%, compared to previous CMS algorithms. In addition, for the first time algorithms have been developed to identify jets containing two b hadrons in Lorentz-boosted event topologies, as well as to tag c jets. The large data sample recorded in 2016 at a centre-of-mass energy of 13 TeV has also allowed the development of new methods to measure the efficiency and misidentification probability of heavy-flavour jet identification algorithms. The b jet identification efficiency is measured with a precision of a few per cent at moderate jet transverse momenta (between 30 and 300 GeV) and about 5% at the highest jet transverse momenta (between 500 and 1000 GeV).

1 Introduction

The success of the physics programme of the CMS experiment at the CERN LHC requires the particles created in the LHC collisions to be reconstructed and identified as accurately as possible. With the exception of the top quark, quarks and gluons produced in pp collisions develop a parton shower and eventually hadronize giving rise to jets of collimated particles observed in the CMS detector. Heavy-flavour jet identification techniques exploit the properties of the hadrons in the jet to discriminate between jets originating from b or c quarks (heavy-flavour jets) and those originating from light-flavour quarks or gluons (light-flavour jets). The CMS Collaboration presented in ref. [1] a set of b jet identification techniques used in physics analyses performed on LHC Run 1 pp collision data, collected in 2011 and 2012 at centre-of-mass energies of 7 and 8 TeV. This paper presents a comprehensive summary of the newly developed and optimized techniques compared to our previous results. In particular, the larger recorded data set of pp collisions at a centre-of-mass energy of 13 TeV during Run 2 of the LHC in 2016, allows the study of rarer high-momentum topologies in which daughter jets from a Lorentz-boosted parent particle merge into a single jet. Examples of such topologies include the identification of boosted Higgs bosons decaying to two b quarks, and of b jets from boosted top quarks. The identification of c jets is also of significant interest, e.g. for the study of Higgs boson decays to a pair of c quarks, and for top squark searches in the c quark plus neutralino final-state topology.

The paper is organized as follows. A brief summary of particle and jet reconstruction in the CMS detector is given in section 2. Details about the simulated proton-proton collision samples and the data-taking conditions are given in section 3. The properties of heavy-flavour jets and the variables used to discriminate between these and other jets are discussed in section 4, while

the algorithms are presented in sections 5 and 6. For some physics processes, it is important to identify b jets at the trigger level. This topic is discussed in section 7. The large recorded number of proton-proton (pp) collisions permits the exploration of new methods to measure the efficiency of the heavy-flavour jet identification algorithms using data. These new methods, as well as the techniques used during the Run 1, are summarized in sections 8 and 9 for efficiency measurements in nonboosted and boosted event topologies, respectively.

2 The CMS detector

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter and a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter (ECAL), and a brass and scintillator hadron calorimeter (HCAL), each composed of a barrel and two endcap sections, together providing coverage in pseudorapidity (η) up to $|\eta| = 3.0$. Forward calorimeters extend the coverage to $|\eta| = 5.2$. Muons are detected in the pseudorapidity range $|\eta| < 2.4$ using gas-ionization chambers embedded in the steel flux-return yoke outside the solenoid.

The silicon tracker measures charged particles within the range $|\eta| < 2.5$. During the first two years of Run 2 operation at a centre-of-mass energy of 13 TeV, the silicon tracker setup did not change compared to the Run 1 of the LHC. The trajectories of charged particles are reconstructed from the hits in the silicon tracking system using an iterative procedure with a Kalman filter. The tracking efficiency is typically over 98% for tracks with a transverse momentum (p_T) above 1 GeV. For nonisolated particles with $1 < p_T < 10$ GeV and $|\eta| < 1.4$, the track resolutions are typically 1.5% in p_T and 25–90 (45–150) μm in the transverse (longitudinal) impact parameter (IP) [2]. The pp interaction vertices are reconstructed by clustering tracks on the basis of their z coordinates at their points of closest approach to the centre of the beam spot using a deterministic annealing algorithm [3]. The position of each vertex is estimated with an adaptive vertex fit [4]. The resolution on the position is around 20 μm in the transverse plane and around 30 μm along the beam axis for primary vertices reconstructed using at least 50 tracks [2].

The global event reconstruction, also called particle-flow (PF) event reconstruction [5], consists of reconstructing and identifying each individual particle with an optimized combination of all subdetector information. In this process, the identification of the particle type (photon, electron, muon, charged hadron, neutral hadron) plays an important role in the determination of the particle direction and energy. Photons, e.g. coming from neutral pion decays or from electron bremsstrahlung, are identified as ECAL energy clusters not linked to the extrapolation of any charged-particle trajectory to the ECAL. Electrons, e.g. coming from photon conversions in the tracker material or from heavy-flavour hadron semileptonic decays, are identified as combinations of charged-particle tracks reconstructed in the tracker and multiple ECAL energy clusters corresponding to both the passage of the electron through the ECAL plus any associated bremsstrahlung photons. Muons, e.g. from the semileptonic decay of heavy-flavour hadrons, are identified as tracks reconstructed in the tracker combined with matching hits or tracks in the muon system, and matching energy deposits in the calorimeters. Charged hadrons are identified as charged particles not identified as electrons or muons. Finally, neutral hadrons are identified as HCAL energy clusters not matching

any charged-particle track, or as ECAL and HCAL energy excesses with respect to the expected charged-hadron energy deposit.

For each event, particles originating from the same interaction vertex are clustered into jets with the infrared and collinear safe anti- k_T algorithm [6, 7], using a distance parameter $R = 0.4$ (AK4 jets). Compared to the $R = 0.5$ jets that were used in Run 1 physics analyses, jets reconstructed with $R = 0.4$ are found to still contain most of the particles from the hadronization process, while at the same time being less sensitive to particles from additional pp interactions (known as pileup) appearing in the same or adjacent bunch crossings. For studies involving boosted topologies, jets are clustered with a larger distance parameter $R = 0.8$ (AK8 jets). The jet momentum is determined as the vectorial sum of all particle momenta in the jet. Jet energy corrections are derived from the simulation and are confirmed with in situ measurements using the energy balance in dijet, multijet, photon + jet, and leptonically decaying Z + jets events [8]. The jet energy resolution amounts typically to 15% at 10 GeV, 8% at 100 GeV, and 4% at 1 TeV [8]. For the studies presented here, jets are required to lie within the tracker acceptance ($|\eta| < 2.4$) and have $p_T > 20$ GeV. The missing transverse momentum vector is defined as the projection of the negative vector sum of the momenta of all reconstructed particles in an event on the plane perpendicular to the beams. Its magnitude is referred to as p_T^{miss} .

The reconstructed vertex with the largest value of summed physics-object p_T^2 is taken to be the primary pp interaction vertex (PV). The physics objects are the jets, clustered using the jet finding algorithm with the tracks assigned to the vertex as inputs, and the associated missing transverse momentum, taken as the negative vector sum of the p_T of those jets.

The energy of electrons is determined from a combination of the track momentum at the main interaction vertex, the corresponding ECAL cluster energies, and the energies of all bremsstrahlung photons associated with the track. The momentum resolution for electrons with $p_T \approx 45$ GeV from $Z \rightarrow ee$ decays ranges from 1.7% for nonshowering electrons, i.e. not producing additional photons and electrons, in the barrel region ($|\eta| < 1.48$), to 4.5% for showering electrons in the endcaps ($1.48 < |\eta| < 3.0$) [9]. Muons with $20 < p_T < 100$ GeV have a relative p_T resolution of 1.3–2.0% in the barrel and less than 6% in the endcaps. The p_T resolution in the barrel is better than 10% for muons with p_T up to 1 TeV [10]. The energy of charged hadrons is determined from a combination of the track momentum and the corresponding ECAL and HCAL energy deposits, corrected for zero-suppression effects and for the response function of the calorimeters to hadronic showers. Finally, the energy of neutral hadrons is obtained from the corresponding corrected ECAL and HCAL energy deposits.

Events of interest are selected using a two-tiered trigger system [11]. The level-1 trigger (L1), composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events at a rate of around 100 kHz. The second level, known as the high-level trigger (HLT), consists of a farm of processors running a version of the full event reconstruction software optimized for fast processing, and reduces the event rate to less than 1 kHz before data storage.

A more detailed description of the CMS detector, together with a definition of the coordinate system used and the relevant kinematic variables, can be found in ref. [12].

3 Data and simulated samples

The results presented in this paper are based on the pp collision data set recorded at a centre-of-mass energy of 13 TeV by the CMS detector in 2016, corresponding to an integrated luminosity of 35.9 fb^{-1} . Various event generators are used to model the relevant physics processes. The interactions between particles and the material of the CMS detector are simulated using `GEANT 4` [13–15]. The data and simulated samples are used to determine the heavy-flavour jet identification efficiency in various event topologies. When measuring the heavy-flavour jet identification efficiency or when comparing the data to the simulation, the number of simulated events is large enough to neglect the statistical uncertainty in the simulation unless mentioned otherwise.

The pair production of top quarks and electroweak single top quark production is performed with the `POWHEG 2.0` generator at next-to-leading order (NLO) accuracy [16–21]. The value of the top quark mass used for the generation of the simulated samples is 172.5 GeV. The systematic uncertainty related to the value of the top quark mass m_t is evaluated by varying it by ± 1 GeV. Alternative samples are used to assess parton shower uncertainties, as well as factorization and normalization scale uncertainties at the matrix element and parton shower levels. Diboson WW, WZ, and ZZ events, referred to collectively as “VV” events, are generated at NLO accuracy with the `MADGRAPH5_AMC@NLO 2.2.2` generator [22], including `MADSPIN` [23] and the FxFx merging scheme [24] between jets from matrix element calculations and the parton shower description, or with the `POWHEG 2.0` generator [25, 26]. The Z + jets and W + jets events are generated with `MADGRAPH5_AMC@NLO 2.2.2` at leading order (LO), using the MLM matching scheme [27]. Samples of events with a Kaluza-Klein graviton [28] decaying to two Higgs bosons are also simulated with `MADGRAPH5_AMC@NLO 2.2.2` at LO for graviton masses ranging between 1 and 3.5 TeV. Background events comprised uniquely of jets produced through the strong interaction (multijet events) are generated with `PYTHIA 8.205` [29] in different \hat{p}_T bins, where \hat{p}_T is defined as the average p_T of the final-state partons. Muon-enriched multijet samples are produced by forcing the decay of charged pions and kaons into muons and by requiring a generated muon with $p_T > 5$ GeV.

`PYTHIA 8.205` is also used for the parton showering and hadronization of all the simulated samples with the CMS underlying event tunes CUETP8M1 [30] using the NNPDF 2.3 [31] parton distribution functions. In the case of top quark pair production a modification of this tune is used, CUETP8M2T4 [32] using the NNPDF 3.0 [33] parton distribution functions.

Pileup interactions are modelled by overlaying the simulated events with additional minimum bias collisions generated with `PYTHIA 8.205`. These additional simulated events are then reweighted to match the observed number of pileup interactions or the primary vertex multiplicity in data.

4 Heavy-flavour jet discriminating variables

4.1 Properties of heavy-flavour jets

Algorithms for heavy-flavour jet identification use variables connected to the properties of heavy-flavour hadrons present in jets resulting from the radiation and hadronization of b or c quarks. For instance, the lifetime of hadrons containing b quarks is of the order of 1.5 ps, while the lifetime of c hadrons is 1 ps or less. This leads to typical displacements of a few mm to one cm for b hadrons, depending on their momentum, thus giving rise to displaced tracks from which a secondary vertex

Figure 1. Illustration of a heavy-flavour jet with a secondary vertex (SV) from the decay of a b or c hadron resulting in charged-particle tracks (including possibly a soft lepton) that are displaced with respect to the primary interaction vertex (PV), and hence with a large impact parameter (IP) value.

(SV) may be reconstructed, as illustrated in figure 1. The displacement of tracks with respect to the primary vertex is characterized by their impact parameter, which is defined as the distance between the primary vertex and the tracks at their points of closest approach. The vector pointing from the primary vertex to the point of closest approach is referred to as the impact parameter vector. The impact parameter value can be defined in three spatial dimensions (3D) or in the plane transverse to the beam line (2D). The longitudinal impact parameter is defined in one dimension, along the beam line. The impact parameter is defined to be positive or negative, with a positive sign indicating that the track is produced “upstream”. This means that the angle between the impact parameter vector and the jet axis is smaller than $\pi/2$, where the jet axis is defined by the primary vertex and the direction of the jet momentum. In addition, b and c quarks have a larger mass and harder fragmentation compared to the light quarks and massless gluons. As a result, the decay products of the heavy-flavour hadron have, on average, a larger p_T relative to the jet axis than the other jet constituents. In approximately 20% (10%) of the cases, a muon or electron is present in the decay chain of a heavy b (c) hadron. Hence, apart from the properties of the reconstructed secondary vertex or displaced tracks, the presence of charged leptons is also exploited for heavy-flavour jet identification techniques and for measuring their performance in data.

In order to design and optimize heavy-flavour identification techniques, a reliable method is required for assigning a flavour to jets in simulated events. The jet flavour is determined by clustering not only the reconstructed final-state particles into jets, but also the generated b and c hadrons that do not have b and c hadrons as daughters respectively. To prevent these generated hadrons from affecting the reconstructed jet momentum, the modulus of the hadron four-momentum is set to a small number, retaining only the directional information. This procedure is known as ghost association [34]. Jets containing at least one b hadron are defined as b jets; the ones containing at least one c hadron and no b hadron are defined as c jets. The remaining jets are considered to be light-flavour (or “uds-g”) jets. Since pileup interactions are not included during the hard-scattering event generation, jets from pileup interactions (“pileup jets”) in the simulation are tentatively identified as jets without a matched generated jet. The generated jets are reconstructed with the jet clustering algorithm mentioned in section 2 applied to the generated final-state particles (excluding neutrinos). The matching between the reconstructed PF jets and the generated jets with $p_T > 8$ GeV

is performed by requiring the angular distance between them to be $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.25$. Using this flavour definition, jets arising from gluon splitting to $b\bar{b}$ are considered as b jets. In sections 6, 8 and 9, these $g \rightarrow b\bar{b}$ jets are often shown as a separate category. In this case, two b hadrons without b hadron daughters should be clustered in the jet. The studies presented in sections 4 and 5 are based on simulated events. For these studies, jets are removed if they are closer than $\Delta R = 0.4$ to a generated charged lepton from a direct V boson decay. In addition, electrons or muons originating from gauge boson decays that are reconstructed as jets are removed if they carry more than 60% of the jet p_T , i.e. $p_T^\ell/p_T^{\text{jet}} < 0.6$ is required, where p_T^ℓ (p_T^{jet}) is the p_T of the lepton (jet). No additional identification or isolation requirements are applied for muons or electrons.

4.2 Track selection and variables

The properties of the tracks clustered within the jet represent the basic inputs of all heavy-flavour jet identification (tagging) algorithms. Input variables for the tagging algorithms are constructed from the tracks after applying appropriate selection criteria. In particular, to ensure a good momentum and impact parameter resolution, tracks are required to have $p_T > 1$ GeV, a χ^2 value of the trajectory fit normalized to the number of degrees of freedom below 5, and at least one hit in the pixel layers of the tracker detector. The last of these requirements is less stringent than the requirement used for b jet identification in Run 1, where at least eight hits were required in the pixel and strip tracker combined, of which at least two were pixel detector hits. The requirement on the number of hits was relaxed to cope with saturation effects that were observed at high occupancy in the readout electronics of the strip tracker during the first part of the 2016 data taking, leading to a reduced tracking and b tagging performance. The issues with the readout electronics have been fully resolved, with no side effects on the tracking performance, but the relaxed requirement on the number of hits was kept since there was no impact on the final b tagging performance. Apart from the requirements on the quality of the tracks, the presence of tracks from long-lived K_S^0 or Λ hadrons as well as from material interactions is reduced by requiring the track decay length, defined as the distance from the primary vertex to the point of closest approach between the track and the jet axis, to be less than 5 cm. The contribution from tracks originating from pileup vertices is reduced with the following set of requirements: the absolute value of the transverse (longitudinal) impact parameter of the track is required to be smaller than 0.2 (17) cm and the distance between the track and the jet axis at their point of closest approach is required to be less than 0.07 cm. Figure 2 presents typical distributions of the latter variable for jets in $t\bar{t}$ events after applying the rest of the track selection requirements, showing the origin of each track separately. The origin of a track is labelled with “ b hadron” if the track corresponds to a particle originating from a b hadron decay. A track corresponding to a particle from the decay of a c hadron that itself originates from the decay of a b hadron is also labelled as “ b hadron”. The category with the “ c hadron” label contains only tracks corresponding to a particle from the decay of a c hadron without a b hadron ancestor. The label “ uds hadron” indicates tracks corresponding to particles without heavy-flavour hadron ancestors. The label “pileup” refers to tracks from charged particles originating from a different primary vertex. A category with mismeasured tracks is defined containing tracks that are more likely to have been misreconstructed, e.g. by wrongly combining hits created by different particles. A track belongs to this category if the number of hits from the simulated charged particle closest to the track over the number of hits associated with the track, is less than 75%. This category is

Figure 2. Distribution of the distance between a track and the jet axis at their point of closest approach for tracks associated with b (left) and light-flavour (right) jets in $t\bar{t}$ events. This distance is required to be smaller than 0.07 cm, as indicated by the arrow. The tracks are divided into categories according to their origin as defined in the text. The distributions are normalized such that their sum has unit area. The last bin includes the overflow entries.

labelled as “fake”. In figure 3, the impact of the track selection requirements on the number of tracks in a given category is shown for various jet flavours in $t\bar{t}$ events. The track selection requirements clearly enhance the fraction of tracks originating from heavy-flavour hadron decays in bottom and charm jets. The track selection requirements reduce the number of tracks in the fake and pileup categories to a few per cent for all jet flavours. Figure 4 shows the track multiplicity dependence on the jet p_T and $|\eta|$ for various jet flavours in $t\bar{t}$ events before and after applying the track selection requirements. For b jets, the average track multiplicity is higher than for light-flavour jets, before and after applying the track selection requirements, and the ratio of the average track multiplicity for b jets to other jet flavours is roughly constant. The average track multiplicity increases with increasing jet p_T for all jet flavours. Before the track selection, the average track multiplicity is almost constant with respect to the jet $|\eta|$. The small variations seen are due to the tracker geometry that has an impact on the track reconstruction efficiency. In addition, since the η of the jet is defined as the η of the jet axis, some of the charged particles in the jet are outside the tracker acceptance for high jet $|\eta|$ values, resulting in a lower track multiplicity in the highest bin. When the track selection requirements are applied, the average track multiplicity decreases with respect to the jet $|\eta|$, because of the relatively larger impact of the track selection requirements near the edge of the acceptance window for the tracker.

The aforementioned track selection requirements are always applied when reconstructing the variables used in the tagging algorithms. An exception is given by the variables relying on the inclusive vertex finding algorithm, as discussed in section 4.3. Figure 5 shows the distribution of the 3D impact parameter and its significance for the different jet flavours. The impact parameter significance is defined as the impact parameter value divided by its uncertainty, IP/σ . In addition, the lower panels in figure 5 also show the distribution of the 2D impact parameter significance for the track with the highest and second-highest 2D impact parameter significance for different jet flavours. From figure 5 it is clear that tracks in heavy-flavour jets have larger impact parameter and impact parameter significance compared to tracks in light-flavour jets. The lower left panel in

Figure 3. Fraction of tracks from different origins before (left) and after (right) applying the track selection requirements on b (upper), c (middle), and light-flavour (lower) jets in $t\bar{t}$ events. The average number of tracks of each origin is given in the legend as well as the average fraction of tracks of a certain origin with respect to the total number of tracks in the jet, indicated in per cent. The number of tracks corresponding to pileup vertices or mismeasured tracks is strongly reduced after applying the track selection requirements. The distributions are normalized such that their sum has unit area. The last bin includes the overflow entries.

Figure 4. Average track multiplicity as a function of the jet p_T (left) and $|\eta|$ (right) for jets of different flavours in $t\bar{t}$ events before (open symbols) and after (filled symbols) applying the track selection requirements.

Figure 5. Distribution of the 3D impact parameter value (upper left) and significance (upper right) for tracks associated with jets of different flavours in $t\bar{t}$ events. Distribution of the 2D impact parameter significance for the track with the highest (lower left) and second-highest (lower right) 2D impact parameter significance for jets of different flavours in $t\bar{t}$ events. The distributions are normalized to unit area. The first and last bin include the underflow and overflow entries, respectively.

figure 5 shows that tracks with a large impact parameter significance are also present in light-flavour jets. These originate from the decays of relatively long-lived hadrons, for example K_S^0 or Λ , or from heavy-flavour hadrons where the tracks have been incorrectly clustered into a light-flavour jet. For the track with the second-highest impact parameter significance in light-flavour jets, the distribution is much more symmetric as expected for hadrons with a short lifetime.

4.3 Secondary vertex reconstruction and variables

If the secondary vertex from the decay of a heavy-flavour hadron is reconstructed, powerful discriminating variables can be derived from it. An example is the (corrected) secondary vertex mass, which is directly related to the mass of the heavy-flavour hadron. The corrected secondary vertex mass is defined as $\sqrt{M_{SV}^2 + p^2 \sin^2 \theta} + p \sin \theta$, where M_{SV} is the invariant mass of the tracks associated with the secondary vertex, p is the secondary vertex momentum obtained from the tracks associated with it, and θ the angle between the secondary vertex momentum and the vector pointing from the primary vertex to the secondary vertex, which is referred to as the secondary vertex flight direction. Using this definition, the secondary vertex mass is corrected for the observed difference between its flight direction and its momentum, taking into account particles that were not reconstructed or which failed to be associated with the secondary vertex. It should be noted that the energy of a track is obtained using its momentum and assuming the π^\pm mass [35]. Another example of a discriminating secondary vertex variable is its flight distance (significance), defined as the 2D or 3D distance between the primary and secondary vertex positions (divided by the uncertainty on the secondary vertex flight distance). Reconstructing the secondary vertex from the heavy-flavour hadron decay is not always possible for two main reasons: the heavy-flavour hadron decays too close to the primary vertex, or there are less than two selected tracks. The latter may be due to having less than two charged particles in the decay, less than two reconstructed tracks, or less than two tracks passing the selection requirements.

Two algorithms for reconstructing secondary vertices are used. The first one is the adaptive vertex reconstruction (AVR) algorithm [36]. This secondary vertex reconstruction algorithm was used for b jet identification by the CMS Collaboration during the LHC Run 1 [1]. The algorithm uses the tracks clustered within jets and passing the selection requirements discussed in section 4.2. In addition, the tracks are required to be within $\Delta R < 0.3$ of the jet axis and to have a track distance below 0.2 cm. The vertex pattern recognition iteratively fits all tracks with an outlier-resistant adaptive vertex fitter [4]. At each iteration, tracks close enough to the fitted vertex are removed and a new iteration is made with the remaining tracks. Given that the first iteration often finds a vertex close to the primary vertex, the first iteration is explicitly run with a constraint on the primary vertex. Vertices are rejected if it is found that they share more than 65% of their tracks with the primary vertex, or if their 2D secondary vertex flight distance is more than 2.5 cm or less than 0.01 cm. In addition, the 2D secondary vertex flight distance significance is required to be larger than 3. To reduce the impact of long-lived hadron decays and material interactions, only secondary vertices with $M_{SV} < 6.5$ GeV are considered. Pairs of tracks are rejected if they are compatible with the mass of the relatively long-lived K_S^0 hadron within 50 MeV. Additionally, the angular distance between the jet axis and the secondary vertex flight direction should satisfy $\Delta R < 0.4$. When all these requirements are fulfilled, the reconstructed AVR secondary vertex is associated with the jet.

At the start of LHC Run 2, the inclusive vertex finding (IVF) algorithm was adopted as the standard secondary vertex reconstruction algorithm used to define variables for heavy-flavour jet tagging. In contrast with AVR, which uses as input the selected tracks clustered in the reconstructed jets, IVF uses as input all reconstructed tracks in the event with $p_T > 0.8$ GeV and a longitudinal IP < 0.3 cm. The algorithm was initially developed to perform a measurement of the angular correlations between the b jets in $b\bar{b}$ pair production [37]. It is well suited for b hadron decays at small relative angle giving rise to overlapping, or completely merged, jets. The IVF procedure starts by identifying seed tracks with a 3D impact parameter value of at least $50 \mu\text{m}$ and a 2D impact parameter significance of at least 1.2. After identifying the seed tracks, the procedure includes the following steps:

- **Track clustering:** the compatibility between a seed track and any other track is evaluated using requirements on the distance at the point of closest approach of the two tracks and the angle between them. In addition, the distance between the seed track and any other track at their points of closest approach is required to be smaller than the distance between the track and the primary vertex at their points of closest approach.
- **Secondary vertex fitting and cleaning:** in order to determine the position of the secondary vertices, the sets of clustered tracks are fitted with the adaptive vertex fitter also used in the AVR algorithm. After the fit, secondary vertices with a 2D (3D) flight distance significance smaller than 2.5 (0.5) are removed. For IVF vertices used in the c tagging algorithm presented in section 5.2.1, the threshold is relaxed to 1.25 (0.25). In addition, if two secondary vertices share 70% or more of their tracks, or if the significance of the flight distance between the two secondary vertices is less than 2, one of the two secondary vertices is dropped from the collection of secondary vertices.
- **Track arbitration:** at this stage, a track could be assigned to both the primary vertex and secondary vertex. To resolve this ambiguity, a track is discarded from the secondary vertex if it is more compatible with the primary vertex. This is the case if the angular distance between the track and the secondary vertex flight direction is $\Delta R > 0.4$, and if the distance between the secondary vertex and the track is larger than the absolute impact parameter value of the track.
- **Secondary vertex refitting and cleaning:** the secondary vertex position is refitted after track arbitration and if there are still two or more tracks associated with the secondary vertex. After refitting the secondary vertex positions, a second check for duplicate vertices is performed. This time, a secondary vertex is removed from the collection of secondary vertices when it shares at least 20% of its tracks with another secondary vertex and the significance of the flight distance between the two secondary vertices is less than 10.

The selection criteria applied to the remaining IVF secondary vertices are mostly the same as in the case of the AVR vertices. However, to maximize the secondary vertex reconstruction efficiency, some requirements are relaxed. In particular, secondary vertices are rejected when they share 80% or more of their tracks, and when the 2D flight distance significance is less than 2 (1.5) for secondary vertices used in b (c) tagging algorithms. The remaining secondary vertices are then associated

with the jets by requiring the angular distance between the jet axis and the secondary vertex flight direction to satisfy $\Delta R < 0.3$.

Figure 6 shows the discriminating power between the various jet flavours for the IVF secondary vertex mass (left) and 2D flight distance significance (right). The secondary vertex mass for b jets peaks at higher values compared to that of the other jet flavours. For c jets, a peak is observed around 1.5 GeV, as expected from the lower mass of c compared to b hadrons.

Figure 6. Distribution of the corrected secondary vertex mass (left) and of the secondary vertex 2D flight distance significance (right) for jets containing an IVF secondary vertex. The distributions are shown for jets of different flavours in $t\bar{t}$ events and are normalized to unit area. The last bin includes the overflow entries.

The secondary vertex reconstruction efficiency for jets is defined as the number of jets containing a reconstructed secondary vertex divided by the total number of jets. For jets with $p_T > 20$ GeV in $t\bar{t}$ events, the efficiency for reconstructing a secondary vertex for b (udsg) jets using the IVF algorithm is about 75% (12%), compared to 65% (4%) for reconstructing a secondary vertex with the AVR algorithm. However, the efficiency gain is largest for c jets with an IVF secondary vertex reconstruction efficiency of about 37%, compared to 23% for the efficiency of the AVR algorithm. Averaged over all jet flavours, 66% of the IVF secondary vertices in jets are also found by the AVR algorithm. The other way around, 86% of the AVR secondary vertices are also found by the IVF algorithm. Figure 7 (left) compares the number of secondary vertices in b jets for the IVF and AVR algorithms. As expected, more secondary vertices are reconstructed with the IVF algorithm because of the inclusive approach of using all tracks instead of only those associated with the jet and passing the selection requirements. The right panel in figure 7 shows the correlation between the corrected mass of the secondary vertices obtained with the two approaches. From the correlation it is clear that the same secondary vertex is found in most cases. Since the efficiency of the IVF algorithm is higher, IVF secondary vertices are used to compute the secondary vertex variables for the heavy-flavour jet identification algorithms. AVR secondary vertices are only used in one of the b jet identification algorithms discussed in section 5.

4.4 Soft-lepton variables

Although an electron or muon is present in only 20% (10%) of the b (c) jets, the properties of this low-energy nonisolated “soft lepton” (SL) permit the selection of a pure sample of heavy-flavour jets. Therefore, some of the heavy-flavour taggers use the properties of these soft leptons. Soft

Figure 7. Distribution of the number of secondary vertices in b jets for the two vertex finding algorithms described in the text (left). The distributions are normalized to unit area. Correlation between the corrected secondary vertex mass for the vertices obtained with the two vertex finding algorithms (right). Both panels show jets in $t\bar{t}$ events.

muons are defined as particles clustered in the jet passing the loose muon identification criteria and with a p_T of at least 2 GeV [10]. Electrons are associated with a jet by requiring $\Delta R < 0.4$. Soft electrons should pass the loose electron identification criteria, have an associated track with at least three hits in the pixel layers, and be identified as not originating from a photon conversion [9].

Discriminating variables using soft lepton information are typically similar to the variables based on track information alone. As an example, figure 8 shows the distribution of the 3D impact parameter value of soft leptons associated with jets. The 3D impact parameter value of the soft

Figure 8. Distribution of the 3D impact parameter value for soft muons (left) and soft electrons (right) for jets of different flavours in $t\bar{t}$ events. The distributions are normalized to unit area. The first and last bins include the underflow and overflow entries, respectively.

lepton discriminates between the various jet flavours. For the low- p_T muons expected from the heavy-flavour hadron decays, it should be noted that the impact parameter resolution is worse than at high p_T [10], which is reflected in the relatively large spread of the impact parameter values. The soft lepton variables are used in the soft lepton algorithms discussed in section 5.1.3 and in the c tagger discussed in section 5.2.1.

5 Heavy-flavour jet identification algorithms

5.1 The b jet identification

The jet probability (JP) and combined secondary vertex (CSV) taggers used during Run 1 [1] are also used for the Run 2 analyses. Likewise, the combined multivariate analysis (cMVA) tagger, which combines the discriminator values of various taggers, was retrained. Apart from the retraining, the CSV algorithm was also optimized and the new version is referred to as CSVv2. In addition, another version of the CSV algorithm was developed that uses deep machine learning [38] (DeepCSV). These taggers are presented in more detail in the sections 5.1.1 to 5.1.3. The new developments result in a performance that is significantly better than that of the Run 1 taggers, as discussed in section 5.1.4.

5.1.1 Jet probability taggers

There are two jet probability taggers, the JP and JBP algorithms. The JP algorithm is described in ref. [1] and uses the signed impact parameter significance of the tracks associated with the jet to obtain a likelihood for the jet to originate from the primary vertex. This likelihood, or jet probability, is obtained as follows. The negative impact parameter significance of tracks from light-flavour jets reflects the resolution of the measured track impact parameter values. Hence, the distribution of the negative impact parameter significance is used as a resolution function. The probability for a track to originate from the primary vertex, P_{tr} , is obtained by integrating the resolution function $\mathcal{R}(s)$ from $-\infty$ to the negative of the absolute track impact parameter significance, $-|\text{IP}|/\sigma$:

$$P_{\text{tr}} = \int_{-\infty}^{-|\text{IP}|/\sigma} \mathcal{R}(s) ds. \quad (5.1)$$

The resolution function depends strongly on the quality of the reconstructed track, e.g. the number of hits in the pixel and strip layers of the tracker. Moreover, the probability for a given track to originate from the primary vertex will be smaller for tracks with a large number of missing hits. Therefore, different resolution functions are defined for various track quality classes. In addition, the track quality may be different in data and simulated events. To calibrate the JP algorithm, the resolution functions are determined separately for data and simulation. Using eq. (5.1), tracks corresponding to particles from the decay of a displaced particle will have a low track probability, indicating that the track is not compatible with the primary vertex. The individual track probabilities are combined to obtain a jet probability P_j as follows:

$$P_j = \Pi \sum_{\text{tr}=0}^{N-1} \frac{(-\ln \Pi)^{\text{tr}}}{\text{tr}!}, \quad (5.2)$$

where Π is the product over the track probabilities, P_{tr} , and the sum runs over the selected tracks index tr , with N the number of selected tracks associated with the jet. To avoid instabilities due to the multiplication of small track probabilities, the probability is set to 0.5% for track probabilities below 0.5%. Only tracks with a positive impact parameter and for which the angular distance between the track and the jet axis satisfies $\Delta R < 0.3$ are used. A variant of the JP algorithm also exists for which the four tracks with the highest impact parameter significance get a higher weight in the jet

probability calculation. This algorithm is referred to as jet b probability (JBP) and uses tracks with $\Delta R < 0.4$. For a light-flavour jet misidentification probability of around 10%, the JBP algorithm has a b jet identification efficiency of 80% compared to 78% for the JP algorithm. The discriminators for the jet probability algorithms were constructed to be proportional to $-\ln P_j$. Figure 9 shows the distributions of the discriminator values for the JP and JBP algorithms. The discontinuities in the discriminator distributions are due to the minimum track probability threshold of 0.5%.

The jet probability algorithms are interesting for two reasons. First, the fact that the calibration of the resolution function is performed independently for data and simulation results in a robust reference tagger. Second, these algorithms rely only on the impact parameter information of the tracks. Therefore, they are used by some methods when measuring the efficiency of other b jet identification algorithms that rely on secondary vertex or soft lepton information, as discussed in sections 8 and 9.

Figure 9. Distribution of the JP (left) and JBP (right) discriminator values for jets of different flavours in $t\bar{t}$ events. Jets without selected tracks are assigned a negative value. The distributions are normalized to unit area. The first and last bin include the underflow and overflow entries, respectively.

5.1.2 Combined secondary vertex taggers

The CSVv2 tagger. The CSVv2 algorithm is based on the CSV algorithm described in ref. [1] and combines the information of displaced tracks with the information on secondary vertices associated with the jet using a multivariate technique. Two variants of the CSVv2 algorithm exist according to whether IVF or AVR vertices are used. As baseline, IVF vertices are used in the CSVv2 algorithm, otherwise we refer to it as CSVv2 (AVR). At least two tracks per jet are required. When calculating the values of the track variables, the tracks are required to have an angular distance with respect to the jet axis of $\Delta R < 0.3$. Moreover, any combination of two tracks compatible with the mass of the K_S^0 meson in a window of 30 MeV is rejected. Jets that have neither a selected track nor a secondary vertex are assigned a default output discriminator value of -1 .

In a first step, the algorithm has to learn the features, e.g. input variable distributions corresponding to the various jet flavours, and combine them into a single discriminator output value. This step is the so-called “training” of the algorithm. During this step, it is important to ensure that the algorithm does not learn any unwanted behaviour, such as b jets having a higher jet p_T ,

on average, compared to other jets in a sample of $t\bar{t}$ events. To avoid discrimination between jet flavours caused by different jet p_T and η distributions, these distributions are reweighted to obtain the same spectrum for all jet flavours in the training sample. The training is performed on inclusive multijet events in three independent vertex categories:

- **RecoVertex**: The jet contains one or more secondary vertices.
- **PseudoVertex**: No secondary vertex is found in the jet but a set of at least two tracks with a 2D impact parameter significance above two and a combined invariant mass at least 50 MeV away from the K_S^0 mass are found. Since there is no real secondary vertex reconstruction, no fit is performed, resulting in a reduced number of variables.
- **NoVertex**: Containing jets not assigned to one of the previous two categories. Only the information of the selected tracks is used.

Figure 10 shows the fraction of jets of each flavour in the various vertex categories of the CSVv2 algorithm using jets in $t\bar{t}$ events with p_T above 20 GeV, where the secondary vertices in the RecoVertex category are obtained with the IVF algorithm. The following discriminating variables are combined in the algorithm.

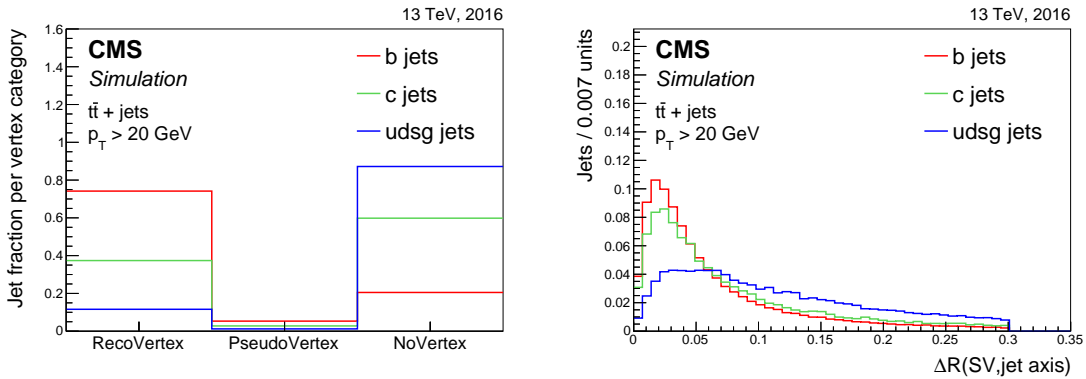

Figure 10. Vertex category for secondary vertices reconstructed with the IVF algorithm (left), and the distribution of the angular distance between the IVF secondary vertex flight direction and the jet axis (right) for jets of different flavours in $t\bar{t}$ events. The distributions are normalized to unit area.

- The “SV 2D flight distance significance”, defined as the 2D flight distance significance of the secondary vertex with the smallest uncertainty on its flight distance for jets in the RecoVertex category.
- The “number of SV”, defined as the number of secondary vertices for jets in the RecoVertex category.
- The “track η_{rel} ”, defined as the pseudorapidity of the track relative to the jet axis for the track with the highest 2D impact parameter significance for jets in the RecoVertex and PseudoVertex categories.

- The “corrected SV mass”, defined as the corrected mass of the secondary vertex with the smallest uncertainty on its flight distance for jets in the RecoVertex category or the invariant mass obtained from the total summed four-momentum vector of the selected tracks for jets in the PseudoVertex category.
- The “number of tracks from SV”, defined as the number of tracks associated with the secondary vertex for jets in the RecoVertex category or the number of selected tracks for jets in the PseudoVertex category.
- The “SV energy ratio”, defined as the energy of the secondary vertex with the smallest uncertainty on its flight distance divided by the energy of the total summed four-momentum vector of the selected tracks.
- The “ $\Delta R(\text{SV}, \text{jet})$ ”, defined as the ΔR between the flight direction of the secondary vertex with the smallest uncertainty on its flight distance and the jet axis for jets in the RecoVertex category, or the ΔR between the total summed four-momentum vector of the selected tracks for jets in the PseudoVertex category.
- The “3D IP significance of the first four tracks”, defined as the signed 3D impact parameter significances of the four tracks with the highest 2D impact parameter significance.
- The “track $p_{T,\text{rel}}$ ”, defined as the track p_T relative to the jet axis, i.e. the track momentum perpendicular to the jet axis, for the track with the highest 2D impact parameter significance.
- The “ $\Delta R(\text{track}, \text{jet})$ ”, defined as the ΔR between the track and the jet axis for the track with the highest 2D impact parameter significance.
- The “track $p_{T,\text{rel}}$ ratio”, defined as the track p_T relative to the jet axis divided by the magnitude of the track momentum vector for the track with the highest 2D impact parameter significance.
- The “track distance”, defined as the distance between the track and the jet axis at their point of closest approach for the track with the highest 2D impact parameter significance.
- The “track decay length”, defined as the distance between the primary vertex and the track at the point of closest approach between the track and the jet axis for the track with the highest 2D impact parameter significance.
- The “summed tracks E_T ratio”, defined as the transverse energy of the total summed four-momentum vector of the selected tracks divided by the transverse energy of the jet.
- The “ $\Delta R(\text{summed tracks}, \text{jet})$ ”, defined as the ΔR between the total summed four-momentum vector of the tracks and the jet axis.
- The “first track 2D IP significance above c threshold”, defined as the 2D impact parameter significance of the first track that raises the combined invariant mass of the tracks above 1.5 GeV. This track is obtained by summing the four-momenta of the tracks adding one track at the time. Every time a track is added, the total four-momentum vector is computed. The 2D impact parameter significance of the first track that is added resulting in a mass of the total

four-momentum vector above the aforementioned threshold is used as a variable. The threshold of 1.5 GeV is related to the c quark mass.

- The number of selected tracks.
- The jet p_T and η .

The discriminating variables in each vertex category are combined into a neural network, specifically a feed-forward multilayer perceptron with one hidden layer [39]. The number of nodes in the hidden layer is different for the three different vertex categories and is set to twice the number of input variables. The discriminator values of the three vertex categories are combined with a likelihood ratio taking into account the fraction of jets of each flavour expected in $t\bar{t}$ events. The fraction of jets of each flavour is obtained as a function of the jet p_T and $|\eta|$, using 19 exclusive bins in total. Two dedicated trainings are performed, one with c jets, and one with light-flavour jets as background. The final discriminator value is a linear combination of the output of these two trainings with relative weights of 1 : 3 for the output of the network trained against c and light-flavour jets, respectively. The value of these relative weights is inspired by $t\bar{t}$ events where one of the two W bosons decays into quarks and the other into leptons, and provides the best performance for a wide variety of physics topologies compared to alternative relative weights.

The main differences from the Run 1 version of the CSV algorithm are the following:

- **The secondary vertex reconstruction algorithm:** the secondary vertices are reconstructed with the IVF algorithm.
- **Input variables:** table 1 lists the variables used for the Run 1 version of the CSV algorithm and for the CSVv2 algorithm. Figure 11 shows two of the variables used for the CSVv2 algorithm and not for the CSV algorithm.
- **Multilayer perceptron:** in the previous version of the algorithm the input variables in a certain vertex category were combined with a likelihood ratio. Depending on the type of correlations present between the input variables, the likelihood ratio performs at a comparable level to the other multivariate methods. The likelihood ratio is particularly useful because of its simplicity and when a small number of variables are used. However, to increase the performance of the algorithm, more input variables were added and combined into an artificial neural network.
- **Jet p_T and η dependence:** the correlation of some of the input variables with the jet p_T and η is taken into account by including the jet kinematics as input variables, after reweighting the distributions to be the same for all jet flavours. In the past, the training was performed in bins of the jet kinematics. In the current procedure, the bins of jet kinematics are only used to combine the vertex categories after the training.

Figure 12 shows the distribution of the discriminator values for the various jet flavours for both versions of the CSVv2 algorithm.

Table 1. Input variables used for the Run 1 version of the CSV algorithm and for the CSVv2 algorithm. The symbol “x” (“—”) means that the variable is (not) used in the algorithm.

Input variable	Run 1 CSV	CSVv2
SV 2D flight distance significance	x	x
Number of SV	—	x
Track η_{rel}	x	x
Corrected SV mass	x	x
Number of tracks from SV	x	x
SV energy ratio	x	x
$\Delta R(\text{SV}, \text{jet})$	—	x
3D IP significance of the first four tracks	x	x
Track $p_{\text{T,rel}}$	—	x
$\Delta R(\text{track}, \text{jet})$	—	x
Track $p_{\text{T,rel}}$ ratio	—	x
Track distance	—	x
Track decay length	—	x
Summed tracks E_{T} ratio	—	x
$\Delta R(\text{summed tracks}, \text{jet})$	—	x
First track 2D IP significance above c threshold	—	x
Number of selected tracks	—	x
Jet p_{T}	—	x
Jet η	—	x

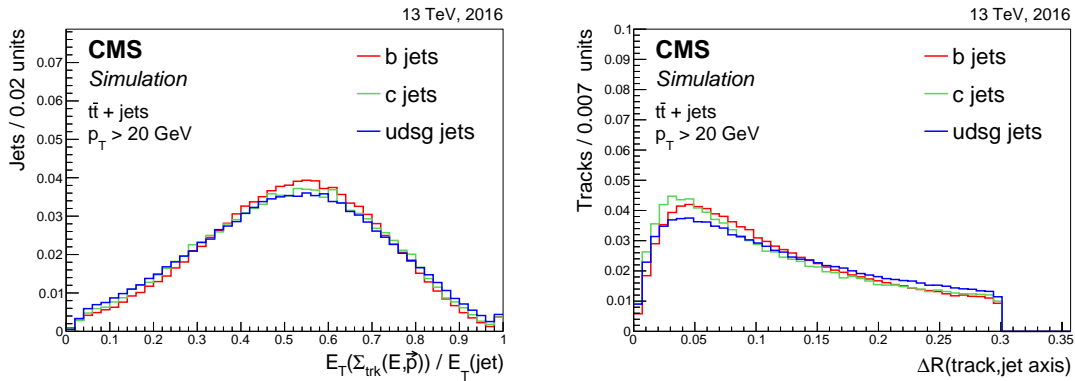

Figure 11. Distribution of the transverse energy of the total summed four-momentum vector of the selected tracks divided by the jet transverse energy (left), and angular distance between the track and the jet axis (right) for jets of different flavours in $t\bar{t}$ events. The distributions are normalized to unit area. The last bin in the left panel includes the overflow entries.

The DeepCSV tagger. The identification of jets from heavy-flavour hadrons can be improved by using the advances in the field of deep machine learning [38]. A new version of the CSVv2 tagger, “DeepCSV”, was developed using a deep neural network with more hidden layers, more nodes per

Figure 12. Distribution of the CSVv2 (left) and CSVv2(AVR) (right) discriminator values for jets of different flavours in $t\bar{t}$ events. The distributions are normalized to unit area. Jets without a selected track and secondary vertex are assigned a negative discriminator value. The first bin includes the underflow entries.

layer, and a simultaneous training in all vertex categories and for all jet flavours.

The same tracks and IVF secondary vertices are used in this approach as for the CSVv2 tagger. The same input variables are also used, with only one difference, namely that for the track-based variables up to six tracks are used in the training of the DeepCSV. Jets are randomly selected in such a way that similar jet p_T and η distributions are obtained for all jet flavours. These jet p_T and η distributions are also used as input variables in the training to take into account the correlation between the jet kinematics and the other variables. The distribution of all input variables is preprocessed to centre the mean of each distribution around zero and to obtain a root-mean-square value of unity. All of the variables are presented to the multivariate analysis (MVA) in the same way because of the preprocessing. This speeds up the training. In case a variable cannot be reconstructed, e.g. because there are less than six selected tracks (or no secondary vertex), the variable values associated with the missing track or vertex are set to zero after the preprocessing.

The training is performed using jets with p_T between 20 GeV and 1 TeV, and within the tracker acceptance. The relative ratio of the number of jets of each flavour is set to 2 : 1 : 4 for b : c : udsg jets. A mixture of $t\bar{t}$ and multijet events is used to reduce the possible dependency of the training on the heavy-flavour quark production process.

The training of the deep neural network is performed using the KERAS [40] deep learning library, interfaced with the TENSORFLOW [41] library that is used for low-level operations such as convolutions. The neural network uses four hidden layers that are fully connected, each with 100 nodes. Increasing the number of hidden layers and the number of nodes per layer had negligible effects on the performance. Each node in one of the hidden layers uses a rectified linear unit as its activation function to define the output of the node given the input values. For the nodes in the last layer, a normalized exponential function is used for the activation to be able to interpret the output value as a probability for a certain jet flavour category, $P(f)$. The output layer contains five nodes corresponding to five jet flavour categories used in the training. These categories are defined according to whether the jet contains exactly one b hadron, at least two b hadrons, exactly one c hadron and no b hadrons, at least two c hadrons and no b hadrons, or none of the aforementioned categories. Each of these categories is completely independent of the others. The reason for

defining five flavour categories in the training is to provide analyses with the possibility to identify jets containing two b or c hadrons.

Figure 13. Distribution of the DeepCSV $P(b)$ (upper left), $P(bb)$ (upper right), $P(c)$ (middle left), $P(cc)$ (middle right), $P(udsg)$ (lower left), and $P(b) + P(bb)$ (lower right) discriminator values for jets of different flavours in $t\bar{t}$ events. Jets without a selected track and without a secondary vertex are assigned a discriminator value of 0. The distributions are normalized to unit area.

Figure 13 shows the discriminator distribution for each of the DeepCSV probabilities $P(f)$. The lower right panel in figure 13 also shows the $P(b) + P(bb)$ discriminator used to tag b jets in physics analyses. It has been checked that summing the probabilities for these two categories is equivalent to using a combined training for these categories.

5.1.3 Soft-lepton and combined taggers

Soft leptons, i.e. electrons or muons reconstructed as described in section 4.4 are sometimes present in a jet. When they are, the information related to the charged lepton is used to construct a soft-electron (SE) and soft-muon (SM) tagger. The discriminating variables that are used as input for the boosted decision tree (BDT) are the 2D and 3D impact parameter significance of the lepton, the angular distance between the jet axis and the lepton, ΔR , the ratio of the p_T of the lepton to that of the jet, and the p_T of the lepton relative to the jet axis, p_T^{rel} . In the case of the SE algorithm an MVA-based electron identification variable is also used as input. The distributions of the SE and SM discriminator values are shown in figure 14. The different range for the algorithm output values is related to different settings in the training when combining the input variables with a BDT.

Figure 14. Distribution of the soft-electron (left) and soft-muon (right) discriminator values for jets of different flavours in $t\bar{t}$ events. Jets without a soft lepton are assigned a discriminator value of 0. The distributions are normalized to unit area.

As a soft lepton is only present in a relatively small fraction of heavy-flavour jets, the soft lepton taggers are not always able to discriminate heavy-flavour jets from other jets. Therefore they are not used standalone, but rather as input for a combined tagger. The combined tagger, cMVA_{v2}, uses six b jet identification discriminators as input variables, namely the two variants of the JP algorithm, the SE and SM algorithms, and the two variants of the CSV_{v2} algorithm. The training is performed using the open source SCIKIT-LEARN package [42] and the variables are combined using a gradient boosting classifier (GBC) as BDT. Prior to the training, the jet p_T and η distributions are reweighted to obtain a similar distribution for all jet flavours. Although the correlation between the two CSV_{v2} discriminator values is close to 100%, a small improvement is seen in the case where the vertex finding algorithms reconstruct different secondary vertices. Figure 15 shows the correlation between the input variables of the cMVA_{v2} algorithm for b jets as well as the distribution of the cMVA_{v2} discriminator values for various jet flavours obtained in a $t\bar{t}$ sample. The correlation between the input variables is similar for other jet flavours. Adding the SL taggers or one of the JP taggers as input variables for the cMVA_{v2} algorithm results in a similar large performance gain with respect to the CSV_{v2} algorithm. Adding the other JP tagger and CSV_{v2} (AVR) algorithm results only in a modest performance gain. The performance of the cMVA_{v2} tagger for discriminating b jets against other jet flavours is discussed more extensively in section 5.1.4.

Figure 15. Correlation between the different input variables for the cMVA2 tagger for b jets in $t\bar{t}$ events (left), and distribution of the cMVA2 discriminator values (right), normalized to unit area, for jets of different flavours in $t\bar{t}$ events.

It is relevant to note that the DeepCSV discriminator output was not included as an input variable, as this algorithm was developed after the cMVA2 tagger. Further optimizations are ongoing, in particular in the context of the new pixel tracker installed in 2017 [43].

5.1.4 Performance in simulation

The tagging efficiency of the JP, CSVv2, cMVA2, and DeepCSV taggers is determined using simulated pp collision events. The efficiency (misidentification probability) to correctly (wrongly) tag a jet with flavour f is defined as the number of jets of flavour f passing the tagging requirement divided by the total number of jets of flavour f . Figure 16 shows the b jet identification efficiency versus the misidentification probability for either c or light-flavour jets in simulated $t\bar{t}$ events requiring jets with $p_T > 20$ GeV and $|\eta| < 2.4$ for various b taggers. In this figure, the tagging efficiency is integrated over the p_T and η distributions of the jets in the $t\bar{t}$ sample. The tagging efficiency is also shown for the Run 1 version of the CSV algorithm. It should be noted that the CSV algorithm was trained on simulated multijet events at centre-of-mass energy of 7 TeV using anti- k_T jets clustered with a distance parameter $R = 0.5$. Therefore, the comparison is not completely fair. The performance improvement expected from a retraining is typically of the order of 1%. The absolute improvement in the b jet identification efficiency for the CSVv2 (AVR) algorithm with respect to the CSV algorithm is of the order of 2–4% when the comparison is made at the same misidentification probability value for light-flavour jets. An additional improvement of the order of 1–2% is seen when using IVF vertices instead of AVR vertices in the CSVv2 algorithm. The cMVA2 tagger performs around 3–4% better than the CSVv2 algorithm for the same misidentification probability for light-flavour jets. The DeepCSV $P(b) + P(bb)$ tagger outperforms all the other b jet identification algorithms, when discriminating against c jets or light-flavour jets, except for b jet identification efficiencies above 70% where the cMVA2 tagger performs better when discriminating against light-flavour jets. The absolute b identification efficiency improves by about 4% with respect to the CSVv2 algorithm for a misidentification probability for light-flavour

Figure 16. Misidentification probability for c and light-flavour jets versus b jet identification efficiency for various b tagging algorithms applied to jets in $t\bar{t}$ events.

jets of 1%. Three standard working points are defined for each b tagging algorithm using jets with $p_T > 30$ GeV in simulated multijet events with $80 < \hat{p}_T < 120$ GeV. The average jet p_T in this sample of events is about 75 GeV. These working points, “loose” (L), “medium” (M), and “tight” (T), correspond to thresholds on the discriminator after which the misidentification probability is around 10%, 1%, and 0.1%, respectively, for light-flavour jets. The efficiency for correctly identifying b jets in simulated $t\bar{t}$ events for each of the three working points of the various taggers is summarized in table 2.

The tagging efficiency depends on the jet p_T , η , and the number of pileup interactions in the event. This dependency is illustrated for the DeepCSV $P(b) + P(bb)$ tagger in figure 17 using jets with $p_T > 20$ GeV in $t\bar{t}$ events. A parameterization of the efficiency as a function of the jet p_T is provided in appendix A. The efficiency for correctly identifying b jets is maximal for jets with $p_T \approx 100$ GeV and decreases at low- and high- p_T values. The lower efficiency at low jet p_T is due to the larger uncertainty on the track impact parameter resolution. At high jet p_T , there are two main effects. First, the misidentification probability for light-flavour jets increases because of the larger number of tracks present in the jet, as can be seen from figure 4. Second, at higher jet transverse momenta, jets are more collimated and their charged particles are closer together, resulting in merged hits in the innermost layers of the tracking system. This effect impacts the track reconstruction efficiency and hence also the b jet identification efficiency. Due to the higher track reconstruction efficiency and the better resolution of the track parameters at small $|\eta|$ values [2], the algorithms are more efficient in identifying b jets in the barrel region of the CMS silicon tracker ($|\eta| < 1$). The efficiency for misidentifying light-flavour jets increases with an increasing number of

Table 2. Taggers, working points, and corresponding efficiency for b jets with $p_T > 20 \text{ GeV}$ in simulated $t\bar{t}$ events. The numbers in this table are for illustrative purposes since the b jet identification efficiency is integrated over the p_T and η distributions of jets.

Tagger	Working point	ε_b (%)	ε_c (%)	$\varepsilon_{\text{uds}g}$ (%)
Jet probability (JP)	JP L	78	37	9.6
	JP M	56	12	1.1
	JP T	36	3.3	0.1
Combined secondary vertex (CSVv2)	CSVv2 L	81	37	8.9
	CSVv2 M	63	12	0.9
	CSVv2 T	41	2.2	0.1
Combined MVA (cMVAv2)	cMVAv2 L	84	39	8.3
	cMVAv2 M	66	13	0.8
	cMVAv2 T	46	2.6	0.1
Deep combined secondary vertex (DeepCSV) $P(b) + P(bb)$	DeepCSV L	84	41	11
	DeepCSV M	68	12	1.1
	DeepCSV T	50	2.4	0.1

pileup interactions. This is explained as follows. First, the increasing number of pileup interactions results in a higher probability to choose the wrong primary vertex resulting in light-flavour jets that are displaced, and b jets for which the displacement is wrong. Second, the increasing number of pileup interactions results in a higher occupancy in the tracker, leading to a larger number of wrongly reconstructed tracks as well as more tracks from a different interaction vertex that are clustered in the jets associated with the primary vertex. It was checked that all taggers presented in table 2 show a similar dependence with respect to the number of pileup interactions, and jet p_T and $|\eta|$.

5.2 The c jet identification

As can be seen from figures 5, 6, and 8 in section 4, the distributions of the tagging variables for c jets lie in between the distributions for b and light-flavour jets. This is due to the lifetime of the c hadrons being shorter than that of the b hadrons. In addition, the secondary vertex multiplicity is also lower and the smaller c quark mass results in a smaller track p_T relative to the jet axis. Therefore, it is particularly challenging to efficiently identify jets originating from c quarks.

5.2.1 Algorithm description

The c jet identification algorithm uses properties related to displaced tracks, secondary vertices, and soft leptons inside the jets. The secondary vertices are obtained using the IVF algorithm with modified parameters for c jets as described in section 4.3. Based on the presence or absence of a secondary vertex associated with a jet, three secondary vertex categories are defined in the same way as for the CSVv2 algorithm. The presence or absence of a soft lepton, as discussed in the previous paragraph, leads to the definition of three soft lepton categories, independent of the secondary vertex categories:

Figure 17. Efficiencies and misidentification probabilities for the DeepCSV $P(b) + P(bb)$ tagger as a function of the jet p_T (left), jet η (middle), and PU multiplicity, i.e. the number of inelastic pp collisions in the event (right), for b (upper), c (middle), and light-flavour (lower) jets in $t\bar{t}$ events. Each panel shows the efficiency for the three different working points with different colours.

- **NoSoftLepton:** including jets without soft leptons found inside the jet;
- **SoftMuon:** at least one soft muon was found inside the jet;
- **SoftElectron:** no soft muon, but at least one soft electron was found inside the jet.

With this categorization, jets containing a muon and an electron will be assigned to the SoftMuon category. Like for the b tagging algorithms, the displaced tracks are ordered by decreasing 2D impact parameter significance, and the secondary vertices are ordered by increasing uncertainty on their 3D flight distance. Some variables are only defined if a secondary vertex was reconstructed or if a soft lepton was found inside the jet. Whenever a variable is not available, a default value is assigned to it. The variables used are similar to the ones used in the CSVv2 algorithm (section 5.1.2) and in the SM or SE algorithms (section 5.1.3). For track- and lepton-based variables, up to two

tracks or leptons are used (if available), while for the secondary vertex variables only the first secondary vertex is used (if available). The list of variables used is the following:

- The vertex-lepton category.
- The 2D and 3D impact parameter significance of the first two tracks, and the 3D impact parameter significance of the first two leptons.
- The pseudorapidity of the track (lepton) relative to the jet axis for the first two tracks (leptons).
- The track (lepton) p_T relative to the jet axis, i.e. the track momentum perpendicular to the jet axis, for the first two tracks (leptons).
- The track p_T relative to the jet axis divided by the magnitude of the track momentum vector, for the first two tracks.
- The track momentum parallel to the jet direction, for the first two tracks.
- The track momentum parallel to the jet direction divided by the magnitude of the track momentum vector, for the first two tracks.
- The ΔR between the track (lepton) and the jet axis for the first two tracks (leptons).
- The distance between the track and the jet axis at their point of closest approach, for the first two tracks.
- The track decay length, i.e. the distance between the primary vertex and the track at the point of closest approach between the track and the jet axis, for the first two tracks.
- The transverse energy of the total summed four-momentum vector of the selected tracks divided by the transverse energy of the jet.
- The ΔR between the total summed four-momentum vector of the tracks and the jet axis.
- The 2D and 3D impact parameter significance of the first track that raises the combined invariant mass of the tracks above 1.5 GeV. This track is obtained by summing the four-momenta of the tracks adding one track at the time. Every time a track is added, the total four-momentum vector is computed. The 2D impact parameter significance of the first track that is added resulting in a mass of the total four-momentum vector above the aforementioned threshold is used as a variable. The threshold of 1.5 GeV is related to the c quark mass.
- The lepton p_T divided by the jet p_T , for the first two leptons.
- The lepton momentum parallel to the jet direction divided by the magnitude of the jet momentum, for the first two leptons.
- The 2D and 3D flight distance significance of the first secondary vertex.
- The secondary vertex energy ratio, defined as the energy of the secondary vertex with the smallest uncertainty on its flight distance divided by the energy of the total summed four-momentum vector of the selected tracks.

- The corrected secondary vertex mass.
- The “massVertexEnergyFraction” variable, which is defined as $X/(X + 0.04)$, where X is the corrected secondary vertex mass divided by the average b meson mass [35] multiplied by the scalar sum of the track energies (assuming the pion mass) for tracks associated with the secondary vertex divided by the scalar sum of the track energies for track associated with the jet:

$$X = \frac{m_{SV}[\text{GeV}]}{5.2794} \frac{\sum_{SV \text{ tracks}} E_i}{\sum_{jet \text{ tracks}} E_i}. \quad (5.3)$$

This variable is first defined in section 7 of ref. [44].

- The “vertexBoost” variable, defined as $Y^2/(Y^2 + 10)$, where Y is the square root of the average b meson mass [35] multiplied with the scalar sum of the track p_T for tracks associated with the vertex, divided by the product of the corrected secondary vertex mass and the square root of the jet p_T . This variable is related to the boost of the secondary vertex. This variable is first defined in section 7 of ref. [44].
- The number of tracks associated with the first secondary vertex.
- The number of secondary vertices.
- The number of tracks associated with the jet.

The training of the algorithm was performed on simulated multijet events. As in the case of the DeepCSV tagger, the variables are first preprocessed to centre their mean at zero and obtain a root-mean-square of unity. Two weights are applied for each jet in the training. To avoid introducing any unwanted dependence on the jet kinematics in the tagger, a first weight is applied to flatten the jet p_T and η distributions in the whole training sample for all jet flavours. Simultaneously, a second weight skews the relative contribution of the different secondary vertex categories in the multijet sample to fit the observed ones in the $t\bar{t}$ sample. Two trainings are performed: one for discriminating c jets from light-flavour jets (CvsL) and another one for discriminating c jets from b jets (CvsB). The training of the two discriminators was performed with the SCIKIT-LEARN package [42] using a GBC as implementation of the BDT.

The GBC settings were optimized by varying them over a wide range of values, to ensure the optimal setting was contained within the scanned range. Both the CvsL and CvsB trainings were optimized by scanning a range of the parameters and comparing the final performance curves. The best performance was achieved with the number of boosting stages set to 500, the learning rate to 0.05, the minimum number of samples required to split an internal node to 0.6% and a maximum depth of the individual regression estimators of 15 (8) for the CvsL (CvsB) training. Some of the optimized values did not change the performance visibly when being varied, but they were chosen to reduce the computation time without a loss in performance.

Figure 18 shows the output discriminator distributions for the CvsL and CvsB taggers. The discriminator distributions exhibit spikes, which originate from the default values for most input variables if a jet has no track passing the selection criteria. These spikes do not affect any

Figure 18. Distribution of the CvsL (left) and CvsB (right) discriminator values for jets of different flavours in $t\bar{t}$ events. The spikes originate from jets without a track passing the track selection criteria, as discussed in the text. The distributions are normalized to unit area.

physics analyses, as the discriminator thresholds defining the working points are not just before or after a spike.

5.2.2 Performance in simulation

The performance is evaluated using jets with $p_T > 20$ GeV and $|\eta| < 2.4$ in a sample of simulated $t\bar{t}$ events. The left panel in figure 19 shows the correlation between the CvsL and CvsB discriminators for various jet flavours. Discriminator values close to one correspond to signal-like c jets. Therefore, the c jets populate the upper right corner of this figure, whereas b jets and light-flavour jets populate the region near the bottom right and the upper left corners, respectively. In the upper left corner there is a relatively large fraction of c jets because of the similarity of c jets and light-flavour jets at CvsL discriminator values below -0.3 and CvsB discriminator values above $+0.5$, as can be seen in figure 18. In order to discriminate c jets from other jet flavours and to evaluate the performance of the c tagger, thresholds are applied on both CvsL and CvsB to select the upper right corner of this phase space. Three working points have been defined corresponding to the efficiency for correctly identifying c jets. These are indicated by the dashed lines. The loose working point has a high efficiency for c jets and rejects primarily b jets, whereas the tight working point rejects primarily light-flavour jets. Table 3 summarizes the efficiencies for the three working points.

Table 3. Efficiency for the working points of the c tagger and corresponding efficiency for the different jet flavours obtained using jets with $p_T > 20$ GeV in simulated $t\bar{t}$ events. The numbers quoted are for illustrative purposes since the efficiency is integrated over the p_T and η distributions of the jets.

Working point	ε_c (%)	ε_b (%)	ε_{udsg} (%)
c tagger L	88	36	91
c tagger M	40	17	19
c tagger T	19	20	1.2

The right panel in figure 19 shows the light-flavour and b jet misidentification probabilities for constant c tagging efficiencies. The arrows indicate the c jet identification efficiency and

misidentification probability for b and light-flavour jets corresponding to the three working points. The discontinuous transition in each of the curves for c tagging efficiencies between 0.35 and 0.7 are due to the largest spike in the CvsL distribution in the left panel in figure 18.

Figure 19. Correlation between CvsL and CvsB taggers for the various jet flavours (left), and misidentification probability for light-flavour jets versus misidentification probability for b jets for various constant c jet efficiencies (right) in $t\bar{t}$ events. The L, M, and T working points discussed in the text are indicated by the dashed lines (left) or arrows (right). The discontinuity in the curves corresponding to c tagging efficiencies between 0.4 and 0.7 are due to the spike in the CvsL distribution of figure 18.

In figure 20 the performance of the CvsL and CvsB taggers is compared with the cMVA_{v2} and CSV_{v2} b tagging algorithms. In the right panel of this figure, the transition in the performance of the curve for a c jet identification efficiency around 0.4 is due to the largest spike in the CvsL discriminator distribution. The performance of the CvsB tagger is similar to the performance of both b taggers, except at small b jet misidentification probabilities where the CvsB tagger is performing slightly worse than the cMVA_{v2} tagger. The CvsL tagger outperforms the cMVA_{v2} and CSV_{v2} tagger for small light-flavour jet misidentification probabilities. The DeepCSV tagger described in section 5.1.2 is outperforming the dedicated c tagger. For the discrimination between c and b jets, the DeepCSV probabilities corresponding to the five flavour categories defined in section 5.1.2, are combined in the following way:

$$\text{DeepCSV CvsB} = \frac{P(c) + P(cc)}{1 - P(\text{udsg})}, \quad (5.4)$$

where the numerator corresponds to the probability to identify c jets and the denominator to the probability to identify b or c jets. Similarly, for the discrimination between c and light-flavour jets, the discriminator is constructed:

$$\text{DeepCSV CvsL} = \frac{P(c) + P(cc)}{1 - (P(b) + P(bb))}, \quad (5.5)$$

with the numerator giving the probability to identify c jets and the denominator the probability to identify light-flavour or c jets. The comparison with the DeepCSV algorithm used for c tagging should be considered as an illustration for the performance of future c taggers since the working points are not yet defined and the efficiency in data is not yet measured.

Figure 20. Misidentification probability for b jets (left) or light-flavour jets (right) versus c jet identification efficiency for various c tagging algorithms applied to jets in $t\bar{t}$ events.

6 Identification of b jets in boosted topologies

6.1 Boosted b jet identification with the CSVv2 algorithm

At the high centre-of-mass energy of the LHC, particles decaying to b quarks can be produced with a large Lorentz boost. Examples are boosted top quarks decaying to $bW \rightarrow bq\bar{q}$, or boosted Higgs or Z bosons decaying to $b\bar{b}$. As a result of the large boost of the parent particle the decay products often give rise to overlapping jets. In order to capture all the decay products, the jets are reconstructed with a distance parameter of $R = 0.8$ (AK8). Jet substructure techniques can then be applied to resolve the subjets corresponding to the decay products in the AK8 jet [45–48]. In this paper, the soft-drop algorithm [45, 46], which recursively removes soft wide-angle radiation from a jet, is used to resolve the substructure of the AK8 jets. The subjet axes are obtained by reclustering the jet constituents using the anti- k_T algorithm and undoing the last step of the clustering procedure.

When the decay of the boosted particle contains a b quark, b tagging can be applied either on the AK8 jet or on its subjets. In both cases the CSVv2 algorithm is used. In the first approach the CSVv2 algorithm is applied to the AK8 jet but using looser requirements for the track-to-jet and vertex-to-jet association criteria, consistent with the $R = 0.8$ parameter. In the second approach the CSVv2 algorithm is applied to the subjets. The two approaches are illustrated by the scheme in figure 21 (left and middle).

Figure 21. Schematic representation of the AK8 jet (left) and subjet (middle) b tagging approaches, and of the double-b tagger approach (right).

To illustrate the performance of b tagging in various boosted topologies, AK8 and subjet b tagging are compared in figures 22 and 23. When studying the performance of b tagging in various boosted topologies, jets originating from the decay of boosted top quarks (boosted top quark jets) are obtained from a Z' sample, where the Z' decays to $t\bar{t}$, with $t \rightarrow bW \rightarrow bq\bar{q}$. The boosted top quark jets are then defined as jets containing at least one b hadron. Jets originating from the decay of boosted Higgs bosons ($H \rightarrow b\bar{b}$ jets) are obtained from a Kaluza-Klein graviton sample, where the graviton decays to two Higgs bosons, with $H \rightarrow b\bar{b}$. The $H \rightarrow b\bar{b}$ jets are then defined as jets containing at least two b hadrons. Jets from a sample of inclusive multijet events are used to determine the misidentification probability.

To obtain a performance similar to what is expected in physics analyses, the jet mass is used to select jets consistent with the top quark or Higgs boson mass. While the jet mass for these particles arises from the kinematics of the decay products present in the jet, the single-parton jet mass arises mostly from soft-gluon radiation. This soft radiation can be removed by applying jet grooming methods [49–51], shifting the single-parton jet mass to smaller values. In this paper, jet pruning [51] is applied to the AK8 jets. The jet mass obtained from the jet four-momentum after pruning is referred to as the pruned jet mass. Jets are then selected when they have a pruned jet mass between 50 (135) and 200 GeV for b tagging boosted $H \rightarrow b\bar{b}$ (top quark) jets.

Figure 22. Misidentification probability for jets in an inclusive multijet sample versus the efficiency to correctly tag boosted top quark jets. The CSVv2 algorithm is applied to three different types of jets: AK8 jets, their subjets, and AK4 jets matched to AK8 jets. The AK8 jets are selected to have a pruned jet mass between 135 and 200 GeV, and $300 < p_T < 500$ GeV (left), or $1.2 < p_T < 1.8$ TeV (right).

Figure 22 shows the b tagging efficiency for boosted top quark jets versus the misidentification probability using jets from a background sample of multijet events. The performance of AK8 and subjet b tagging is compared. When b tagging is applied to the subjets of boosted top quark jets, at least one of the subjets is required to be tagged. In addition, the performance of b tagging applied to AK4 jets matched to AK8 jets within $\Delta R(\text{AK4}, \text{AK8}) < 0.4$ is also shown. When b tagging is applied to AK4 jets matched to the AK8 jet, at least one of the AK4 jets is required to be tagged. In figure 22 (left), for jets with $300 < p_T < 500$ GeV, the AK8 jet b tagging is more efficient than AK4 jet b tagging. In contrast, in figure 22 (right), for jets with $p_T > 1200$ GeV, AK8 and AK4 jet b tagging perform similarly. This can be understood as due to the fact that at large jet p_T most of the tracks and the secondary vertex are also present in the AK4 jet because of the larger boost.

In both cases, subjet b tagging is more efficient than AK8 jet b tagging when identifying the b jet from the boosted top quark decay.

Figure 23. Misidentification probability using jets in a multijet sample (upper), for $g \rightarrow b\bar{b}$ jets (middle), and for single b jets (lower), versus the efficiency to correctly tag $H \rightarrow b\bar{b}$ jets. The CSVv2 algorithm is applied to three different types of jets: AK8 jets, their subjets, and AK4 jets matched to AK8 jets. For the subjet b tagging curves, both subjets are required to be tagged. The double-b tagger, described in section 6.2, is applied to AK8 jets. The AK8 jets are selected to have a pruned jet mass between 50 and 200 GeV, and $300 < p_T < 500$ GeV (left), or $1.2 < p_T < 1.8$ TeV (right).

Figure 23 shows the efficiency for identifying $H \rightarrow b\bar{b}$ jets versus the misidentification probability using jets from a background sample of inclusive multijet events, $g \rightarrow b\bar{b}$ jets or single b jets. When b tagging is applied to the subjets of the $H \rightarrow b\bar{b}$ jet, both subjets are required to be tagged. Similarly, both AK4 jets matched with the AK8 jet are required to be tagged.

When the misidentification probability is determined using inclusive multijet events, as illustrated in the upper panels of figure 23, AK8 jet b tagging performs well at the highest $H \rightarrow b\bar{b}$ jet tagging efficiencies, while subjet b tagging performs better at lower $H \rightarrow b\bar{b}$ jet tagging efficiencies. This can be understood as follows. Some of the input variables used in the CSVv2 tagger rely on the jet axis, as mentioned in section 5.1.2. An example is the ΔR between the secondary vertex flight direction and the jet axis. This variable is expected to have, on average, a smaller value for b jets compared to other jets, as can be seen in the right panel of figure 10. When b tagging is applied to the AK8 jet, the AK8 jet axis is used to calculate some of the variables. However, when two b hadrons are present in the jet, the ΔR between the secondary vertex flight direction and the AK8 jet axis or between the track and the AK8 jet axis may be quite large. Therefore, it is better to calculate these variables with respect to their respective subjet axes. On the other hand, at the highest $H \rightarrow b\bar{b}$ jet tagging efficiencies, subjet b tagging does not fully use variables that rely on the information of the full AK8 jet, such as the number of secondary vertices. This results in a worse performance of subjet b tagging compared to AK8 jet b tagging at the highest $H \rightarrow b\bar{b}$ jet tagging efficiencies.

The middle panels of figure 23 show the efficiency for $H \rightarrow b\bar{b}$ jets versus the misidentification probability for $g \rightarrow b\bar{b}$ in multijet events. Both for jets with $300 < p_T < 500$ GeV and $1.2 < p_T < 1.8$ TeV, subjet b tagging performs better than AK8 jet b tagging. This is understood as due to the fact that the information from both b hadrons is better used by the subjet b tagging approach.

As can be seen in the bottom panels of figure 23, also in the case where the background is composed of single b jets, subjet b tagging performs better. The lower misidentification probability at the same efficiency is explained by the fact that for the subjet b tagging, the two subjets are required to be tagged. Requiring both subjets to be tagged while there is only one b hadron present in the background jets results in a lower misidentification probability. It is worth noting that these performance curves look very similar to the performance curves obtained when b jets from boosted top quarks are considered as background instead of single b jets from multijet events.

The left panels in figure 23 demonstrate that AK8 jet b tagging is more efficient than AK4 jet b tagging using jets with $300 < p_T < 500$ GeV. The reason is that at low jet p_T not all the tracks and secondary vertex are associated with the two AK4 jets, while they are associated with the AK8 jet. In contrast, using jets with $p_T > 1200$ GeV, requiring the two AK4 jets to be tagged results in a similar performance or better than when the AK8 jet is required to be tagged. This can be explained by the fact that the high jet p_T results in tracks and secondary vertices that are more collimated and fully contained in the AK4 jets.

Figures 22 and 23 demonstrate that the performance of subjet and AK8 jet b tagging depends not only on the signal jets to be b tagged and on the background jets under consideration, but also on the jet p_T .

6.2 The double-b tagger

As mentioned in the previous section, the approaches of b tagging AK8 jets, as well as applying subjet b tagging, have limitations when identifying $H \rightarrow b\bar{b}$ jets. In this section, a novel approach is presented to discriminate $H \rightarrow b\bar{b}$ candidates from single-parton jets in multijet events. The strategy followed when developing the new “double-b” tagging algorithm is to fully use not only the presence of two b hadrons inside the AK8 jet but also the correlation between the directions of

the momenta of the two b hadrons. Although the algorithm is developed using simulated $H \rightarrow b\bar{b}$ events, any dependence of the algorithm performance on the mass or p_T of the $b\bar{b}$ pair is avoided. This strategy allows the usage of the tagger in physics analyses with a large range of jet p_T . The dependence on the jet mass is avoided as this variable is often used to define a region for the estimation of the background. In addition, this strategy also permits the use of the double-b tagger for the identification of boosted $Z \rightarrow b\bar{b}$ jets or any other boosted $b\bar{b}$ resonance where the kinematics of the decay products are similar.

A variable sensitive to the substructure is the N-subjettiness, τ_N [47], which is a jet shape variable, computed under the assumption that the jet has N subjets, and it is defined as the p_T -weighted distance between each jet constituent and its nearest subjet axis (ΔR):

$$\tau_N = \frac{1}{d_0} \sum_k p_T^k \min(\Delta R_{1,k}, \dots, \Delta R_{N,k}), \quad (6.1)$$

where k runs over all jet constituents. The normalization factor is $d_0 = \sum_k p_T^k R_0$ and R_0 is the original jet distance parameter, i.e. $R_0 = 0.8$. The τ_N variable has a small value if the jet is consistent with having N or fewer subjets. The subjet axes are used as a starting point for the τ_N minimization. After the minimization, the τ_N axes, also called τ axes, are obtained. These are then used to estimate the directions of the partons giving rise to the subjets, as schematically illustrated in figure 21 (right).

Many of the CSVv2 variables are also used in the double-b tagger algorithm. The variables rely on reconstructed tracks, secondary vertices obtained using the IVF algorithm, as well as the system of two secondary vertices. Tracks with $p_T > 1$ GeV are associated with jets in a cone of $\Delta R < 0.8$ around the jet axis. Each track is then associated with the closest τ axis, where the distance of a track to the τ axis is defined as the distance at their point of closest approach. The selection requirements applied to tracks in the CSVv2 algorithm are also applied here, using the τ axis instead of the jet axis. The reconstructed secondary vertices are associated first with jets in a cone $\Delta R < 0.7$ and then to the closest τ axis within that jet. For each τ axis, the track four-momenta of the constituent tracks from all the secondary vertices associated with a given τ axis are added to compute the secondary vertex mass and p_T for that τ axis.

Input variables are selected that discriminate between $H \rightarrow b\bar{b}$ jets and other jet flavours, and that improve the discrimination against the background from inclusive multijet production by at least 5% compared to the performance of the tagger without the variable. In addition, as mentioned earlier, variables are chosen that do not have a strong dependence on the jet p_T or jet mass. This procedure resulted in the following list of variables:

- The four tracks with the highest impact parameter significance.
- The impact parameter significance of the first two tracks ordered in decreasing impact parameter significance, for each τ axis.
- The 2D impact parameter significance, of the first two tracks (first track) that raise the total mass above 5.2 (1.5) GeV. These tracks are obtained as explained in section 5.1.2 in the context of the CSVv2 algorithm. In the case of the highest threshold, also the second track above the threshold mass is used. The thresholds of 5.2 GeV and 1.5 GeV are related to the b and c hadron masses, respectively.

- The secondary vertex energy ratio, defined as the total energy of all secondary vertices associated with a given τ axis divided by the total energy of all the tracks associated with the AK8 jet that are consistent with the primary vertex, for each of the two τ axes.
- The number of secondary vertices associated with the jet.
- The 2D secondary vertex flight distance significance, for the secondary vertex with the smallest uncertainty on the 3D flight distance, for each of the two τ axes.
- The ΔR between the secondary vertex with the smallest 3D flight distance uncertainty and its τ axis, for each of the two τ axes.
- The relative pseudorapidity, η_{rel} , of the tracks from all secondary vertices with respect to their τ axis for the three leading tracks ordered in increasing η_{rel} , for each of the two τ axes.
- The total secondary vertex mass, defined as the invariant mass of all tracks from secondary vertices associated with the same τ axis, for each of the two τ axes.
- The information related to the system of two secondary vertices, the z variable, defined as:

$$z = \Delta R(SV_0, SV_1) \frac{p_T(SV_1)}{m(SV_0, SV_1)} \quad (6.2)$$

where SV_0 and SV_1 are the secondary vertices with the smallest 3D flight distance uncertainty associated with the two τ axes, $p_T(SV_1)$ is the p_T of the secondary vertex associated with the second τ axis, and $\Delta R(SV_0, SV_1)$ is the distance between the two secondary vertices, and $m(SV_0, SV_1)$ is the invariant mass corresponding to the summed four-momenta of the two secondary vertices.

The most discriminating variables are the impact parameter significance for the most displaced tracks, the 2D impact parameter significance for the first track above the (5.2 GeV) b-hadron mass threshold, and the secondary vertex energy ratio for the secondary vertex with the smallest 3D flight distance uncertainty (SV_0).

Figure 24 shows the distributions for some of the input variables for the signal $H \rightarrow b\bar{b}$ jets and using jets from inclusive multijet production containing zero, one, or two b quarks. Distributions are shown separately for $g \rightarrow b\bar{b}$, single b quark, and light-flavour jets production. The secondary vertex multiplicity and the vertex energy ratio for SV_0 , along with the impact parameter significance of the first track raising the total invariant mass of all tracks above the b hadron mass threshold show a good separation between the $H \rightarrow b\bar{b}$ jets and the different background contributions. The z variable, eq. (6.2), shows good discrimination against $g \rightarrow b\bar{b}$ jets since it uses the different kinematic properties of the $H \rightarrow b\bar{b}$ and $g \rightarrow b\bar{b}$ decays.

Several variables related to the properties of soft leptons arising from the b hadron decay were also investigated. Despite a small gain in performance, these variables were excluded as input variables since they could introduce a bias in the efficiency measurement from data. The bias could arise when using muon information both to define input variables and to select a sample of jets containing a muon for the efficiency measurement in data, presented in section 9.

Figure 24. Distribution of 2D impact parameter significance for the most displaced track raising the mass above the b hadron mass threshold as described in the text (upper left), number of secondary vertices associated with the AK8 jet (upper right), vertex energy ratio for the secondary vertex with the smallest 3D flight distance uncertainty (lower left), and z variable described in the text (lower right). Comparison between $H \rightarrow b\bar{b}$ jets from simulated samples of a Kaluza-Klein graviton decaying to two Higgs bosons, and jets in an inclusive multijet sample containing zero, one, or two b quarks. The AK8 jets are selected with $p_T > 300$ GeV and pruned jet mass between 50 and 200 GeV. The distributions are normalized to unit area. The last bin includes the overflow entries.

The discriminating variables are combined using a BDT and the τ_{MVA} package [52]. The training is performed using $H \rightarrow b\bar{b}$ jets from simulated events with a Kaluza-Klein graviton decaying to two Higgs bosons as signal, and jets from inclusive multijet production as background. Jets are selected when they have a pruned mass between 50 and 200 GeV and p_T between 300 and 2500 GeV. The jet p_T distributions for the simulated signal and background jet samples are similar, therefore no dedicated reweighting of the samples was performed.

The distribution of the double- b discriminator values is shown in the upper panel of figure 25. Four working points are defined corresponding to about 75, 65, 45 and 25% signal efficiency for a jet p_T of about 1 TeV. The signal efficiencies and misidentification probabilities as functions of the jet p_T for these four working points are shown in the lower panels of figure 25. The decreasing signal efficiency at high jet p_T originates from the larger collimation of particles, which results in a lower track reconstruction efficiency due to close by hits. The reduced track reconstruction efficiency for high jet p_T results in a lower tagging efficiency for high jet p_T .

Figure 25. Distribution of the double-b tagger discriminator values normalized to unit area for $H \rightarrow b\bar{b}$ jets in simulated samples of a Kaluza-Klein graviton decaying to two Higgs bosons, and for jets in an inclusive multijet sample containing zero, one, or two b quarks (upper). Efficiency to correctly tag $H \rightarrow b\bar{b}$ jets (lower left) and misidentification probability using jets in an inclusive multijet sample (lower right) for four working points of the double-b tagger as a function of the jet p_T . The AK8 jets are selected with $p_T > 300$ GeV and pruned jet mass between 50 and 200 GeV.

The performance of the double-b tagger is compared with that of the CSVv2 tagger applied to AK8 jets or their subjets. The top and middle panels in figure 23 show the performance when the background consists of jets from inclusive multijet production or $g \rightarrow b\bar{b}$ jets. In these cases, the double-b tagger outperforms the AK8 jet and subjet b tagging approaches for all jet p_T ranges. At high jet p_T the improvement is larger compared to low jet p_T , thereby providing an important gain in the searches for heavy resonances where mostly high- p_T jets are expected. When the background is composed of single b jets, as shown in the bottom panels of figure 23, subjet b tagging outperforms the double-b tagger at low jet p_T , while the two approaches are similar at high jet p_T . The lower misidentification probability for single b jets at the same $H \rightarrow b\bar{b}$ jet tagging efficiency for subjet b tagging at low jet p_T is explained by the fact that the two subjets are very well separated at low jet p_T and the variables related to the AK8 jet used in the double-b tagger are less efficient. In contrast, at high jet p_T the subjets are much closer together, resulting in shared tracks and secondary vertices and thereby leading to a more similar performance.

Whether it is better to use subjet b tagging or the double-b tagger in a physics analysis depends strongly on the flavour composition and p_T distribution of the jets from the signal and background processes under consideration.

7 Performance of b jet identification at the trigger level

The identification of b jets at the trigger level is essential to collect events that do not pass standard lepton, jet, or missing p_T triggers, and to increase the purity of the recorded sample for analyses requiring b jets in the final state. The L1 trigger uses information from the calorimeters and muon detectors to reconstruct objects such as charged leptons and jets. Identification of b jets is not possible at that stage as it relies on the reconstructed tracks from charged particles available only at the HLT. In this section, we describe b jet identification at the HLT. A detailed description of the CMS trigger system can be found in ref. [11].

Because of latency constraints at the HLT, it is not feasible to reconstruct the tracks and primary vertex with the algorithms used for offline reconstruction. The time needed for track finding can be significantly reduced if the position of the primary vertex is known. While the position in the transverse plane is defined with a precision of $20\ \mu\text{m}$, its position along the beam line is not known [2]. However, it is possible to obtain a rough estimate of the primary vertex position along the beam line by projecting onto the z direction the position of the silicon pixel tracker hits (pixel detector hits) compatible with the jets. A pixel tracker hit in the barrel (endcap) is compatible with a jet when the difference in azimuthal angle between the hit and the jet is less than 0.21 (0.14). The region along the beam line with the highest number of projected pixel detector hits is most likely to correspond to the position of the primary vertex. This concept is illustrated in figure 26: the direction of the tracks in a jet is assumed to be approximately the same as the direction of the jet obtained using the calorimeter information.

Figure 26. Scheme of the fast primary vertex finding algorithm used to determine the position of the vertex along the beam line. The pixel detector hits from the tracks in a jet are projected along the calorimeter jet direction onto the beam line.

This fast primary vertex (FPV) finding algorithm is sensitive to pixel detector hits from pileup interactions. Therefore, a number of selection requirements based on the shape of the charge deposition clusters associated with the pixel detector hits are applied to select those that most likely correspond to a particle with a large p_T . In addition, only pixel detector hits compatible with up to four leading jets with $p_T > 30\ \text{GeV}$ and $|\eta| < 2.4$ are used. Finally, each pixel detector hit is assigned a weight reflecting the probability that it corresponds to a track in one of the considered jets. The weight is obtained by using information related to the shape of the charge deposition cluster, the azimuthal angle between the jet and the cluster, and the jet p_T . Since the spread of projected hits from the primary vertex is proportional to the distance from the beam line, a larger weight is assigned to pixel detector hits closer to the beam line.

Figure 27 (left) shows that the resolution of the primary vertex along the beam line, Δz , is about 3 mm for simulated multijet events with 35 pileup interactions on average. Here, events are selected if the scalar sum of the calorimeter jet transverse momenta exceeds 250 GeV. The double-peak structure is caused by a bias in the FPV reconstruction that finds the primary vertex closer to the centre of the CMS detector than it is in reality in the simulation. This bias originates from the higher number of projected hits at the centre of the detector because of the detector geometry and pileup interactions. The efficiency of the FPV algorithm to reconstruct the primary vertex within 1.5 cm of its true position along the beam line is close to 99%.

Figure 27. Distribution of residuals on the position of the primary vertex along the beam line using the fast primary vertex finding algorithm described in the text (left), and on the position of the primary vertex along the beam line after refitting with the tracks reconstructed at the HLT (right). The distributions are obtained using simulated multijet events with 35 pileup interactions on average and a flat \hat{p}_T spectrum between 15 and 3000 GeV for the leading jet. Events are selected for which the scalar sum of the p_T of the jets is above 250 GeV. The first and last bin of each histogram contain the underflow and overflow entries, respectively.

Since b tagging relies on the precise measurement of the displaced tracks with respect to the primary vertex, it is crucial to use tracks that use the information of both the pixel and the silicon strip tracker to improve the spatial and momentum resolutions. To reduce the HLT algorithm processing time, these tracks are only reconstructed when originating near the primary vertex and if they are close to the direction of the leading jets, sorted according to decreasing jet p_T . Up to eight jets with $p_T > 30$ GeV and $|\eta| < 2.4$ are considered in an event. In the first step, the trajectories of charged particles are reconstructed from the pixel detector hits. To reduce the reconstruction time, tracks are only reconstructed when they have a longitudinal (transverse) impact parameter below 15 (2) mm and are compatible with the direction of one of the jets. For simulated $t\bar{t}$ events with 35 pileup interactions on average, this approach of regional pixel tracking reduces the track reconstruction time by a factor of almost 40 with respect to pixel tracking without constraints. Using the reconstructed pixel tracks, the efficiency to find the primary vertex within 0.2 mm of its true position along the beam line is around 97.5%. To increase the efficiency even further, the variable

$$R = \frac{\sum_{j=1}^2 \sum_i p_{T}^{i,j}}{\sum_{j=1}^2 p_{T}^j} \quad (7.1)$$

is defined, where $p_{T}^{i,j}$ is the p_T of track i associated with the leading or subleading jet ($j = 1$ or 2)

and p_T^j is the p_T of jet j obtained from the calorimeter deposits. To calculate R , tracks from the two leading jets are used if they have a χ^2 of the track fit below 20, which reduces the effect of tracks reconstructed from a wrong combination of pixel hits. The impact of mismeasured tracks is reduced by setting the track p_T to 20 GeV if it is larger than this value. If the primary vertex position is not correctly reconstructed, the value of R will be small. If $R < 0.10$, the reconstruction of pixel detector tracks is run without the primary vertex position and using instead the direction of the two leading jets. The pixel detector tracks obtained in this way are then used to obtain a new position for the primary vertex, partially recovering the efficiency loss. The primary vertex position for all events is refitted using the reconstructed pixel detector tracks, resulting in a resolution that is much improved, as can be seen in figure 27 (right). Pairs of vertices that are closer than $70 \mu\text{m}$ to each other are merged into a single vertex. After the full procedure, the efficiency to find the primary vertex within 0.2 mm of its true position is larger than 98.5%, and the resolution on the position of the primary vertex along the beam line is less than $60 \mu\text{m}$, using simulated multijet events with 35 pileup interactions on average.

In the second step, the tracks are reconstructed using the information from the pixel and strip detectors. An iterative procedure is applied that is similar to the offline track reconstruction except for the number of iterations and the seeds used for track finding in each iteration. In the first iteration, the pixel tracks reconstructed as described above with $p_T > 0.9 \text{ GeV}$ are used as seeds if they have a transverse (longitudinal) impact parameter below 1 (3) mm. For the second iteration, triplets of pixel hits are used with $p_T > 0.5 \text{ GeV}$ and a transverse (longitudinal) impact parameter < 0.5 (1) mm. The last iteration uses pairs of pixel hits with $p_T > 1.2 \text{ GeV}$ and a transverse (longitudinal) impact parameter < 0.25 (0.5) mm. It is worth noting that the requirements on the impact parameter do not have a large impact on the reconstruction efficiency for displaced tracks. When refitting the primary vertex using the reconstructed tracks, the resolution on its position along the beam line further improves to less than $30 \mu\text{m}$, as shown in figure 27.

The reconstructed tracks and the refitted primary vertex are then used to reconstruct secondary vertices with the IVF vertex reconstruction algorithm. These vertices and tracks are then used as input for the CSVv2 algorithm described in section 5. No dedicated training of the CSVv2 algorithm is used at the HLT, as studies have not shown any improvement in performance. The processing time of regional tracking used for b tagging with up to eight leading jets with $p_T > 30 \text{ GeV}$ is on average 87 ms, not including the jet reconstruction time. The processing time was evaluated using data with the highest number of pileup interactions observed in 2016 (49 pileup interactions on average) and selecting events using a trigger threshold of 250 GeV on the scalar sum of the calorimeter jet transverse momenta. As a comparison, the average global processing time of the HLT farm is limited to about 200 ms per event. The b tagging algorithm was run in about 6% of the events accepted by the L1 trigger.

The performance of b tagging at the HLT is evaluated using data collected during 2016, selecting events with at least four calorimeter jets with $p_T > 45 \text{ GeV}$ and $|\eta| < 2.4$ and with the sum of the p_T of the jets at the HLT above 800 GeV. Offline CSVv2 discriminator distributions are shown in figure 28 using all jets (in red) as well as using jets with an HLT CSVv2 discriminator exceeding 0.56 (in blue). An estimate of the reduction factor for the trigger rate when requiring a single b tagged jet at HLT is determined as the number of jets passing the initial trigger, based on the sum of the p_T of the jets, divided by the number of jets passing the trigger and having an

HLT CSVv2 discriminator above 0.56. The b tagging efficiency for a threshold of 0.56 on the HLT CSVv2 discriminator is shown as a function of the offline CSVv2 discriminator value in figure 28 (right). In both panels, the structure at a discriminator value of ≈ 0.5 is caused by jets from pileup interactions. In the right panel, the discontinuity indicates that these jets do not behave exactly in the same manner at the HLT and offline, due to their different track reconstruction. The larger efficiency for CSVv2 discriminator values below 0.05 is due to jets for which the chosen primary vertex at the HLT and offline is different. In particular, the primary vertex position is wrongly reconstructed at the HLT, resulting in an apparent displaced jet with a high CSVv2 discriminator value at the HLT and a small offline CSVv2 discriminator value. The impact of this effect is relatively small since there are only a few jets with an offline CSVv2 discriminator value below 0.05, as can be seen in the left panel.

Figure 28. Offline CSVv2 discriminator distribution for all jets and for jets with a value of the CSVv2 discriminator at the HLT exceeding 0.56 (left), and b tagging efficiency at the HLT as a function of the offline CSVv2 discriminator value (right).

Figure 29 compares the HLT and offline b tagging performance using jets in simulated $t\bar{t}$ events with 35 pileup interactions on average. Events are selected if the scalar sum of the jet transverse momenta exceeds 250 GeV. Up to eight leading jets are used with $p_T > 30$ GeV and $|\eta| < 2.4$. As expected, the b tagging performance of the offline reconstruction is better than at the HLT. The maximum b jet identification efficiency at the HLT is $\approx 95\%$ because of three effects that occur more frequently at the HLT:

- The primary vertex is not reconstructed or not identified as the vertex corresponding to the jets on which the b tagging algorithm is applied.
- Since the track reconstruction efficiency at the HLT is lower, it happens more often that less than two tracks are associated with the jet, resulting in no valid discriminator value being assigned to the jet.
- There are at least two reconstructed tracks, but they do not pass the track selection requirements applied in the CSVv2 algorithm.

In the future, the b tagging performance at the HLT will be further improved by replacing the CSVv2 tagger with the DeepCSV tagger.

Figure 29. Comparison of the misidentification probability for light-flavour jets (left) and c jets (right) versus the b tagging efficiency at the HLT and offline for the CSVv2 algorithm applied on simulated $t\bar{t}$ events for which the scalar sum of the jet p_T for all jets in the event exceeds 250 GeV.

8 Measurement of the tagging efficiency using data

In the previous sections, the performance of the taggers was studied on simulated samples. In this section, we present the methods used to measure the efficiency of the heavy-flavour tagging algorithms applied on the data. In section 8.1, the data are compared to the simulation for a few input variables as well as for the output discriminator distributions. The measurement of the misidentification probability in the data is presented in section 8.2. The tagging efficiency for c and b jets is presented in sections 8.3 and 8.4, respectively. Section 8.5 summarizes a method to measure data-to-simulation scale factors as a function of the discriminator value for the various jet flavours. The results of the various measurements are compared and discussed in section 8.6.

8.1 Comparison of data with simulation

The data are compared to simulation in different event topologies, chosen for their different jet flavour composition, and selected according to the following criteria:

- **Inclusive multijet sample:** events are selected if they satisfy a trigger selection requiring the presence of at least one AK4 jet with $p_T > 40$ GeV. Because of the high event rates only a fraction of the events that fulfill the trigger requirement are selected (prescaled trigger). The fraction of accepted events depends on the prescale value, which varies during the data-taking period according to the instantaneous luminosity. The data are compared to simulated multijet events using jets with $50 < p_T < 250$ GeV. This topology is dominated by light-flavour jets and contains also a contribution of jets from pileup interactions.
- **Muon-enriched jet sample:** events are considered if they satisfy an online selection requiring at least two AK4 jets with $p_T > 40$ GeV of which at least one contains a muon with $p_T > 5$ GeV. Also in this case, the trigger was prescaled. The data are compared to a sample of jets with $50 < p_T < 250$ GeV and containing a muon selected from simulated muon-enriched multijet events. Because of the muon requirement this topology is dominated by jets containing heavy-flavour hadrons.

- **Dilepton $t\bar{t}$ sample:** at trigger level, events are selected by requiring the presence of at least one isolated electron and at least one isolated muon. Offline, the leading muon and electron are required to have $p_T > 25$ GeV and be isolated, as expected for leptonic W boson decays [9, 10]. Events are further considered if they contain at least two AK4 jets with $p_T > 20$ GeV. In this event sample we expect an enrichment in b jets from top quark decays. There is also a small contribution from jets from pileup interactions due to the relatively low threshold on jet p_T .
- **Single-lepton $t\bar{t}$ sample:** events are selected at trigger level by requiring the presence of at least one isolated electron or muon [9, 10]. Offline, exactly one isolated electron or muon is required, satisfying tight identification criteria. The electron (muon) is required to have a $p_T > 40$ (30) GeV and $|\eta| < 2.4$. Events are further considered if they contain at least four jets with $p_T > 25$ GeV. In this event sample a higher fraction of c jets is expected in comparison with the other samples. These c jets arise from the decay of the W boson to quarks.

The distributions of all input variables and output discriminators in the four aforementioned event topologies are monitored to assess the agreement between data and simulation. Figure 30 shows a selection of four input variables. For the secondary vertex variables that are shown the secondary vertices are reconstructed with the IVF algorithm, discussed in section 4.3. In the top left panel, the 3D impact parameter significance of the tracks is shown for jets in the dilepton $t\bar{t}$ sample. The observed discrepancy around zero is explained by the sensitivity of this variable to the tracker alignment and the uncertainty in the track parameters. The top right panel shows the corrected secondary vertex mass for the leading secondary vertex (sorted according to increasing uncertainty in the 3D flight distance), using jets in an inclusive multijet sample. The bottom left panel shows the 3D flight distance significance of the leading secondary vertex using jets in the muon-enriched jet sample. As was the case for the impact parameter significance, the disagreement between the data and the simulation is related to the sensitivity of this variable to the tracker alignment and the uncertainty in the track parameters and hence on the secondary vertex position. The bottom right panel shows the “massVertexEnergyFraction” variable, defined in section 5.2.1, using jets in the single-lepton $t\bar{t}$ sample.

While the simulation models the secondary vertex mass reasonably well, some discrepancies are observed for the impact parameter significance of the tracks and the secondary vertex flight distance. The imperfect modelling of the input variables will also have an impact on the modelling of the output discriminator distributions, which are shown in figure 31. The upper panels show the JP and cMVA_{v2} discriminators using jets in the dilepton $t\bar{t}$ sample. The discontinuities in the distribution of the JP discriminator values are due to the minimum track probability requirement of 0.5%, as explained in section 5.1.1. The middle panels show the CSV_{v2} and DeepCSV discriminators using jets in the muon-enriched sample. The lower panels show the CvsL and the CvsB discriminators, using jets in the inclusive multijet sample. The discontinuities in both distributions arise from jets for which no tracks pass the track selection criteria, as discussed in section 5.2.1. Deviations of up to 20% are observed at the highest discriminator values. These deviations may be related to the modelling of the detector in the simulation and to the accuracy of the generators in their modelling of the parton shower and hadronization. It is therefore important to measure the efficiencies directly from the data. In physics analyses, the difference between the tagging efficiency in the data and

Figure 30. Examples of input variables used in heavy-flavour tagging algorithms in data compared to simulation. Impact parameter significance of the tracks in jets from the dilepton $t\bar{t}$ sample (upper left), corrected secondary vertex mass for the secondary vertex with the smallest uncertainty in the 3D flight distance for jets in an inclusive multijet sample (upper right), secondary vertex flight distance significance for jets in a muon-enriched jet sample (lower left), and distribution of the massVertexEnergyFraction variable described in the text for jets in the single-lepton $t\bar{t}$ sample (lower right). The simulated contributions of each flavour are shown with different colours. The total number of entries in the simulation is normalized to the number of observed entries in data. The first and last bin of each histogram contain the underflow and overflow entries, respectively.

simulation is then corrected for by taking into account a per jet data-to-simulation scale factor

$$SF_f = \varepsilon_f^{\text{data}}(p_T, \eta) / \varepsilon_f^{\text{MC}}(p_T, \eta), \quad (8.1)$$

where $\varepsilon_f^{\text{data}}(p_T, \eta)$ and $\varepsilon_f^{\text{MC}}(p_T, \eta)$ are the tagging efficiencies for a jet with flavour f in data and simulation, respectively. For most of the efficiency measurements, the number of jets in the data is too limited to provide a dependence on the jet $|\eta|$. For those methods, only the dependence on the jet p_T is measured. In simulation, the b/c tagging efficiency (misidentification probability) is defined as the number of b/c (light-flavour) jets that are tagged, according to the working point of a given algorithm (section 5), with respect to the total number of b/c (light-flavour) jets. Using simulated events, the number of jets with flavour f is determined by matching the jets with the generated hadrons. In data, the tagging efficiency is measured with a pure sample of jets with a

Figure 31. Examples of discriminator distributions in data compared to simulation. The JP (upper left) and cMVAv2 (upper right) discriminator values are shown for jets in the dilepton $t\bar{t}$ sample, the CSVv2 (middle left) and DeepCSV (middle right) discriminators for jets in the muon-enriched multijet sample, and the CvsL (lower left) and CvsB (lower right) discriminators for jets in the inclusive multijet sample. The simulated contributions of each jet flavour are shown with different colours. The total number of entries in the simulation is normalized to the number of observed entries in data. The first and last bin of each histogram contain the underflow and overflow entries, respectively.

certain flavour f , using selection requirements that do not bias the jets with respect to the variables used in the tagging algorithm.

8.2 The misidentification probability

The misidentification probability for light-flavour jets is measured with a sample of inclusive multijet events. The inclusive multijet data are collected using triggers requiring at least one jet above a certain p_T threshold, with $p_T > 40$ GeV being its lowest value. Because of the high trigger rates for the lowest trigger thresholds, the triggers are prescaled. The selected events are reweighted to take into account the different prescales for each trigger threshold in order to obtain the same jet p_T distribution as if unprescaled triggers were used. The simulated events are reweighted to match the distribution of the number of pileup interactions in the data.

The negative-tag method [1] is used for the measurement of the misidentification probability and the data-to-simulation scale factor, SF_1 . The method is based on the definition of positive and negative taggers, which are identical to the default algorithms, except that for each jet only tracks with either positive or negative impact parameter values and secondary vertices with either positive or negative flight distance are used. To first order, the discriminator values for negative and positive taggers are expected to be symmetric for light-flavour jets, with nonzero values of the impact parameter and flight distance arising because of resolution effects. Some asymmetries are present for light-flavour jets due to long-lived hadrons, such as K_S^0 and Λ hadrons. The positive and negative discriminator distributions are presented in figure 32 using jets with $p_T > 50$ GeV. For convenience, the discriminator values of the negative taggers are shown with a negative sign. Note that since the cMVA2 and c tagger discriminator values range between -1 and 1 , a shift was introduced such that the positive cMVA2 discriminator is defined between 0 and 2 , while the negative discriminator is shown with a negative sign and obtains values between -2 and 0 . Deviations of up to 10% are observed between the data and simulation for some discriminator values.

Figure 32. Distributions of the DeepCSV (left) and the cMVA2 (right) discriminators for jets in an inclusive multijet sample. For visualization purposes the discriminator output of the negative DeepCSV tagger is shown with a negative sign. For the cMVA2 tagger, the discriminator output of the positive tagger is shifted from $[-1, 1]$ to $[0, 2]$ and the discriminator values of the negative tagger are shown with a negative sign. The simulation is normalized to the number of entries in the data.

We define negative-tagged (positive-tagged) jets as the jets with a discriminator value of the negative (positive) tagger passing the working point of the tagger. The misidentification probability, ε_1 , is determined from the fraction of negative-tagged jets passing the working point, ε^- , in an

inclusive multijet sample

$$\varepsilon_1 = \varepsilon^- R_{\text{LF}} \quad (8.2)$$

where the correction factor $R_{\text{LF}} = \varepsilon_1^{\text{MC}} / \varepsilon^{-,\text{MC}}$ is the ratio of the misidentification probability of light-flavour jets to the negative tagging probability of all jets in simulation. The correction factor R_{LF} is typically between 0.3 and 1, with the exact value depending on the working point and tagger.

Systematic uncertainties in the misidentification probability are related to possible effects that may have an impact on R_{LF} . In particular, the following systematic uncertainties are evaluated:

- **Fraction of heavy-flavour jets:** if the fraction of jets from heavy-flavour quarks in the negative-tag sample increases, the value of R_{LF} decreases. The fraction of b jets has been measured by the CMS collaboration to agree with the simulation within $\pm 20\%$ [53]. To assess the effect of this systematic uncertainty, the fraction of heavy-flavour jets in the simulation is varied by $\pm 20\%$.
- **Gluon fraction:** the fraction of gluon jets affects the misidentification probability in the simulation as well as the negative tagging probability, because of the larger track multiplicity in gluon jets compared to jets originating from light-flavour quarks. In addition, the fraction of gluon jets depends on the parton density and parton showering in the simulation. The systematic effect due to the uncertainty in the fraction of gluon jets is evaluated by varying the gluon fraction by $\pm 20\%$ [54].
- **K_S^0 and Λ decays (V^0):** the observed numbers of reconstructed K_S^0 and Λ hadrons are found to be a factor of 1.30 ± 0.30 and 1.50 ± 0.50 larger than expected [55, 56], respectively. To determine the nominal value of the data-to-simulation scale factor, the amount of reconstructed K_S^0 or Λ hadrons is reweighted in the simulation to be consistent with the observed yields. To obtain the size of the systematic effect due to the reweighting, the fraction of K_S^0 and Λ hadrons is varied by the uncertainty in the measured fraction, i.e. by ± 30 and $\pm 50\%$, respectively.
- **Secondary interactions:** the rate of secondary interactions from photon conversions or nuclear interactions in the pixel tracker layers has been measured with a precision of $\pm 5\%$ [55, 56]. The number of secondary interactions is varied by this amount to obtain the systematic uncertainty in the data-to-simulation scale factor.
- **Mismeasured tracks:** according to the simulation, there are more positive- than negative-tagged jets containing a reconstructed track that cannot be associated with a genuine charged particle. This is expected because the positive-tagged light-flavour jets contain K_S^0 or Λ hadrons, resulting in more hits and hence a higher probability for a wrong combination of those hits leading to a mismeasured track. To correct for this residual effect of mismeasured tracks, a $\pm 50\%$ variation of this contribution is taken into account for the systematic uncertainty in R_{LF} .
- **Sign flip:** the number of jets with a negative tag is sensitive to the angular resolution on the jet axis and 3D impact parameter since these may affect the impact parameter sign. In particular, a difference between data and simulation in the probability of sign flips will affect the ratio of the negative tagging probability in data to that in simulation. The difference between data and

simulation on the fraction of negative-tagged jets with respect to all tagged jets is measured with a muon-enriched jet sample and used to estimate the size of this systematic effect.

- **Sampling:** the dependence of the data-to-simulation scale factor on the event topology is estimated by the trigger dependence of the scale factor. The scale factor is computed separately for each of the trigger requirements used to select the inclusive multijet sample. The maximum variation of the scale factor for these different measurements with respect to the nominal value using the unbiased jet p_T spectrum is taken as the size of the systematic effect.
- **Pileup:** the simulated events are reweighted according to the observed amount of pileup interactions in data. A 5% uncertainty in the total inelastic cross section of pp collisions [57] is propagated to the distribution of the number of pileup interactions to assess the impact of the uncertainty in the pileup reweighting.
- **Statistical uncertainty in the simulation:** the limited amount of simulated multijet events is taken into account as an additional systematic uncertainty.

Figure 33 shows an example of the measured misidentification probabilities, data-to-simulation scale factors, and relative systematic uncertainties for the medium working point of the DeepCSV and cMVA2 taggers. In the top right panel of figure 33, the “step” in the misidentification probability around 450 GeV is caused by the p_T - (and $|\eta|$ -) dependent weights for the jet flavours in the vertex categories in the training of the CSVv2 algorithm, discussed in section 5.1.2. The middle panels in figure 33 show the scale factors as a function of the jet p_T with the result of the fit superimposed. The fit functions are typically parameterized by a third degree polynomial with four free parameters. The dashed lines around the fit function represent the overall statistical and systematic uncertainty in the measurement. For jets with $p_T > 1000$ GeV the uncertainty in the scale factor is doubled. The scale factors are typically larger than one in a broad jet p_T range. The relative precision that is achieved on the scale factors for light-flavour jets when using b tagging algorithms is 5–10% for the loose working point and rises to 20–30% for the tight working point using jets with $20 < p_T < 1000$ GeV. The statistical uncertainty is typically a factor of 10 times smaller than the systematic uncertainty. For the c tagger, the relative precision varies between 3 and 7% for the loose and tight working points, respectively. The reason for the smaller uncertainty for the c tagger compared to the b taggers is the different definition of the working points. The working points for the c tagger have a much higher misidentification probability for light-flavour jets, ranging from over 90% for the loose working point to about a per cent for the tight working point, compared to 10% and 0.1%, respectively, for the b tagging algorithms (section 5). The tight working point of the c tagger corresponds to a misidentification probability that is in between the loose and medium working points of the b taggers. Taking this into account, the corresponding systematic uncertainties are of a similar size.

8.3 The c jet identification efficiency

In this section, the methods are presented to obtain a jet sample enriched in c quark content, which is subsequently employed to measure the efficiency for (mis)identifying c jets in data. The efficiency in data and simulation is then used to determine the data-to-simulation scale factor for c jets, SF_c ,

Figure 33. Misidentification probability, data-to-simulation scale factors, and relative uncertainty in the scale factors for light-flavour jets for the medium working point of the DeepCSV (left) and cMVA2 (right) algorithm. The upper panels show the misidentification probability in data and simulation as a function of the jet p_T . The middle panels show the scale factors for light-flavour jets, where the solid curve is the result of a fit to the scale factors, and the dashed lines represent the overall statistical and systematic uncertainty in the measurement. The lower panels show the relative systematic uncertainties in the scale factors for light-flavour jets. The sampling and pileup uncertainties are not shown since they are below 1%, but are included in the total systematic uncertainty covered by the black dots.

for each algorithm and working point. The first method relies on the $W + c$ topology. The second method uses c jets from the W boson decay to quarks in the single-lepton $t\bar{t}$ topology, where one of the W bosons decays into quarks and the other one into leptons.

8.3.1 Measurement relying on $W + c$ events

The efficiency to identify c jets using heavy-flavour jet identification algorithms is measured with a sample enriched in c jets obtained from events with a W boson produced in association with a c quark. At leading order, the production of a W boson in association with a c quark proceeds mainly through $s + g \rightarrow W^- + c$ and $\bar{s} + g \rightarrow W^+ + \bar{c}$ as shown in figure 34 (left and middle). A key property of this production process is that the c quark and W boson have opposite-sign (OS) electric charge. The dominant background are $W + q\bar{q}$ events, which are produced with an equal amount of OS and

same-sign (SS) events, as can be seen in figure 34 (right). After the event selection, a sample with a high purity of $W + c$ events is obtained by subtracting the SS distribution of a variable from the OS distribution for that variable. The remaining events are referred to as “OS-SS”.

Figure 34. Leading order production of $W + c$ with opposite-sign electric charges (left and middle), and of $W + q\bar{q}$ through gluon splitting (right). In gluon splitting there is an additional c quark with the same sign as the W boson.

The $W + c$ events are selected according to the criteria of ref. [58]. Events are selected by requesting one isolated electron (muon) with a p_T^ℓ above 34 (26) GeV and satisfying medium (tight) identification criteria [9, 10]. When the event has more than one isolated electron or muon satisfying the selection criteria, the highest- p_T lepton is considered as the lepton from the W boson decay. The contribution from $Z + \text{jets}$ events is reduced by vetoing events with a same-flavour dilepton invariant mass between 70 and 110 GeV. To reduce the background from multijet events to a negligible level, the transverse mass $M_T = \sqrt{p_T^\ell p_T^{\text{miss}} [1 - \cos(\phi^\ell - \phi^{\text{miss}})]}$ is required to be larger than 55 GeV. In this expression, ϕ^ℓ and ϕ^{miss} (p_T^ℓ and p_T^{miss}) are the azimuthal angles (transverse momenta) of the isolated lepton and the \vec{p}_T^{miss} vector, respectively. At least one jet is required in the tracker acceptance, with $p_T > 25$ GeV and separated from the isolated lepton by $\Delta R > 0.5$. In addition, the leading jet should contain a nonisolated soft muon among the jet constituents with $p_T < 25$ GeV. The charge of the c quark is determined from the charge of the soft muon inside the jet. The OS (SS) events are then defined as events for which the muon in the jet has the opposite (same) charge as the isolated lepton from the W decay. After these requirements, the expected signal purity is about 60% for $W \rightarrow \mu\nu$ events and 80% for $W \rightarrow e\nu$ events. Remaining $Z + \text{jets}$ and $t\bar{t}$ events are the main sources of background for the $W \rightarrow \mu\nu$ channel, and $t\bar{t}$ events for the $W \rightarrow e\nu$ channel. As an example, the distributions of the c tagger discriminators are shown in figure 35 for the OS-SS sample, for the $W \rightarrow \mu\nu$ and $W \rightarrow e\nu$ channels combined.

The efficiency to tag a c jet using a certain working point and tagger is obtained as the fraction of tagged c jets over the total number of c jets in $W + c$ events in the OS-SS sample:

$$\varepsilon_c = \frac{N(W + c)_{\text{tagged}}^{\text{OS-SS}}}{N(W + c)^{\text{OS-SS}}}, \quad (8.3)$$

where the number of $W + c$ events in data, $N(W + c)^{\text{OS-SS}}$, is obtained as the observed number of OS-SS events times the fraction of $W + c$ events among these, derived from simulation as $f_{W+c}^{\text{MC}} = 1 - f_{\text{bkg}}^{\text{MC}}$. Analogously, $N(W + c)_{\text{tagged}}^{\text{OS-SS}}$ corresponds to the number of $W + c$ events with a tagged c jet, obtained as the observed number of OS-SS events with a tagged c jet times the fraction of expected $W + c$ events with a tagged c jet, where the fraction is obtained as $f_{W+c}^{\text{tagged,MC}} = 1 - f_{\text{bkg}}^{\text{tagged,MC}}$. The simulated c jet tagging efficiency is obtained by repeating the procedure on simulated data.

Figure 35. Distribution of the CvsL (left) and CvsB (right) discriminators in the $W \rightarrow \mu\nu$ and $W \rightarrow e\nu$ channels after the OS-SS subtraction. The spikes originate from jets without a track passing the track selection criteria, as discussed in section 5.2.1. The last bin includes the overflow entries.

Apart from the statistical uncertainty, the measurement may also be affected by several sources of systematic effects:

- **Background subtraction:** the number of $W+c$ events in data is obtained under the assumption that the fraction of (tagged) background events in data and simulation is the same. The effect of this assumption is quantified by varying $f_{\text{bkg}}^{\text{MC}}$ and $f_{\text{bkg}}^{\text{tagged,MC}}$ by 50%. The impact on the measured efficiency for tagging c jets is of the order of 2%, becoming one of the dominant uncertainties.
- **Branching fraction of $D \rightarrow \mu X$ and fragmentation of $c \rightarrow D$:** the branching fractions for $D \rightarrow \mu X$ are varied to match the latest PDG data [35]. In particular, the branching fractions are shifted by -2% for $D^+ \rightarrow \mu X$, $+13\%$ for $D^0 \rightarrow \mu X$, and $+16\%$ for $D_s \rightarrow \mu X$. In addition, also the fragmentation rate of a c quark to a D meson is varied to be consistent with the PDG data [59]. This implies the following `PYTHIA 8` variations: $+37\%$ for $c \rightarrow D^+$, -9% for $c \rightarrow D^0$, and -33% for $c \rightarrow D_s$. The difference in the measured c jet tagging efficiency after this simultaneous variation is less than 1% and is taken as a systematic uncertainty.
- **Number of tracks:** the uncertainty in the modelling of the number of selected tracks per jet in the simulation is taken into account by reweighting the distribution to match the data and remeasuring the data-to-simulation scale factor. The difference between the nominal scale factor value and the one after reweighting is less than 1%.
- **Soft-muon requirement:** requiring a muon in a jet may introduce a potential bias in the efficiency measurement when the tagger also relies on muon variables, as is the case for the c tagger and the `cMVA2` tagger. The bias may arise if the tagger response is different for jets with and without a soft lepton. The potential bias is estimated by repeating the measurement using a modified version of the tagger, which treats the muon as a track and assigns a default value to the soft-muon input variables. The difference between the values measured with the modified tagger and the default one is taken as systematic uncertainty. The effect of this variation is less than 3%. This is the dominant systematic uncertainty.

- **Jet energy scale:** since the measurements are performed in bins of jet p_T , the fraction of jets in each bin may vary depending on the jet energy corrections. The data-to-simulation scale factors are remeasured after varying the jet energies by ± 1 standard deviation of the nominal jet energy scale. The systematic effect due to this variation is less than 1%.
- **Electron and muon efficiency:** the uncertainties related to the lepton reconstruction and identification are taken into account by varying the corresponding correction factors within their uncertainty and reevaluating the efficiency for tagging c jets. The effect of this variation is smaller than 1%.
- **Pileup:** the effect of the uncertainty in the number of additional pileup interactions is evaluated as described in section 8.2, having an impact on the c tagging efficiency below 1%.
- **Factorization and renormalization scales:** in ref. [58] the normalized cross section for W+c events has been measured and the impact of the factorization and renormalization scales used at matrix element and parton shower levels was evaluated. The systematic uncertainty related to the variation of these scales was found to be well below 1% because of the cross section normalization. When measuring data-to-simulation scale factors, this systematic uncertainty also cancels in the ratio.
- **Parton distribution functions:** the NNPDF parton densities are varied within their uncertainties resulting in additional templates for the systematic uncertainty. The effect was found to be less than 1%.

The total systematic uncertainty in the data-to-simulation scale factor measurement is obtained as the quadratic sum of the individual systematic uncertainties.

The c jet tagging efficiency and the data-to-simulation scale factor SF_c are computed as a function of jet p_T and presented in figure 36 for the loose and medium working points of the c tagger. Scale factors for misidentifying c jets are also derived for the b tagging algorithms.

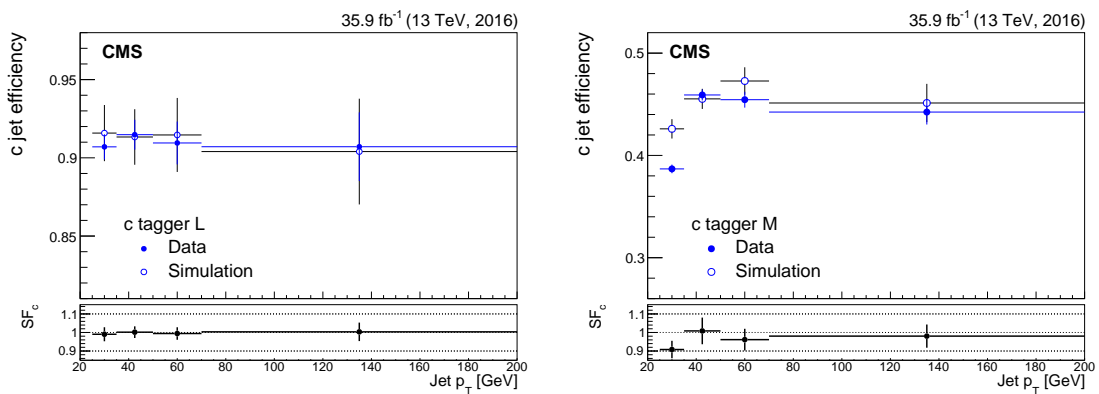

Figure 36. Efficiency for tagging c jets in data and simulation as a function of the jet p_T , and corresponding data-to-simulation scale factors (bottom panels) for the loose (left) and medium (right) working points of the c tagger.

8.3.2 Measurement relying on the single-lepton $t\bar{t}$ events

If a W boson decays hadronically, the decay contains a c quark in about 50% of the cases. Therefore, in a pure sample of single-lepton $t\bar{t}$ events, about one event out of two will contain a c jet. Because of the particular decay chain of the top quark, the energy of up-type quarks from the W boson decay is, on average, larger than for down-type quarks. This property, verified in simulated $t\bar{t}$ events, is used to obtain samples of jets enriched and depleted in c quarks. The c tagging efficiency is obtained by fitting the distribution of a variable in both of these samples simultaneously to the data, as will be explained in the following.

Events are selected by requiring exactly one isolated muon satisfying the tight identification criteria and with a p_T exceeding 30 GeV [10]. In addition, exactly four jets with $p_T > 30$ GeV are required. All objects are required to be within the tracker acceptance. The background from multijet events is reduced to a negligible level by requiring the reconstructed transverse mass formed by the muon and \vec{p}_T^{miss} , to be $M_T(\mu, p_T^{\text{miss}}) > 50$ GeV. The $t\bar{t}$ event is reconstructed by assigning the jets to the quarks from which they originate, using a mass discriminant λ_M . This mass discriminant is defined as the 2D probability for the invariant mass of a correct combination of two jets to be consistent with the W boson mass, and the invariant mass of a correct three-jet combination to be consistent with the top quark mass. The jet-quark assignment for which the negative logarithm of λ_M is minimal is chosen as the reconstructed $t\bar{t}$ topology candidate for the event. The two jets assigned to the b quarks from the top quark decay are required to be b-tagged; one jet should pass the tight working point of the CSVv2 tagger and the other one its loose working point. By requiring those jets to be b-tagged only after the jet-quark assignment is done, a bias is avoided on the c jet tagging efficiency measurement. Figure 37 shows the distribution of λ_M and of the highest (leading) and second-highest (subleading) energy for the two jets corresponding to the W decay after the full event selection. The $t\bar{t}$ simulation is divided into three different subsamples:

- **$t\bar{t}$, right W_h :** the W boson is correctly reconstructed, hence the two jets are correctly assigned to the quarks from the W boson decay.
- **$t\bar{t}$, wrong W_h :** the W boson is wrongly reconstructed, hence at least one of the two jets is not correctly assigned to the quarks from the W boson decay.
- **Other $t\bar{t}$ decay:** the generated event is not a single-lepton $t\bar{t}$ event.

The non- $t\bar{t}$ background is relatively small, with contributions from single top quark, W + jets, Z + jets, and multijet production.

From figure 37 it is clear that the λ_M distribution has discrimination power to separate jets that are correctly associated with the W boson decay and jets for which this is not the case. Therefore, this distribution is used to measure the efficiency and data-to-simulation scale factor for c jets.

Four event categories are defined according to whether or not the jets that are assigned to the W boson decay (i.e. the probe jets) pass the tagging working point for which the efficiency is to be measured:

- **Notag:** both probe jets fail the tagging requirement;
- **Leadtag:** only the most energetic probe jet passes the tagging requirement;

Figure 37. Distributions of the leading- (left) and subleading- (middle) jet energy as well as of the mass discriminant λ_M (right) after the full event selection, jet-quark assignment, and b tagging requirement on the two b jet candidates.

- **Subleadttag:** only the least energetic probe jet passes the tagging requirement; and
- **Ditag:** both probe jets pass the tagging requirement.

For $t\bar{t}$ events in the “right W_h ” subsample, the number of events in the various categories can be written as:

$$\begin{aligned}
 N_{\text{notag}} &= N_T((1 - \varepsilon_1^c)(1 - \varepsilon_2^{\text{LF}})f_1 + (1 - \varepsilon_1^{\text{LF}})(1 - \varepsilon_2^c)f_2 + (1 - \varepsilon_1^{\text{LF}})(1 - \varepsilon_2^{\text{LF}})(1 - f_1 - f_2)), \\
 N_{\text{leadttag}} &= N_T(\varepsilon_1^c(1 - \varepsilon_2^{\text{LF}})f_1 + \varepsilon_1^{\text{LF}}(1 - \varepsilon_2^c)f_2 + \varepsilon_1^{\text{LF}}(1 - \varepsilon_2^{\text{LF}})(1 - f_1 - f_2)), \\
 N_{\text{subtag}} &= N_T((1 - \varepsilon_1^c)\varepsilon_2^{\text{LF}}f_1 + (1 - \varepsilon_1^{\text{LF}})\varepsilon_2^c f_2 + (1 - \varepsilon_1^{\text{LF}})\varepsilon_2^{\text{LF}}(1 - f_1 - f_2)), \\
 N_{\text{ditag}} &= N_T(\varepsilon_1^c\varepsilon_2^{\text{LF}}f_1 + \varepsilon_1^{\text{LF}}\varepsilon_2^c f_2 + \varepsilon_1^{\text{LF}}\varepsilon_2^{\text{LF}}(1 - f_1 - f_2)),
 \end{aligned} \tag{8.4}$$

with N_T the total number of events, $f_{1,2}$ the fraction of leading (subscript 1) and subleading (subscript 2) c jets, and $\varepsilon_{1,2}^{c,L}$ the tagging efficiencies for leading and subleading jets for c (superscript c) and light-flavour (superscript LF) quarks. The indentation highlights the different components, namely the probability for a jet pair to be composed of (c, light), (light, c), and (light, light) jet flavours as (leading, subleading) jets from the W boson decay. The (c, c) pair is not present since it is unphysical. Instead of measuring the efficiency $\varepsilon_{1,2}^{c,\text{LF}}$, the data-to-simulation scale factor is measured. Therefore, $\varepsilon_{1,2}^{c,\text{LF}}$ is replaced with $SF_{c,l}\varepsilon_{1,2}^{c,\text{LF}}(\text{MC})$ in eq. (8.4). In the latter expression $\varepsilon_{1,2}^{c,\text{LF}}(\text{MC})$ is the efficiency obtained from simulation and SF_c (SF_l) is the scale factor for c (light-flavour) jets. To reduce the number of unknown parameters, the value for SF_l is taken to be the measured value using the negative-tag method presented in section 8.2.

A maximum likelihood fit is performed on the binned λ_M distributions using the signal and background distributions (templates) obtained from the simulated events. The measurement is performed inclusively, since the selected number of events is not sufficient for a precise measurement in bins of jet p_T . Systematic uncertainties are included in the fit as nuisance parameters that are profiled. Each nuisance parameter is floating with a Gaussian constraint around the central value with a standard deviation proportional to the systematic uncertainty. It is possible to group the systematic uncertainties in two sets based on their effect on the templates. The following systematic effects only affect the normalization of the templates:

- **Scale factor for light-flavour jets:** the data-to-simulation scale factor for the misidentification of light-flavour jets is varied within its uncertainty. This is the dominant uncertainty in the scale factor measurement for c jets.
- **Cross sections of the simulated processes:** an uncertainty of 16, 50 and 20% is assumed in the cross section of the $t\bar{t}$ [60], single top quark [61, 62], and the combined W + jets and Z + jets [63, 64] processes, respectively. The limited number of simulated W + jets and Z + jets events requires an additional uncertainty in their yield, fully uncorrelated among the event categories.
- **Integrated luminosity and pileup:** the uncertainty in the integrated luminosity measurement of 6.2% [65] and on the number of additional pileup interactions are considered as yield uncertainties. These uncertainties as well as the uncertainty in the cross sections for the simulated processes are the same for each working point probed, and are applied to the related samples in a correlated way between categories.
- **Scale factors for b tagging:** since b tagging is applied for the event selection, the uncertainty in the b tagging data-to-simulation scale factor is considered as a systematic effect. The simulation has been processed with b jet scale factors shifted by their uncertainties. In case the b-tagged jets in the event selection are actually originating from c quarks, the scale factor is varied by a conservative 50%. The size of the combined effect due to the uncertainty of correctly tagging b jets and wrongly tagging c or light-flavour jets for the event selection depends on the samples, the categories, and the working points considered. However, the effect of these uncertainties has limited impact on the final result, being fully correlated across samples and categories.

A potential source of systematic uncertainty for the normalization of the templates may arise from the uncertainty in the cross section of $t\bar{t}$ events produced in association with heavy-flavour jets, which is constrained to within 35% [66]. Such an uncertainty is covered by the systematic variation on the inclusive $t\bar{t}$ production cross section and the uncertainty in the b tagging scale factor for the event selection, which is taken to be 50% for jets arising from c quarks.

In addition to a possible impact on the normalization of the templates, the following systematic effects affect the shape of the templates:

- **Jet energy scale:** new templates are constructed by varying the jet energy scale by ± 1 standard deviation from its nominal value. The uncertainty is propagated to the fraction of c jets in leading and subleading jets.
- **Jet energy resolution:** for the nominal efficiency measurement, the jet energies in the simulation are smeared according to a Gaussian function to accommodate the slightly worse resolution in data. The uncertainty in the jet energy resolution is propagated to the data-to-simulation scale factor measurement by varying the standard deviation of the Gaussian function by its uncertainty.
- **Factorization and renormalization scales:** the factorization and renormalization scales used at matrix element and parton shower levels affect the number of additional jets from

initial-state radiation (ISR) and final-state radiation (FSR), and may impact the fraction of leading and subleading c jets. The factorization and renormalization scales used at matrix element level are varied independently and simultaneously by factors of 2 and 0.5 with respect to their default values. Also the scale for ISR (FSR) in the parton shower is varied by a factor of 2 ($\sqrt{2}$) and 0.5 ($\sqrt{0.5}$) [67]. A different way to assess the uncertainty in the modelling of ISR and FSR is to vary the “hdamp” parameter in POWHEG. This parameter is used to limit the resummation of higher-order effects using a reference energy scale. The real emissions are reweighted by a step-function $h^2/(p_T^2 + h^2)$, where h is the hdamp parameter and p_T is the transverse momentum of the top quark in the $t\bar{t}$ rest frame. The hdamp parameter is varied between $0.5m_t$ and $2m_t$ to evaluate the uncertainty related to additional jets from ISR and FSR. The variations upwards and downwards having the largest impact on the templates, are used to repeat the data-to-simulation scale factor measurements independently for ISR and FSR. The deviation from the nominal scale factor value is taken as the uncertainty. Together with the uncertainties in the jet energy scale and resolution, the effect is 1% for both the leading and subleading jets.

- **Top quark mass:** the uncertainty in the top quark mass may affect the measurement of the data-to-simulation scale factor. The size of the uncertainty is estimated using alternative simulated samples with a mass that is shifted within the uncertainty in the measured value [35].
- **Parton distribution functions:** the uncertainties in the parton densities is evaluated in the same way as in section 8.3.1 and found to be negligible.
- **Bin-by-bin statistical uncertainty:** statistical uncertainties related to the single bin population in the templates have been addressed through bin-by-bin variations, i.e. fully uncorrelated shape uncertainties in which only one bin of the template is shifted according to its uncertainty. In order to reduce the computational time required by the fit to converge, this uncertainty is only considered for template bins having an uncertainty larger than 5% of the yield observed in the same bin, thus rejecting most of the low-yield backgrounds.

Table 4 summarizes the values of the measured data-to-simulation scale factors for all tagging requirements. The uncertainty in the scale factors in the table are a combination of the statistical and systematic uncertainties obtained from the fit.

8.3.3 Combination of the measured c tagging efficiencies

In the previous sections two methods have been described to measure the c tagging efficiency. In this section, a combination of the measurements is performed. The combination is a weighted average taking into account the full covariance matrix for the uncertainties using the best linear unbiased estimator (BLUE) method [68]. This technique was also used for combining the SF_b measurements in Run 1 [1], but here it has been extended to fit all the jet p_T bins simultaneously [69], treating more correctly the bin-to-bin correlations for the systematic uncertainties. Systematic uncertainties shared by the two measurements are treated as correlated in the combination. The averaging has been done using the finer jet p_T binning of the $W + c$ topology. The relative contribution of the single-lepton $t\bar{t}$ measurement in each jet p_T bin is taken into account by assigning weights to this

Table 4. Measured data-to-simulation scale factors for c jets for various algorithms and working points in single-lepton $t\bar{t}$ events. The uncertainty in the scale factor includes both the statistical and systematic uncertainties, while the last column shows the statistical uncertainty alone.

Working point	SF_c	Statistical uncertainty
CSVv2 L	0.89 ± 0.05	± 0.02
CSVv2 M	0.87 ± 0.08	$+0.04$ -0.03
CSVv2 T	$1.15^{+0.35}_{-0.33}$	$+0.15$ -0.14
c tagger L	1.05 ± 0.03	± 0.01
c tagger M	0.93 ± 0.05	± 0.02
c tagger T	$0.88^{+0.05}_{-0.04}$	± 0.02
DeepCSV L	$0.98^{+0.05}_{-0.04}$	± 0.02
DeepCSV M	0.96 ± 0.09	± 0.04
DeepCSV T	$0.87^{+0.37}_{-0.38}$	± 0.15
cMVAv2 L	0.87 ± 0.04	± 0.02
cMVAv2 M	0.76 ± 0.09	± 0.03
cMVAv2 T	$0.86^{+0.31}_{-0.29}$	± 0.13

measurement corresponding to the fraction of jets from top quark decays expected in each of the jet p_T bins. These fractions are obtained from simulation. The result of the combination is shown in figure 38 for the loose and medium working points of the c tagger. In each panel the combined value is represented as the hatched area. The individual measurements are represented in the upper panel as markers with different colours. The inner thicker error bar represents the statistical uncertainty of the measurement. The lower panel includes a fit of the data-to-simulation scale factor dependence on the jet p_T , which is parameterized by a linear function.

For the c tagging algorithm, the relative precision on the data-to-simulation scale factors for c jets is 2% (4%) for the loose (tight) working point. For the b tagging algorithms, the relative precision is 3–5% for the loose working points, and 10–38% for the tight working points. Overall, the statistical uncertainty is 40–90% of the total uncertainty.

8.4 The b jet identification efficiency

The data-to-simulation scale factor for b jets, SF_b , is obtained using a sample of jets enriched in b quark content, e.g. by selecting multijet events with at least one jet containing a muon, or $t\bar{t}$ events that contain two b jets from the decay of the two top quarks. To enhance the purity when selecting $t\bar{t}$ events, the decay of one or both of the W bosons into leptons is required. This section describes the various SF_b measurements and their combination.

8.4.1 Measurements relying on a muon-enriched topology

Events are selected using various online criteria requiring the presence of two jets with at least one of those jets containing a muon. The different prescales of the various triggers are taken into account

Figure 38. Data-to-simulation scale factors for c jets for the loose (left) and medium (right) working points of the c tagger. The upper panels show the scale factors for c jets as a function of the jet p_T obtained with the two methods described in the text. The inner error bars represent the statistical uncertainty and the outer error bars the combined statistical and systematic uncertainty. The combined scale factor values with their overall uncertainty are displayed as a hatched area. The lower panels show the same combined scale factor values with superimposed the result of a fit function represented by the solid curve. The combined statistical and systematic uncertainty is centred around the fit result, represented by the points with error bars. The last bin includes the overflow entries.

by reweighting the selected events according to the value of the prescale. Offline, the sample is enriched with events containing b jets by requiring that at least one jet has a muon with $p_T > 5$ GeV and with $\Delta R < 0.4$ from the jet axis, referred to as the “muon jet”. The selected simulated events are reweighted to match the pileup profile observed in the data. The muon jet sample is used for three measurements, using the PtRel, LifeTime (LT), and System-8 methods [1]. As discussed in section 8.3.1, the muon enrichment may introduce a bias for the efficiency measurement of taggers that rely on soft muon information, such as the cMVA2, CvsB, and CvsL discriminators. Therefore, the methods described in this section are only used to derive data-to-simulation scale factors for the other taggers.

PtRel method. The p_T of the muon relative to the jet axis, p_T^{rel} , is a variable that is able to discriminate between b jets and non-b jets. On average, this variable is expected to be larger for muons coming from the decay of b hadrons because of the large mass of these hadrons. Therefore, this variable can be used to measure the efficiency for tagging b jets with algorithms relying on track and secondary vertex variables. The fraction of b jets in data can be estimated by fitting the observed p_T^{rel} distribution to the sum of the templates for the different jet flavours. The p_T^{rel} templates for the different flavours are obtained from the simulated muon-enriched multijet samples. To reduce the fraction of non-b jets, the presence of a second jet is required away from the first one (“away jet”) with $\Delta R > 1.5$ and exceeding a JBP discriminator value corresponding to the medium

working point.

For light-flavour jets, a difference is observed between data and simulation in the distribution of the number of charged particles per jet. Therefore, the jets are reweighted with the ratio of the distribution of the observed number of charged particles in inclusive multijet data to that expected in simulation (without the muon enrichment). The template for b jets is corrected by applying a factor corresponding to the ratio of the p_T^{rel} distribution in data to that in simulation for b jets passing the tight JP tagging requirement. The fraction of non-b jets in the JP-tagged samples is found to be of a few per cent and is subtracted. After this correction, we apply the algorithm working point for which the efficiency is to be measured. The observed p_T^{rel} distribution is then fitted with the templates for the jet flavours to obtain the number of b jets passing (N_b^{tagged}) or failing (N_b^{vetoed}) the requirement. The b tagging efficiency in data is obtained as

$$\varepsilon_b = \frac{N_b^{\text{tagged}}}{N_b^{\text{vetoed}} + N_b^{\text{tagged}}} \quad (8.5)$$

Examples of the fitted p_T^{rel} distributions using jets passing and failing the medium working point of the CSVv2 algorithm and with $50 < p_T < 70$ GeV, are shown in figure 39.

Figure 39. Fitted p_T^{rel} distribution for muon jets passing (left) and failing (right) the medium working point of the CSVv2 algorithm. The distribution is shown for jets with $50 < p_T < 70$ GeV. The simulation is normalized to the observed number of events.

LifeTime method. The muon jet sample used in the LT method is the same as for the PtRel method, except that the away jet is not required to be tagged. Also the strategy is similar to the PtRel method, but the fit is performed on the JP discriminator distribution. The track probabilities are calibrated using templates with negative impact parameter tracks in multijet events. The calibration is done separately on data and simulation to take into account a potential difference in the impact parameter resolution between both samples. The fraction of b jets is fitted including all shape systematic uncertainties via a correlation matrix. The tagging efficiency is then obtained as the ratio of the number of b jets obtained from the fit after and before applying the algorithm working point

$$\varepsilon_b = C_b \frac{N_b^{\text{tagged}}}{N_b}. \quad (8.6)$$

The factor C_b is a correction factor, which takes into account the fraction of jets for which the JP discriminant can be computed. It is defined as

$$C_b = \frac{n_{b,MC}^{\text{tag}} N_{b,MC}}{N_{b,MC}^{\text{tag}} n_{b,MC}}, \quad (8.7)$$

with $N_{b,MC}$ the number of b jets with JP information, $n_{b,MC}$ the number of all selected b jets, $N_{b,MC}^{\text{tag}}$ the number of b jets with JP information passing the algorithm working point for which the efficiency is being measured and $n_{b,MC}^{\text{tag}}$ the number of b jets passing the tagging requirement for which the data-to-simulation scale factor is being measured. The fraction of jets without a JP discriminant value is maximum at very low jet p_T (8%) and drops below 1% using jets with $p_T > 120$ GeV.

As an illustration, figure 40 shows the fitted JP distributions using jets with $200 < p_T < 300$ GeV before and after applying the medium working point of the CSVv2 algorithm.

Figure 40. Fitted JP distribution for muon jets (left) and for the subsample of those jets passing the medium working point of the CSVv2 algorithm (right). The distribution is shown for jets with $200 < p_T < 300$ GeV. The simulation is normalized to the integrated luminosity for the data set. The last bin includes the overflow entries.

System-8 method. In contrast with the two methods described before, the System-8 method [70] does not rely on simulated templates of a discriminating variable. Instead, it is based on the usage of two weakly correlated b taggers and two samples containing muons within jets. The first b tagging requirement corresponds to the working point of the algorithm for which the efficiency is to be measured (tag); the second b tagging requirement is $p_T^{\text{rel}} > 0.8$ GeV. This requirement is weakly correlated with the working points for algorithms that do not rely on soft-muon information. The first sample consists of all events with a muon jet (sample n); the second sample is a subset where an away jet satisfies the medium working point of the JBP algorithm (sample p). For each combination of a sample with either zero, one of the two, or both tagging requirements applied, the observed number of jets can be written as the sum of the two (b and non-b) flavour contributions. The efficiency of the algorithm working point under study and the efficiency of the $p_T^{\text{rel}} > 0.8$ GeV requirement are assumed to be factorizable modulo a correlation factor that is determined from simulated events. In total eight equations can be written, with eight unknown parameters, namely

the b tagging efficiencies of the two requirements and the number of b and non-b jets in the two samples:

$$\begin{aligned}
n &= n_b + n_{c,\text{udsg}} \\
p &= p_b + p_{c,\text{udsg}} \\
n^{\text{tag}} &= \varepsilon_b^{\text{tag}} n_b + \varepsilon_{c,\text{udsg}}^{\text{tag}} n_{c,\text{udsg}} \\
p^{\text{tag}} &= \beta \varepsilon_b^{\text{tag}} p_b + \alpha \varepsilon_{c,\text{udsg}}^{\text{tag}} p_{c,\text{udsg}} \\
n^{p_T^{\text{rel}}} &= \varepsilon_b^{p_T^{\text{rel}}} n_b + \varepsilon_{c,\text{udsg}}^{p_T^{\text{rel}}} n_{c,\text{udsg}} \\
p^{p_T^{\text{rel}}} &= \delta \varepsilon_b^{p_T^{\text{rel}}} p_b + \gamma \varepsilon_{c,\text{udsg}}^{p_T^{\text{rel}}} p_{c,\text{udsg}} \\
n^{\text{tag}, p_T^{\text{rel}}} &= \kappa_b \varepsilon_b^{\text{tag}} \varepsilon_b^{p_T^{\text{rel}}} n_b + \kappa_{c,\text{udsg}} \varepsilon_{c,\text{udsg}}^{\text{tag}} \varepsilon_{c,\text{udsg}}^{p_T^{\text{rel}}} n_{c,\text{udsg}} \\
p^{\text{tag}, p_T^{\text{rel}}} &= \kappa_b \beta \delta \varepsilon_b^{\text{tag}} \varepsilon_b^{p_T^{\text{rel}}} p_b + \kappa_{c,\text{udsg}} \alpha \gamma \varepsilon_{c,\text{udsg}}^{\text{tag}} \varepsilon_{c,\text{udsg}}^{p_T^{\text{rel}}} p_{c,\text{udsg}}
\end{aligned} \tag{8.8}$$

where $\alpha, \beta, \gamma, \delta, \kappa_b$ and $\kappa_{c,\text{udsg}}$ are the correlation factors. This system of eight equations is solved numerically. The solution has to pass some physical constraints, e.g. the b tagging efficiency is required to be larger than the non-b tagging efficiency, and the fraction of b jets in the initial sample needs to be smaller than the fraction of non-b jets in the sample.

Systematic uncertainties. Various systematic uncertainties are taken into account that may affect the SF_b measurement. For the three measurements based on the muon-enriched jet samples, the following systematic effects are considered:

- **Gluon splitting:** a variation in the fraction of b and c jets from gluon splitting may have an important impact on the b tagging efficiency since heavy-flavour jets from gluon splitting have a higher track multiplicity. The fraction of events with b jets from gluon splitting is varied by $\pm 25\%$ [71] to estimate the potential effect. For the tight working point of the taggers, this is one of the dominating uncertainties for the System-8 method. In the case of the LT method, the fraction of events with c jets from gluon splitting is also varied by this amount. For the System-8 and PtRel methods, the fraction of c jets in the non-b template is varied when evaluating other systematic effects.
- **b quark fragmentation:** the modelling of the b quark fragmentation may affect the p_T distribution of the b jets in the sample. The size of this effect is estimated by varying the p_T of the primary b hadron in the muon jet by $\pm 5\%$, which is the observed variation between the distribution of the energy fraction of the b jet carried out by the b hadron in PYTHIA and HERWIG. This variation between PYTHIA and HERWIG is typically larger than the variation observed between PYTHIA and data.
- **Branching fraction of $D \rightarrow \mu X$ and fragmentation of $c \rightarrow D$:** these systematic effects are evaluated in the same way as described in section 8.3.1, with the exception that the PDG 2008 values [72] are used for the fragmentation rates. While the nominal values and uncertainties vary slightly in the PDG 2008 and 2016 references, they are fully consistent.
- **K_S^0 and Λ decays (V^0):** this systematic effect is evaluated in the same way as described in section 8.2.

- **Muon p_T and ΔR :** the fraction of muons that reach the muon chambers depends on the muon p_T . The threshold on the muon p_T is varied between 5 and 8 GeV to assess the size of the systematic uncertainty. In addition, the dependence of the measured data-to-simulation scale factor on the ΔR requirement is tested by tightening the requirement to $\Delta R < 0.3$. These systematic effects are among the dominant uncertainties for the System-8 method.
- **Away jet tag:** the dependence of the b tagging efficiency on the away jet tagging requirement is studied by repeating the data-to-simulation scale factor measurement after changing the tagging requirement from the medium to the loose or tight working points. The largest deviation from the scale factor value obtained using the default away-jet tagging requirement is taken as the size of the systematic effect. This systematic effect is typically the dominant uncertainty for the PtRel method, and it is one of the dominating uncertainties for the System-8 method.
- **JP correction factor C_b :** for the LT method, the fit is performed using only jets that have a JP discriminant value. The applicability of the measured data-to-simulation scale factor to all jets is ensured through the correction factor C_b . The systematic uncertainty associated with C_b is defined as $(\delta C_b)^{SF} = \pm \frac{1-C_b}{2}$. This systematic effect induces an uncertainty in the measured scale factor of a few per cent using jets in the lowest p_T bin and is negligible at high jet p_T .
- **JP calibration:** the LT method relies on the calibrated JP discriminator distribution. For the nominal data-to-simulation scale factor value, the calibration of the impact parameter resolution derived from data is applied to the data, and the calibration derived from simulated events is applied to the simulation. However, a bias could be induced in the measurement if there are significant differences between data and simulation in the distribution of track impact parameter resolutions used. Therefore, an additional uncertainty is taken into account by applying the calibration derived on simulation, also on the data. The difference in the measured scale factor is included as additional systematic uncertainty. The inverse approach was also tested, i.e. applying the JP calibration derived on data to both data and simulation. In that case, the shape changed in a similar way, yielding consistent results for the size of the systematic effect. The systematic effect due to the JP calibration is the dominating uncertainty for the LT method.
- **JP bin-to-bin correlation:** for the LT method the systematic uncertainties are taken into account via a correlation matrix. This requires an assumption on the bin-to-bin correlation factors. To assess the impact of an uncertainty in these correlation factors, the data-to-simulation scale factors were remeasured when varying the bin-to-bin factors within $\pm 25\%$. The size of the systematic effect is given by the maximal difference with the nominal SF value.
- **Muon p_T^{rel} requirement:** for the System-8 method, the default requirement of $p_T^{\text{rel}} > 0.8$ GeV on the muon is set to a value of 0.5 or 1.2 GeV. The largest deviation from the measured nominal data-to-simulation scale factor is taken as a systematic uncertainty.
- **udsg-to-c jet ratio:** in the PtRel method the c and light-flavour jets are combined in a single template. The uncertainty in the ratio of light-flavour to c jets is changed by varying it by

$\pm 30\%$ to cover the observed discrepancy in the fraction of light-flavour jets in inclusive and muon-enriched multijet events.

- **Non-b jet template correction:** for the PtRel method, the non-b jet templates are corrected to accommodate the difference in the number of selected tracks for data and simulation. The difference between the measured data-to-simulation scale factors when applying these corrections or not is considered as the size of the systematic effect.
- **b jet template correction:** similarly as in the case for the non-b jet template, also for the b jet template the difference between the nominal data-to-simulation scale factor value and that measured without template correction is taken as an additional uncertainty for the PtRel method.
- **Jet energy scale:** the impact of the uncertainty in the jet energy corrections is evaluated as described in section 8.3.1.
- **Pileup:** the effect of the uncertainty in the number of additional pileup interactions is evaluated as described in section 8.2.

For the System-8 and PtRel methods the largest deviation from the nominal data-to-simulation scale factor value is taken as the size of the systematic effects. For the LT method, the shape variations are taken into account in the template fit. Table 5 summarizes the list of systematic effects taken into account for each of the three methods to measure SF_b .

Results. The measurements of SF_b obtained on muon-enriched multijet events are combined using the BLUE method as described in section 8.3.3. The weighted average is calculated taking into account the correlations between the three methods. The combination is performed as a function of the jet p_T , ranging from 20 to 1000 GeV. Jets with a higher p_T are included in the last bin. The PtRel and LT methods provide measurements on the full jet- p_T range from 20 to 1000 GeV, while the sensitivity of the System-8 method is limited to the lower part of the spectrum, $20 < p_T < 140$ GeV.

The PtRel, System-8, and LT methods are applied on the same events. However, the requirement on the second jet is different for each method. The fraction of events with b quarks that is in common between each pair of methods is obtained from simulated events, and is used to estimate the statistical correlation in the combination of the results. Systematic uncertainties that are in common for two or three methods are treated as correlated. Some of the systematic effects that induce a large uncertainty are however related to a specific method and are treated as uncorrelated.

The data-to-simulation scale factor measurements obtained with the PtRel, System-8, and LT methods for the loose (tight) working point of the CSVv2 (DeepCSV) algorithm as a function of the jet p_T are compared in the upper panel of figure 41. For each point, the thick error bar corresponds to the statistical error and the thin one to the overall statistical and systematic uncertainty. The combined SF_b value is displayed as a hatched area in both panels with its overall uncertainty. In the lower panel the result of a fit function is superimposed. The function used in the fit is $SF_b(p_T) = \alpha \frac{1+\beta p_T}{1+\gamma p_T}$, where α , β , γ are free parameters. The combined statistical and systematic uncertainty is centred around the fit result. The measured data-to-simulation scale factors for the loose working point of the CSVv2 algorithm range from 0.96 to 1.03, and from 0.9 to 1.0 for the

Table 5. Summary of the potential sources of systematic effects taken into account for the muon-enriched SF_b measurements. The symbol “x” means that the uncertainty is considered, “—” means that it is negligible, and “n/a” that it is not applicable. The systematic effects are separated by horizontal lines according to the type of uncertainty. The first set indicates the modelling uncertainty of heavy-flavour jets in the simulation, the second set are uncertainties related to the selection requirements or to the method that is applied, and the third set covers any other type of uncertainty.

Systematic effect	PtRel	LT	System-8
Gluon splitting to $b\bar{b}$	x	x	x
b quark fragmentation	x	x	x
Branching fraction of $D \rightarrow \mu X$	n/a	x	n/a
c \rightarrow D fragmentation rate	n/a	x	n/a

Pileup	x	—	x

tight working point of the DeepCSV algorithm. The relative precision on the scale factors is 1–1.5% using jets with $70 < p_T < 100$ GeV and rises to 3–5% at the highest considered jet p_T .

8.4.2 Measurements relying on the dilepton $t\bar{t}$ topology

The b jet identification efficiency is also measured using dilepton $t\bar{t}$ events, where two b jets are expected from the decay of the top quark pair. Events are selected with exactly two isolated leptons (muons or electrons) fulfilling tight identification criteria [9, 10] with opposite charge and p_T above 25 GeV. Events are selected if there are at least two jets with $p_T > 30$ GeV. All aforementioned objects are required to be in the tracker acceptance.

Kinematic selection method For the kinematic selection (Kin) method, events are further selected by requiring the presence of exactly one isolated electron and one isolated muon with opposite sign and with a dilepton invariant mass $M_{\mu e} > 90$ GeV. These requirements significantly reduce the background from Z + jets events. In addition, p_T^{miss} is required to be larger than 40 GeV. While two jets are expected in dilepton $t\bar{t}$ events, it is possible that more than two jets (or the wrong two jets) are selected because of, e.g. ISR and FSR. A discriminator is constructed that is able to separate b

Figure 41. Data-to-simulation scale factors for b jets as a function of the jet p_T for the loose CSVv2 (left) and the tight DeepCSV (right) algorithms working points. The upper panels show the scale factors for tagging b as a function of the jet p_T measured with three methods in muon jet events. The inner error bars represent the statistical uncertainty and the outer error bars the combined statistical and systematic uncertainty. The combined scale factors with their overall uncertainty are displayed as a hatched area. The lower panels show the same combined scale factors with the result of a fit function (solid curve) superimposed. The combined scale factors with the overall uncertainty are centred around the fit result. To increase the visibility of the individual measurements, the scale factors obtained with various methods are slightly displaced with respect to the bin centre for which the measurement was performed. The last bin includes the overflow entries.

jets and non-b jets. To avoid biasing the measurement of the b jet efficiency, only variables related to the kinematics of the event are used. For each jet j in the event, the angular distance $\Delta R(\ell, j)$ is calculated between the jet and the two leptons. The following variables are calculated for each jet:

- $M(\ell, j)$: invariant mass of the (ℓ, j) pair with the smallest and the largest $\Delta R(\ell, j)$.
- $\Delta\eta(\ell, j)$ and $\Delta\phi(\ell, j)$: difference in pseudorapidity and in azimuthal angle between the lepton and jet for the (ℓ, j) pair with the smallest and the largest $\Delta R(\ell, j)$.
- $\Delta\eta(\ell\ell, \ell j)$ and $\Delta\phi(\ell\ell, \ell j)$: difference in pseudorapidity and azimuthal angle between the dilepton system and an (ℓ, j) pair for the (ℓ, j) pair with the smallest and the largest $\Delta R(\ell, j)$.
- $\Delta\eta(\ell\ell, j)$ and $\Delta\phi(\ell\ell, j)$: difference in pseudorapidity and azimuthal angle between the dilepton system and the jet.

The variables in the first two items are sensitive to (ℓ, j) pairs originating from the same top quark decay, while the variables in the two latter items use the correlation between the spin of the top quark and the top antiquark that is present in $t\bar{t}$ events [73]. The 12 variables listed above are combined with a BDT using the TMVA package [52]. Prior to the training on simulated $t\bar{t}$ events, jets in the event are classified according to their rank when ordered according to decreasing p_T . In

particular, the training is performed in three different categories for the leading, subleading, and other jets. This classification helps to better use the correlations between the variables for the signal and background, in particular for events with a high jet multiplicity. The parameters of the BDT, such as the number of trees, the depth and the shrinkage factor of the gradient learning algorithm, were roughly optimized to obtain a smooth background shape at large discriminator values without reducing the discriminating power.

A binned likelihood fit is performed on the kinematic discriminator of jets passing and failing the b tagging requirement, inclusively for all jets together. For each flavour f , the total number of jets N_f can be expressed as a function of the tagging efficiency in simulation, $\varepsilon_f^{\text{MC}}$, and the data-to-simulation scale factor SF_f :

$$\begin{cases} N_f^{\text{tagged}} = SF_f \varepsilon_f^{\text{MC}} N_f = SF_f N_f^{\text{MC, tagged}} \\ N_f^{\text{vetoed}} = (1 - SF_f \varepsilon_f^{\text{MC}}) N_f = \frac{(1 - SF_f \varepsilon_f^{\text{MC}})}{SF_f \varepsilon_f^{\text{MC}}} N_f^{\text{MC, tagged}}, \end{cases} \quad (8.9)$$

where $N_f^{\text{MC, tagged}}$ is the expected number of jets of flavour f passing the requirement determined from simulation. The templates for light-flavour and c jets are similar. The measured value of the mistag data-to-simulation scale factor, as presented in section 8.2, is used to correct for the different misidentification probability in the data and simulation. It is not necessary to use a dedicated scale factor for c jets since the fraction of c jets is expected to be less than 1% and fully covered by the systematic uncertainties. The scale factor for b jets is the only free parameter to be determined from the fit. The fit is performed simultaneously in bins of jet multiplicity, with up to four jets. For convenience, the discriminator values are transformed from $[-1, 1]$ to $[-1, 1] + 2(N_{\text{jets}} - 2)$.

Several sources of systematic uncertainties are considered:

- **Factorization and renormalization scales:** the uncertainty in the factorization and renormalization scales is evaluated in the same way as in section 8.3.2, except that the scale for FSR in the parton shower is varied by a factor of two up and down, and not by a factor of $\sqrt{2}$. In addition, both the variation of the scale in the parton shower as well as the variation of the hdamp parameter in POWHEG are taken into account to assess the impact of ISR and FSR instead of using the largest variation. Although these systematic uncertainties are correlated, they are conservatively treated as uncorrelated.
- **Cross section of background processes:** the cross section of each non- $t\bar{t}$ background process is varied by 30% to assess the systematic effect due to the uncertainty in the background contributions.
- **Top quark mass:** the uncertainty in the top quark mass is evaluated in the same way as in section 8.3.2.
- **Scale factor for non-b jets:** the data-to-simulation scale factor for light-flavour jets, SF_l , is applied to correct the expected fraction of light-flavour and c jets. To evaluate the uncertainty related to SF_l , the value is changed to $SF_l \pm 1\sigma$, where σ represents the uncertainty in SF_l . The effect of this variation on the measured value of SF_b is taken as the size of the uncertainty due to SF_l .

Figure 42. Fitted distribution of the kinematic discriminator for jets with $100 < p_T < 140$ GeV passing (left) and failing (right) the medium working point of the CSVv2 algorithm. The discriminator distribution is shown in bins of jet multiplicity with the discriminator output transformed from $[-1, 1]$ to $[-1, 1] + 2(N_{\text{jets}} - 2)$. The dominant systematic uncertainty due to initial- and final-state radiation is represented by the band.

- **Jet energy scale:** the uncertainty in the jet energy scale is assessed in the same way as in section 8.3.2. The variation in jet momentum is simultaneously propagated to the p_T^{miss} value for a consistent approach.
- **Jet energy resolution:** the uncertainty in the jet energy resolution is assessed in the same way as in section 8.3.2.
- **Selection efficiency:** the uncertainty in the lepton identification and isolation efficiency is propagated to the measurement by reweighting the simulation using a lepton efficiency scale factor that is shifted up or down by one standard deviation with respect to the nominal value.
- **Pileup:** the uncertainty in the pileup modelling is assessed as described in section 8.2.

The systematic effect induced by the uncertainty in the parton distribution functions is negligible.

To determine the dependence of the data-to-simulation scale factor on the jet p_T , independent fits are performed in mutually exclusive bins of jet p_T . An example of the fitted distribution in the jet p_T range between 100 and 140 GeV using jets passing and failing the medium working point of the CSVv2 algorithm is shown in left and right panels of figure 42, respectively. Discrepancies between the data and simulation are covered by the combined statistical and systematic uncertainty. The scale factor as a function of the jet p_T is shown in figure 43 for the three working points of the CSVv2 and DeepCSV algorithms.

Two-tag counting method. The two-tag counting (TagCount) method is mainly used as a cross check of the Kin method. While the Kin method is able to determine data-to-simulation scale factors at higher jet p_T , the TagCount method is a simple and robust approach to assess the size of the scale factors. The dilepton $\bar{t}t$ events are selected by requiring the dilepton invariant mass $M_{\ell\ell} > 12$ GeV. If the two leptons have the same flavour, the contribution from Z + jets events is reduced by applying a veto around the Z boson mass, $|M_{\ell\ell} - M_Z| > 10$ GeV, and requiring $p_T^{\text{miss}} > 50$ GeV. In addition, each event is required to have exactly two jets.

Figure 43. Data-to-simulation scale factors for b jets obtained with the Kin method as a function of the jet p_T for the three CSVv2 (left) and the three DeepCSV (right) working points. The uncertainty corresponds to the combined statistical and systematic uncertainty. For clarity, the points for the loose and tight tagging requirement are shifted by -5 and $+5$ GeV with respect to the bin centre.

The b jet identification efficiency, ε_b , can be obtained by counting the number of events with two b-tagged jets in the selected sample of events:

$$N_{2 \text{ b-tagged}} - N_{2 \text{ b-tagged}}^{\text{non-b jet}} = \varepsilon_b^2 n_{2 \text{ b jets}}, \quad (8.10)$$

where $N_{2 \text{ b-tagged}}$ is the number of events with two b-tagged jets from data, $N_{2 \text{ b-tagged}}^{\text{non-b jet}}$ is the number of events with two b-tagged jets with at least one of them being a light-flavour or c jet, and $n_{2 \text{ b jets}}$ is the number of events with two true b jets. This equation can be solved for ε_b if $N_{2 \text{ b-tagged}}^{\text{non-b jet}}$ and $n_{2 \text{ b jets}}$ are known. To reduce the dependence on the $t\bar{t}$ production cross section, the equation is divided by the number of selected events,

$$\varepsilon_b = \sqrt{\frac{F_{2 \text{ b-tagged}} - F_{2 \text{ b-tagged}}^{\text{non-b jet}}}{f_{2 \text{ b jets}}}} \quad (8.11)$$

where $F_{2 \text{ b-tagged}}$ is the fraction of events with two b-tagged jets, $F_{2 \text{ b-tagged}}^{\text{non-b jet}}$ is the fraction of events with two b-tagged jets of which at least one is a non-b jet, and $f_{2 \text{ b jets}}$ is the fraction of events with two true b jets. The two latter fractions are obtained from simulation. When the method is used to measure the efficiency as a function of the jet p_T , the two tagged jets are required to be in the same jet p_T bin.

While the method is sensitive to the uncertainties in the predicted fraction of events with non-b jets $F_{2 \text{ b-tagged}}^{\text{non-b jet}}$, using the fraction of events ensures that systematic uncertainties related to the number of $t\bar{t}$ events cancel out. The dominant uncertainties originate from the normalization of background events and the fraction of non-b jet events in the bin with two b-tagged jets. The following systematic effects were studied:

- **The fraction of non-b jets ($F_{2 \text{ b-tagged}}^{\text{non-b jet}}$):** a conservative variation of 50% is used to estimate the uncertainty in the fraction of non-b jets. This represents the leading uncertainty in the final data-to-simulation scale factor for the loose working point of the b jet identification algorithms.

- **Background yield:** the effect of the uncertainty in the background estimation for the $Z + \text{jets}$ background obtained from data is evaluated by varying its normalization by 50%. For the background yields that are estimated from the simulation, an uncertainty of 30% is assumed. This uncertainty is the subleading source of uncertainty.
- **Factorization and renormalization scales:** the uncertainty in the factorization and renormalization scales is assessed as described in section 8.3.2, except for the scale for FSR in the parton shower that is varied by a factor of two up and down, and not by factor of $\sqrt{2}$.
- **Jet energy scale:** the uncertainty in the jet energy scale is propagated to an uncertainty in the data-to-simulation scale factor as described in section 8.3.1.
- **Jet energy resolution:** the uncertainty in the jet energy resolution is addressed as described in section 8.3.2.
- **Pileup:** the systematic effect related to the uncertainty in the number of pileup interactions is evaluated as described in section 8.2.

The systematic effects related to the uncertainty in the top quark mass and the parton distribution functions are negligible compared to the impact of the uncertainty in the background yield and the number of non-b jets.

The b jet identification efficiency is determined in bins of jet p_T and the corresponding data-to-simulation scale factors are shown in figure 44. Large bin-to-bin variations are observed for low- p_T jets, in particular for the tight working points of the taggers, for which the statistical uncertainty dominates.

Figure 44. Data-to-simulation scale factors for b jets measured with the TagCount method as a function of the jet p_T for the three DeepCSV (left) and cMVA2 (right) working points. The uncertainty corresponds to the combined statistical and systematic uncertainty. For clarity, the points for the loose and tight tagging requirement are shifted by -5 and $+5$ GeV with respect to the bin centre.

8.4.3 Tag-and-probe technique using single-lepton $\bar{t}t$ events

In addition to dilepton $\bar{t}t$ events, one can also use the $\bar{t}t$ topology where only one of the W bosons decays to leptons. In this case, two b jets are expected from the top quark decays as well as two non-b

jets from the decay of one of the W bosons. The decay chain $t \rightarrow bW \rightarrow bq\bar{q}$ is referred to as the hadronic side, while $t \rightarrow bW \rightarrow b\ell\nu$ is the leptonic side. The event selection criteria are similar to those described in section 8.3.2, requiring exactly one isolated muon or electron with $p_T > 30$ GeV and satisfying tight identification criteria [9, 10] and exactly four jets with $p_T > 30$ GeV to reduce the possible number of jet-quark assignments.

To enhance the b quark content in the jet sample on which the b tagging efficiency will be determined, the jets need to be correctly assigned to the quarks from which they originate. To achieve this, a likelihood method is used that is described in detail in ref. [60]. The reconstruction of the $t\bar{t}$ topology is enhanced by determining first the four-momentum of the neutrino p_ν using the W boson and top quark mass constraints, $(p_\nu + p_\ell)^2 = m_W^2$ and $(p_\nu + p_\ell + p_{b,\ell})^2 = m_t^2$, with p_ℓ and $p_{b,\ell}$ being the four-momenta of the charged lepton and of the b jet candidate on the leptonic side, respectively. If both equations need to be satisfied, the possible solutions are found on an ellipsoid in the 3D momentum space of the neutrino. For each solution, the distance D_ν is computed between the ellipse projection on the transverse plane and the \vec{p}_T^{miss} vector. The solution of p_ν for which this distance is minimal, $D_{\nu,\text{min}}$, is used. More details on this procedure and its performance can be found in ref. [74]. Once the neutrino momentum is defined, the jets are assigned to the quarks by choosing the jet-quark assignment that minimizes the negative logarithm of the likelihood λ . For each permutation $-\log(\lambda)$ is obtained as:

$$-\log(\lambda) = -\log(\lambda_M) - \log(\lambda_\nu), \quad (8.12)$$

where $\lambda_M = \mathcal{P}_m(m_2, m_3)$ is the 2D probability distribution of the invariant mass of the correctly reconstructed W boson on the hadronic side (m_2) and the invariant mass of the correctly reconstructed top quark on the hadronic side (m_3), that was already introduced in section 8.3.2. Similarly, $\lambda_\nu = \mathcal{P}_\nu(D_{\nu,\text{min}})$ is the probability distribution of $D_{\nu,\text{min}}$ for the correct assignment of the b jet on the leptonic side. While λ_M is sensitive to the correct reconstruction of the top quark on the hadronic side, λ_ν is sensitive to the correct reconstruction of the top quark on the leptonic side.

Once the jets are assigned to the quarks, a tag-and-probe (TnP) technique is applied to determine the b tagging efficiency from data. As a tagging requirement, the medium working point of the CSVv2 algorithm is applied to either the b jet on the hadronic or leptonic side while the b jet from the other side is used as probe. The event is rejected if the tagging requirement is not satisfied. The probe jets are used to determine the b tagging efficiency of a given working point for each tagger under consideration. To achieve that, the distributions of $-\log(\lambda)$ and p_T^{miss} for probe jets passing and failing the tagging requirement are fitted with their expected templates to determine their number in data for the correctly-reconstructed $t\bar{t}$ events. During the fit, the normalization of the template for the non- $t\bar{t}$ background is naturally constrained by the p_T^{miss} distribution during the simultaneous fit. The b tagging efficiency in data is then obtained from the fitted fraction of probe jets passing the tagging requirement with respect to all probe jets, as in eq. (8.5). To increase the number of probe jets and to avoid a possible bias in the measurement, each b jet is used once as tag and once as probe. While the measurements are performed separately with either the b jet from the hadronic or the leptonic side as probe jet, they are afterwards combined by treating all systematic uncertainties as correlated. The measurement is performed in bins of jet p_T .

Figure 45 shows an example of the fitted $-\log(\lambda)$ and p_T^{miss} distributions for probe jets from the leptonic side, with $70 < p_T < 100$ GeV, passing and failing the medium working point of the

CSVv2 algorithm. The template distributions for correctly and wrongly reconstructed $t\bar{t}$ events are

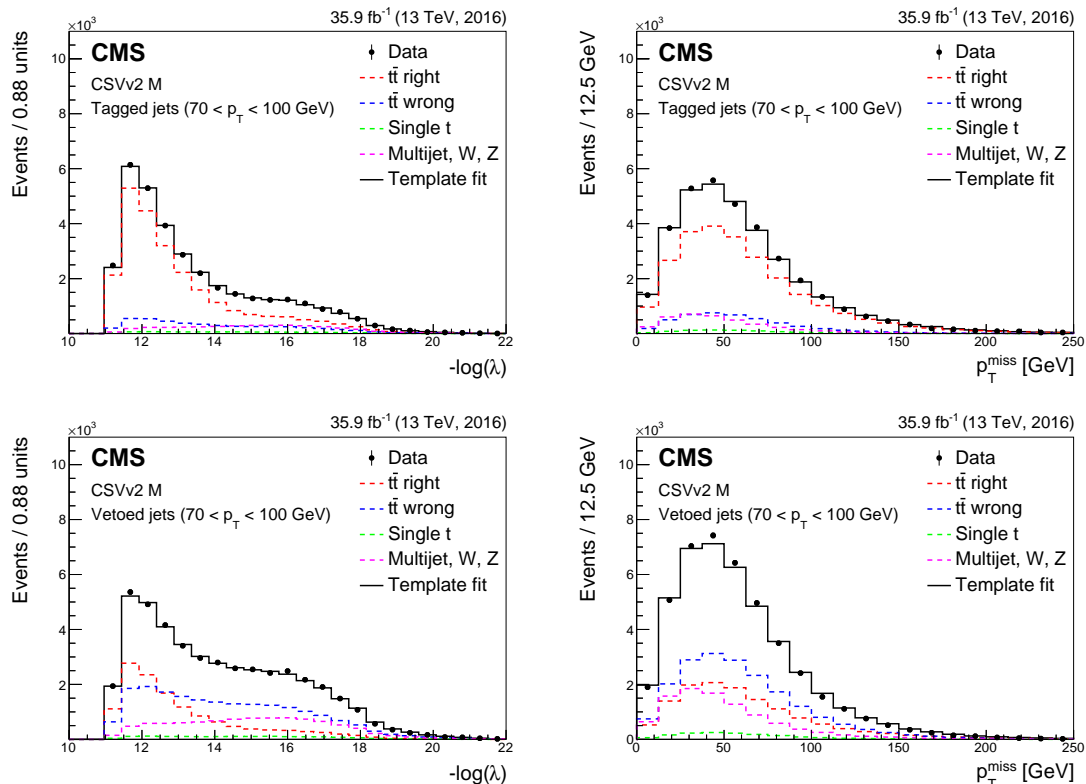

Figure 45. Distributions of fitted $-\log(\lambda)$ (left) and p_T^{miss} (right) for jets from the $t\bar{t}$ leptonic side with $70 < p_T < 100$ GeV passing (upper) and failing (lower) the medium working point of the CSVv2 algorithm.

obtained from simulation. Also the template distribution for single top quark events is taken from simulation and in addition, its normalization is constrained within 20% of the expected standard model yield. The non- $t\bar{t}$ background is composed of multijet, Z + jets, and W + jets events and the combined template for these background processes is derived from data in a control region. The control region contains the events for which the jet with the highest CSVv2 discriminator value is below 0.6.

Several sources of systematic effects may impact the measurement of the b tagging efficiency. These effects are related to the data-taking conditions or to the uncertainty in the object reconstruction, affecting the selection of events and reconstruction of the $t\bar{t}$ topology. On the other hand, systematic effects are related to the modelling of the $t\bar{t}$ production and decay. In particular the following sources of systematic effects have been taken into account:

- **Factorization and renormalization scales:** the uncertainty due to the factorization and renormalization scales is assessed as described in section 8.3.2.
- **Top quark mass:** the uncertainty in the top quark mass is propagated to the data-to-simulation scale factor measurement as described in section 8.3.2.

- **Background:** the non- $\bar{t}t$ background template is derived using events for which the jet with the highest CSVv2 discriminator value is below 0.6. The systematic effect due to this requirement is evaluated by varying its value to less than 0.3, or to values between 0.4 and 0.7. Although these alternative selections result in a different relative fraction of b and non-b jets, as well as in a different background composition, the overall template shape and the fitted value for the number of correctly reconstructed $\bar{t}t$ events is stable.
- **Gluon splitting:** the uncertainty in the gluon splitting into a heavy quark pair is estimated by reweighting events with at least one additional heavy quark that is not originating from the $\bar{t}t$ decay. Events with an additional c and b quark are reweighted by $\pm 15\%$ [75] and $\pm 25\%$ [71], respectively. As can be seen in figure 46 (right) the effect is relatively small.
- **b quark fragmentation:** the uncertainty in the b quark fragmentation function is estimated by varying the Bowler-Lund parameterization within the tune uncertainties. In particular, the parameter `StringZ:rFactB` in PYTHIA is varied by +0.184 and -0.197 to obtain alternative distributions for the ratio of the b hadron p_T to the jet p_T . The $\bar{t}t$ simulation is then reweighted using these functions and the impact on the measured data-to-simulation scale factor is taken as the size of the systematic effect.
- **Branching fraction of $B \rightarrow \ell X$:** the systematic uncertainty induced by the values of the branching fractions of the semileptonic decay of b hadrons may affect the b jet energy response. It is evaluated by reweighting the fractions to the values in ref. [35]. In particular, the branching fraction to leptons is varied by 2.7% for B^0 , by 8% B_s , by 2.5% for B^+ , and by 21% for Λ_B . As can be seen in figures 46 (right) and 47 (right), the impact of this variation, labelled “b hadron decay”, is negligible compared to the other systematic effects.
- **Jet energy scale:** the impact of the uncertainty in the jet energy scale and its propagation to p_T^{miss} is assessed as described in section 8.3.2.
- **Jet energy resolution:** the uncertainty in the jet energy resolution is propagated to the data-to-simulation scale factor measurement as described in section 8.3.2.
- p_T^{miss} : the uncertainty in the lepton, photon, and unclustered energy is estimated by changing p_T^{miss} within its uncertainty and repeating the measurement.
- **Pileup:** the uncertainty in the pileup modelling is assessed as described in section 8.2.

The TnP method is applied to derive data-to-simulation scale factors for the three working points of the CSVv2, DeepCSV, cMVA_{v2}, and c taggers. An example of the size of the systematic uncertainties as a function of the jet p_T is shown in figure 46 (right). In the same figure the scale factor SF_b as a function of the jet p_T is also shown for the medium working point of the CSVv2 algorithm. As discussed previously, SF_b is derived separately for b jets from the hadronic or leptonic side of the single-lepton $\bar{t}t$ decay. As expected, both results are consistent over the full jet p_T range. To reduce the overall uncertainty, the results are combined using the BLUE method, assuming fully correlated systematic uncertainties and uncorrelated statistical uncertainties.

Figure 46. Data-to-simulation scale factors for b jets from the hadronic or leptonic side of the single-lepton $t\bar{t}$ decay as well as for their combination, as a function of the jet p_T for the medium working point of the CSVv2 tagger (left). The error bars represent the combined statistical and systematic uncertainty. Size of the individual uncertainties in the combined scale factors for the CSVv2 medium working point (right).

Figure 47 (left) shows the data-to-simulation scale factors for b jets for the medium working point of the c tagger as a function of the jet p_T . Since the probability to tag non-b jets is higher for the c tagger than for the b taggers, the systematic uncertainties will be larger. On the other hand, since the probability to tag b jets with the c tagger is also smaller compared to the b tagger, also the statistical uncertainty increases. This can be seen in figure 47 (right); while the statistical uncertainty on the measured scale factors still dominates, the systematic uncertainties are significantly larger compared to figure 46 (right). As a result, the total uncertainty for the scale factors for b jets is larger for the c tagger than for the b taggers.

Figure 47. Data-to-simulation scale factors for b jets from the hadronic or leptonic side of the single-lepton $t\bar{t}$ decay as well as for their combination, as a function of the jet p_T for the medium working point of the c tagger (left). The error bars represent the combined statistical and systematic uncertainty. Size of the individual uncertainties in the combined scale factors for the medium working point of the c tagger (right).

8.4.4 Combination of the data-to-simulation scale factors from multijet and $t\bar{t}$ events

For the CSVv2 and DeepCSV taggers, the data-to-simulation scale factors measured with the muon-enriched multijet events are combined with the ones measured in $t\bar{t}$ events using the Kin and TnP methods. Since the c tagger and the cMVAv2 tagger rely on the information from muons from the b hadron decay, the scale factors are only measured with $t\bar{t}$ events since the muon enrichment of the multijet sample may bias the scale factor measurement. Since the Kin method relies on dilepton $t\bar{t}$ events and the TnP method on single-lepton $t\bar{t}$ events, the two scale factor measurements are statistically independent. Similarly as for the combination of the scale factors on the muon-enriched sample, the correlations between the systematic uncertainties are taken into account when combining all measurements with the BLUE method. In particular, when combining the scale factors measured with the TnP and Kin methods, the systematic uncertainty associated to final-state radiation for the TnP method is assessed in the same way as done for the Kin method.

Figure 48 shows the combination of $t\bar{t}$ measurements for the medium working point of the cMVAv2 tagger (right), and for the loose working point of the DeepCSV algorithm (left). As

Figure 48. Data-to-simulation scale factors for b jets as a function of jet p_T for the loose DeepCSV (left) and the medium cMVAv2 (right) algorithms working points. The upper panels show the scale factors for tagging b as function of jet p_T measured with the various methods. The inner error bars represent the statistical uncertainty, and the outer error bars the combined statistical and systematic uncertainty. The combined scale factors with their overall uncertainty are displayed as a hatched area. The lower panels show the same combined scale factors with the result of a fit function (solid curve) superimposed. The combined scale factors with the overall uncertainty are centred around the fit result. To increase the visibility of the individual measurements, the scale factors obtained with various methods are slightly displaced with respect to the bin centre for which the measurement was performed. The last bin includes the overflow entries.

an illustration of the consistency between the measurements performed on $t\bar{t}$ and muon-enriched multijet events, the data-to-simulation scale factors are shown for the tight working point of the CSVv2 tagger in figure 49. Within the uncertainty, no sample dependence is observed. As

a conservative estimate to cover any residual sample dependence, a 1% systematic uncertainty is included when combining the measurements. Both in figures 48 and 49 the fit function is parameterized as described in section 8.4.1 for jets with $20 < p_T < 1000$ GeV. For jets with $p_T > 1000$ GeV the uncertainty of the scale factor is doubled. For all taggers and for an average jet

Figure 49. Data-to-simulation scale factors for b jets as a function of jet p_T measured in muon-enriched multijet and $t\bar{t}$ events for the tight working point of the CSVv2 tagger. The green area shows the combined scale factors with their overall uncertainty, including an additional 1% uncertainty to cover any residual sample dependence, fitted to the superimposed solid curve. For visibility purposes, the scale factors are slightly displaced with respect to the bin centre for which the measurement was performed. The last bin includes the overflow entries.

p_T found in $t\bar{t}$ events the data-to-simulation scale factors vary from about 0.99 for the loose working point to 0.95 for the tight working point. The achieved relative precision on the scale factor for b jets is 1 to 1.5% using jets with $70 < p_T < 100$ GeV and rises to 3–5% at the highest considered jet p_T . Overall, the statistical uncertainty is 15–30% of the total uncertainty.

In some physics analyses of precision measurements, a correlation is present between the quantity to measure and the method to derive the b tagging scale factors. An example is the measurement of the $t\bar{t}$ production cross section in an analysis requiring one or more b-tagged jets. In that case, the scale factors derived from $t\bar{t}$ events are correlated with the production cross section to be measured and the scale factor measured with muon-enriched multijet events should be used.

8.5 Measurement of the data-to-simulation scale factors as a function of the discriminator value

The last method to measure data-to-simulation scale factors is a technique of iterative fitting (IterativeFit) first described in ref. [76], which aims at correcting the full discriminator shape. This method is designed to meet the needs of analyses in which the full distribution of the b tagging discriminator values is used instead of applying a working point of the algorithm to select jets or events. If the full discriminator distribution is used, the distribution using jets in simulated events has to be corrected to match the one observed in data. Scale factors for both b and light-flavour jets are derived as a function of the discriminator value in bins of jet p_T and η . An iterative procedure is used based on a tag-and-probe technique to measure the scale factors for both b and light-flavour jets simultaneously. The scale factors are derived from events with two oppositely charged leptons (electron or muon) within the tracker acceptance and satisfying the tight identification and isolation

requirements [9, 10]. The leading (subleading) lepton is required to have $p_T > 25$ (15) GeV. Exactly two jets are required with $p_T > 20$ GeV and to lie within the tracker acceptance.

The data-to-simulation scale factors for b jets are derived from events passing the above requirements. In addition, for the events with same-flavour leptons, the dilepton invariant mass is required to be away from the Z boson mass, $|M_{\ell\ell} - M_Z| > 10$ GeV, and $p_T^{\text{miss}} > 30$ GeV. These two requirements reduce the contribution from Z + jets events. The tag jet should pass the medium working point of the algorithm for which the scale factor is to be measured. The other jet is used as probe. After these criteria have been applied, the simulated event sample is composed of 87% $t\bar{t}$, 6% single top and 7% Z + jets events. Other backgrounds are reduced to a negligible level.

The data-to-simulation scale factors for light-flavour jets are measured with Z + jets events selected among the same-flavour dilepton events with a dilepton invariant mass close to that of the Z boson, $|M_{\ell\ell} - M_Z| < 10$ GeV, and inverting the requirement on p_T^{miss} . A b jet veto is applied on the tag jet using the loose working point of the tagger for which the scale factor is to be measured. After the event selection, the sample is very pure in Z + jets events (99.9%).

After the event selection and tagging or vetoing one of the two jets, the data-to-simulation scale factors are measured using the other jet in the event as the probe. The scale factors are extracted by first normalizing the b tagging discriminator distribution of the probe jets in simulation to that observed in data. Then, when measuring the scale factor for b jets, the contribution from non-b jets is subtracted using the simulated events. Similarly, when measuring the scale factor for light-flavour jets, the expected contributions from b and c jets are subtracted. The scale factor is determined separately in exclusive bins of the b tagging discriminator distribution, p_T , and η (for light-flavour jets). Since the scale factors for light-flavour jets have an impact on the measured scale factors for b jets, an iterative procedure is performed. In the first iteration no scale factor is applied, while for the next iteration the background is subtracted using the scale factors obtained in the previous iteration. The iterative procedure stops once the scale factors obtained in the current iteration are stable with respect to those obtained in the previous iteration. Convergence is typically achieved after three iterations. When estimating the scale factor for b jets and light-flavour jets, the scale factor for c jets is set to unity with an uncertainty that is twice the uncertainty in the scale factor for b jets.

For the IterativeFit method, the following list of systematic uncertainties is considered. This list covers possible shape discrepancies between data and simulation for the tagger discriminator distribution.

- **Sample purity:** several systematic uncertainties impact the sample purity. These need to be taken into account when measuring the data-to-simulation scale factor for light-flavour or b jets. The sample purity may be affected by background processes or the modelling of the signal in the simulation, e.g. related to the production of additional jets in association with the top quark pair when measuring the scale factor for b jets. All sources of systematic uncertainties influencing the sample purity are combined in a single systematic uncertainty. For the scale factor for light-flavour jets, the expected contribution from processes other than Z + jets is negligible. However, the sample purity can be contaminated by heavy-flavour jets produced in association with the Z boson. The fraction of heavy-flavour jets in the sample is conservatively varied upwards and downwards by 20% when calculating SF_1 . For SF_b , the dominant contribution originates from $t\bar{t}$ events. The dilepton $t\bar{t}$ events are selected requiring

exactly two jets, consistent with the two b jets expected from the $t\bar{t}$ decay. However, because of ISR and FSR and the acceptance of the event selection, also non-b jets are selected. The rate of $t\bar{t}$ events produced with ≥ 2 additional partons varies within up to 20%. Therefore, the fraction of non-b jets is varied by this amount to evaluate the uncertainty in the purity of the sample.

- **Jet energy scale:** the uncertainty in the jet energy scale is assessed in the same way as described in section 8.3.1.
- **Statistical uncertainty:** an uncertainty arises due to the limited number of entries in each bin of the discriminator distribution, resulting in statistical fluctuations in certain regions, e.g. at high discriminator values for light-flavour jets and at low discriminator values for b jets. Linear and quadratic functions, $f_1(x) = 1 - 2x$ and $f_2(x) = 1 - 6x(1 - x)$, are introduced, where x corresponds to the central value of a discriminator bin. The linear function parameterizes the effect of statistical fluctuations that would tilt the discriminator distribution. In contrast, the quadratic function represents fluctuations that would increase or decrease the data-to-simulation scale factor in the centre of the discriminator distribution compared to the low and high discriminator values. To assess the size of the systematic uncertainty related to statistical fluctuations, the scale factor value is varied according to $\pm\sigma(x)f_i(x)$, where $\sigma(x)$ is the statistical uncertainty in the scale factor in that bin. The scale factors are refitted after applying these variations, resulting in two independent functions that span an envelope around the nominal scale factor function for each of the two types of statistical fluctuations.
- **Treatment of SF_c :** for c jets the data-to-simulation scale factor, SF_c , is set to unity. The uncertainty in this value is obtained by doubling the aforementioned relative uncertainties in the scale factor for b jets and adding them in quadrature to obtain a relative uncertainty in SF_c . Similarly as for the statistical uncertainty, two separate uncertainties are constructed using linear and quadratic functions $f_i(x)$. The scale factor value is then varied according to $\pm\sigma(x)f_i(x)$, where $\sigma(x)$ is the relative uncertainty in SF_c . These linear and quadratic variations of SF_c are applied independently from the other uncertainties after which the scale factors are refitted to obtain the functions corresponding to the uncertainty in SF_c .

Figures 50 and 51 show an example of the distribution for the CSVv2 tagger and the derived data-to-simulation scale factors using jets with $40 < p_T < 60$ GeV in a topology enriched in b jets and a topology enriched in light-flavour jets, respectively. The scale factors are parameterized as a function of the CSVv2 discriminator value. The scale factor for light-flavour jets as a function of the discriminator value is fitted with a sixth-order polynomial function. For the scale factor for b jets, no satisfactory parameterization was found. Therefore, a smooth function is obtained by interpolating between the scale factors measured in bins of the CSVv2 discriminator distribution. No interpolation is done between the bin below 0, which includes jets with a negative CSVv2 discriminator value, and the first bin above 0.

The data-to-simulation scale factors obtained with the IterativeFit method have been validated in various control regions. One example is the validation in a control region dominated by single-lepton $t\bar{t}$ events. The flavour composition in this control region is very different from both the dilepton $t\bar{t}$ and $Z +$ jets topologies used to derive the scale factors, thereby providing a powerful

Figure 50. Distribution of the CSVv2 discriminator values for jets with $40 < p_T < 60$ GeV before the data-to-simulation scale factors are applied in the $t\bar{t}$ dilepton sample (left). The simulation is normalized to the number of entries in data. Measured scale factors for b jets as a function of the CSVv2 discriminator value (right). The line is an interpolation between the scale factors measured in each bin of the CSVv2 discriminator distribution. The bin below 0 contains the jets with a default discriminator value.

Figure 51. Distribution of the CSVv2 discriminator values for jets with $40 < p_T < 60$ GeV and $0.8 < |\eta| < 1.6$ before the data-to-simulation scale factors are applied in the Z + jets sample (left). The simulation is normalized to the number of entries for data. Measured scale factors for light-flavour jets as a function of the CSVv2 discriminator value (right). The line represents a polynomial fit to the scale factors measured in each bin of the CSVv2 discriminator distribution. The bin below 0 contains the jets with a default discriminator value.

cross check. Events are selected requiring an isolated electron or muon with $p_T > 30$ GeV and $|\eta| < 2.1$ and exactly four jets with $p_T > 30$ GeV, of which exactly two are b tagged according to the medium working point of the CSVv2 algorithm. The distribution of the CSVv2 discriminator values is shown in figure 52 for all the jets in the control region. The agreement between the data and simulation improves significantly after applying the measured scale factors, and the remaining fluctuations are covered by the systematic uncertainties.

8.6 Comparison of the measured data-to-simulation scale factors

In most cases, the measured data-to-simulation scale factors for heavy- (light-) flavour jets are smaller (larger) than unity. This is expected because the quantities of relevance for heavy-flavour

Figure 52. Distribution of the CSVv2 discriminator values for the single-lepton $t\bar{t}$ sample. Exactly four jets are required, two of which passing the medium working point of the CSVv2 algorithm. The values of the discriminator are shown before (left) and after (right) applying the data-to-simulation scale factors derived with the IterativeFit method. The hatched band around the ratios shows the statistical uncertainty (left), and the total uncertainty (right) in the measured scale factors. The simulation is normalized to the total number of data events. The bin below 0 contains the jets with a default discriminator value.

jet identification are not perfectly modelled by the simulation. The scale factors derived with the various methods are compared to each other after averaging the measured scale factor following the p_T spectrum for $t\bar{t}$ events. Figure 53 compares the measured scale factors. However, this figure should not be used to decide which method performs best, since, e.g. for the TagCount method the scale factors were remeasured inclusively over the jet p_T range, resulting in a smaller uncertainty than when the weighted average is used over the measurements in bins of jet p_T . This is because for the measurement as a function of the jet p_T the two tagged jets are required to be in the same jet p_T bin, resulting in a loss of events compared to the inclusive measurement. Moreover, to allow a comparison, the scale factors for the IterativeFit method are remeasured using only one bin above the discriminator value corresponding to the working point for which the scale factor is derived. As can be seen from figure 53, the measured scale factors are consistent within their uncertainties. Only for the tight working point of the CSVv2 and DeepCSV taggers there is a hint of tension between the TagCount method and the other methods. This is explained by the fact that the central value of the TagCount method is quite sensitive to the background subtraction and the sample purity. The scale factor for b jets for the cMVAv2 and c tagger working points is not measured with muon-enriched multijet events to avoid a bias due to the muon information used in these taggers. The right panels in figure 53 show that the precision on the scale factors for c jets for the loose and medium working points of the b taggers, is on the same level as the precision reached on the scale factors for b jets, for jets with a p_T distribution as expected in $t\bar{t}$ events. For the tight working point of the b taggers, the uncertainty in the average scale factor is relatively large because of the low number of c jets passing the tagging requirement. Similarly, as can be seen from the lower left panel in figure 53 the uncertainty in the average scale factor for b jets for the c tagger working points is larger compared to the corresponding uncertainty for the working points of the b taggers, because of two reasons. First, the uncertainty for the c tagger tight working point is large because of the low efficiency for b jets to pass this tagging requirement (section 5.2.2), resulting in a relatively large statistical uncertainty.

Figure 53. Comparison of the data-to-simulation scale factors derived with various methods and their combination, for b (left) and c (right) jets. The scale factors measured with the different methods agree within their uncertainties. For the left panels, the combination includes all measurements with the exception of the IterativeFit and the TagCount methods.

Second, the uncertainty for the c tagger loose and medium working points is large due to the larger contribution from light-flavour jets resulting in a larger systematic uncertainty. It was also checked that the scale factor for light-flavour jets obtained with the IterativeFit method is consistent with the one obtained using the negative tag method.

9 Measurement of the tagging efficiency for boosted topologies

In section 6, the performance of b tagging algorithms in boosted topologies was discussed and the double- b tagger was presented to identify boosted particles decaying to two b quarks. This section summarizes the efficiency measurements for b tagging in boosted topologies. In section 9.1 the data are compared to the simulation for two topologies: a sample of muon-enriched subjets of AK8 jets and a sample of double-muon-tagged AK8 jets. Section 9.2 discusses the methods to measure the efficiency for b tagging subjets with the CSVv2 tagger. The efficiency measurement of the double- b tagger is presented in section 9.3. In both cases, the data-to-simulation scale factors are measured as a function of the jet p_T . At this stage, the size of the jet sample is not yet large enough to provide also scale factors as a function of the jet $|\eta|$.

9.1 Comparison of data with simulation

The data are compared to the simulation using jets in boosted topologies. Jets are selected from events satisfying the following description:

- **Muon-enriched boosted subjets sample:** a sample of muon-enriched multijet events is obtained using a combination of single-jet (AK4 and AK8) triggers requiring a muon in the jet. The data are compared to the simulation for soft-drop subjets (section 6) of AK8 jets with $p_T > 350$ GeV and within the tracker acceptance. The subjets are required to contain at least one muon with $p_T > 7$ GeV and $\Delta R < 0.4$. In addition, to reduce the contribution from prompt muons, the ratio of the p_T of the muon to that of the jet is required to be smaller than 0.5. The subjet p_T distribution in simulation is reweighted to match the observed distribution.
- **Double-muon-tagged boosted jet sample:** a second sample of muon-enriched multijet events is obtained by combining the triggers used to select the previous sample with dijet triggers with a lower jet p_T threshold, and by requiring a muon in each of the two jets. In this way, the sample contains also AK8 jets with $250 < p_T < 350$ GeV. Each subjet is required to contain a muon with $p_T > 7$ GeV and $\Delta R < 0.4$. The sum of the p_T of the two muons with respect to the p_T of the AK8 jet is required to be less than 0.6. Some of the triggers are prescaled. The p_T distribution of the AK8 jet in the simulation is reweighted to match the observed distribution in data.

In figure 54 the data are compared to the simulation for subjets in the muon-enriched sample. The distributions of a few selected input variables are shown as well as the CSVv2 discriminator output distribution. The agreement is reasonable, with variations of up to 20%. Similarly, figure 55 shows the simulation and data for double-muon-tagged AK8 jets. Some of the input variables of the double- b tagger are shown as well as the discriminator output distribution itself.

Figure 54. Distribution of the 3D impact parameter significance of the tracks (upper left), the secondary vertex 3D flight distance significance (upper right), the corrected secondary vertex mass (lower left), and the CSVv2 discriminator (lower right) for muon-tagged subjects of AK8 jets with $p_T > 350 \text{ GeV}$. The simulated contributions of each jet flavour are shown with a different colour. The total number of entries in the simulation is normalized to the number of observed entries in data. The first and last bin of each histogram contain the underflow and overflow entries, respectively.

9.2 Efficiency for subjects

9.2.1 Misidentification probability

The CSVv2 algorithm is used when applying b jet identification on subjects of AK8 jets. Data-to-simulation scale factors for light-flavour subjects from AK8 jets are derived with the negative-tag method used to measure the scale factors for light-flavour jets in section 8.2. A sample of inclusive multijet events is selected using single-jet triggers with different p_T thresholds ranging from 140 to 500 GeV. The AK8 jet is required to have an offline reconstructed soft-drop jet mass between 50 and 200 GeV, where the jet mass is obtained from the invariant mass of the two subjects. The scale factors are measured for the loose and medium working points of the CSVv2 taggers using subjects with $p_T > 20 \text{ GeV}$ within the tracker acceptance. The same sources of systematic effects are taken into account as for the scale factor measurement for AK4 light-flavour jets.

The measured data-to-simulation scale factors are shown in figure 56 for the loose and medium working points of the CSVv2 algorithm as a function of the subject p_T . The measurement is compared to the corresponding AK4 jet scale factors, and within the uncertainty both scale factors agree for

Figure 55. Distribution of the 2D flight distance significance of the secondary vertex associated with the first τ axis (upper left), the mass of the secondary vertex associated with the second τ axis (upper right), the z variable (lower left), and the double- b discriminator (lower right) for double-muon-tagged AK8 jets with $p_T > 250$ GeV. The simulated contributions of each jet flavour are shown with a different colour. The total number of entries in the simulation is normalized to the number of observed entries in data. The first and last bin of the upper and lower right histograms contain the underflow and overflow entries, respectively.

jets with $p_T > 200$ GeV. The difference for low jet p_T is because of the very different environment for low- p_T subjets in a boosted AK8 jet compared to low- p_T AK4 jets.

9.2.2 Measurement of the b tagging efficiency

The data-to-simulation scale factors for subjets originating from b quarks are measured on subjets of AK8 jets using the selection requirements described in section 9.1. The LifeTime LT method presented in section 8.4.1 is applied to measure the scale factors for the loose and medium working points of the CSVv2 algorithm. The templates of the JP distribution for the various flavours obtained from simulation are fitted to the distribution observed in the data before and after applying the tagging requirement. An example of the fitted JP distribution for subjets with $240 < p_T < 450$ GeV is shown in figure 57 for all subjets and for subjets passing the medium working point of the CSVv2 algorithm. The systematic uncertainties associated with the scale factor measurements are the same as evaluated for AK4 jets discussed in section 8.4.1. Compared to the measurements in section 8.4.1, the calibration of the track probabilities used in the resolution function of the JP algorithm (section 5.1.1) is performed differently. In particular, for the nominal scale factor values

Figure 56. Data-to-simulation scale factors for light-flavour subjects of AK8 jets as a function of the subject p_T , as well as for AK4 jets as a function of jet p_T , for the loose (left) and medium (right) working points of the CSVv2 algorithm. The solid curve is the result of a fit to the scale factors, and the dashed lines represent the overall statistical and systematic uncertainty of the measurements.

Figure 57. Fitted JP discriminator distribution for all soft-drop subjects with $240 < p_T < 450$ GeV (left) and for the subsample of those subjects passing the medium working point of the CSVv2 algorithm (right). The last bin contains the overflow entries.

considered here, the calibration of the track probabilities is derived from simulation and applied to both data and simulation. The systematic effect is evaluated from the difference between the nominal scale factor and that obtained by applying to the data the calibration of the track probabilities derived from the data. The uncertainty due to jets without a JP discriminator value is found to be negligible because of the higher jet p_T .

The measured data-to-simulation scale factors for the loose and medium working points of the CSVv2 tagger are presented as function of the subject p_T in figure 58. As a comparison, the scale factors for AK4 jets obtained with the LT method are also shown. The scale factors for AK4 jets and subjets are consistent within their uncertainties.

Figure 58. Data-to-simulation scale factors for b subjets of AK8 jets as a function of the subjet p_T , as well as for AK4 jets as a function of jet p_T , for the loose (left) and medium (right) working points of the CSVv2 algorithm. The hatched band around the scale factors represents the overall statistical and systematic uncertainty of the measurements.

9.3 Efficiency of the double-b tagger

9.3.1 Measurement of the double-b tagging efficiency

To measure the efficiency of the four working points of the double-b tagger defined in section 6.2, a pure sample of boosted $b\bar{b}$ jets needs to be selected from data. The measurement is performed using a sample of high- p_T jets enriched with $g \rightarrow b\bar{b}$ jets. The enrichment is achieved by requiring each AK8 jet to be double-muon tagged, as described in section 9.1. While additional systematic uncertainties arise from using $b\bar{b}$ jets from gluon splitting, the statistical uncertainty of a measurement performed on boosted $H \rightarrow b\bar{b}$ jets would be too large. Also $Z \rightarrow b\bar{b}$ events cannot be easily used because of the difficulty to obtain a pure sample of those events. Using the simulation, it has been verified that the $g \rightarrow b\bar{b}$ jets can be used as a proxy for the $H \rightarrow b\bar{b}$ jets signal. Indeed, after the selection, the distributions of the double-b tagger discriminator values and its input variables were compared for simulated $g \rightarrow b\bar{b}$ and $H \rightarrow b\bar{b}$ jets. Since a different shape was observed for the discriminator distribution, the $g \rightarrow b\bar{b}$ events were reweighted using the distribution of the z variable and the secondary vertex energy ratio, which are the variable distributions with the largest shape difference. The data-to-simulation scale factors were then computed using either the reweighted $g \rightarrow b\bar{b}$ simulation or the original $g \rightarrow b\bar{b}$ simulation. Both scale factors were found to be compatible, which confirms that the $g \rightarrow b\bar{b}$ events allow for an unbiased measurement of the efficiency.

The efficiency and the corresponding data-to-simulation scale factor $SF_{\text{double-b}}$ is measured using data for the working points of the double-b tagger defined in section 6. The measurement is performed using the LT method, presented in section 8.4.1 and also used in section 9.2.2. The expected templates of the JP discriminator after the tagging requirement consist of two contributions, one arising from $g \rightarrow b\bar{b}$ jets and one from jets not stemming from this process (background jets). These two templates are used to fit the fraction of each contribution to the JP discriminator in data. The fit is performed in three bins of jet p_T for the loose, medium-1, and medium-2 working points, and in two bins of jet p_T for the tight working point. An example of the fitted distributions is shown

in figure 59 for AK8 jets with $350 < p_T < 430$ GeV before and after applying the loose working point of the double-b algorithm. The background jets are shown separately for b and $g \rightarrow c\bar{c}$ jets and for c and light-flavour jets. However, the templates of these two components are merged for the tagged jet sample when performing the fit.

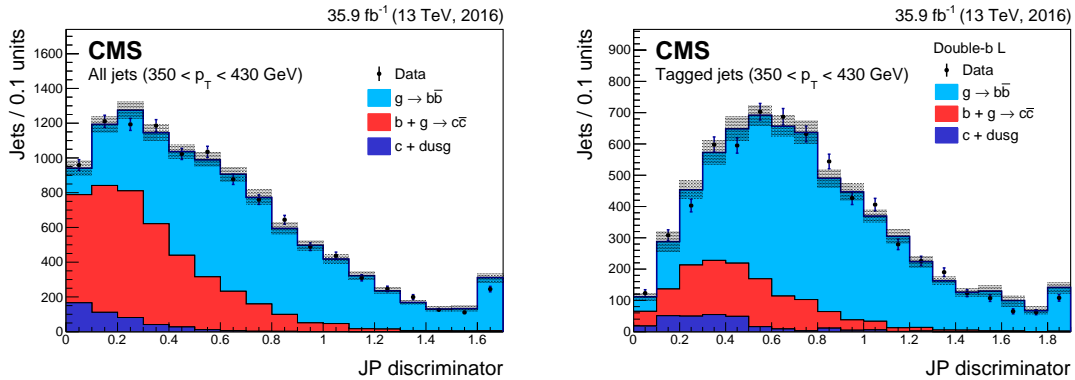

Figure 59. Fitted JP discriminator distribution for all soft-drop subjects with $350 < p_T < 430$ GeV (left) and for the subsample of those subjects passing the loose working point of the double-b algorithm (right). The shaded area represents the statistical and systematic uncertainties in the templates obtained from simulation. The last bin contains the overflow entries.

The measurement is sensitive to the flavour composition of the background sample. The uncertainty due to the flavour composition is estimated by varying by $\pm 50\%$ the normalization of each flavour in the background templates. As a cross check, the potential systematic effect of merging all background jets in a single template is assessed by remeasuring the data-to-simulation scale factor using a separate template for each flavour in the fit. The systematic uncertainty due to the template variation results in a systematic uncertainty of up to 2.3% in the measured scale factor. The uncertainty related to the track probability calibration for the resolution function used in the JP discriminator is evaluated as described in section 9.2.2, and results in an uncertainty of 2.9% in the measured scale factors. The impact of the uncertainty in the number of pileup interactions results in an uncertainty of 1.3% in the scale factors. The following systematic uncertainties were found to be negligible: bin-by-bin correlations, jet energy corrections, the number of tracks, the branching fractions for c hadrons to muons, the b fragmentation function, the fragmentation rate of a c quark to various D mesons, and the K_S^0 and Λ production fractions.

The data-to-simulation scale factor $SF_{\text{double-b}}$ is presented in figure 60 for two working points of the double-b tagger. The measurement is performed using jets with $p_T > 250$ GeV. Jets with $p_T > 840$ GeV are included in the last bin. The scale factor is positioned at the average jet p_T value of the jets populating that bin.

9.3.2 Measurement of the misidentification probability for top quarks

The probability to misidentify a boosted top quark jet corresponding to the decay $t \rightarrow bW \rightarrow bq\bar{q}$ for the four working points of the double-b tagger is estimated from the data. Semileptonic $t\bar{t}$ events are selected by requiring exactly one isolated muon with $p_T > 50$ GeV and $|\eta| < 2.1$. The muon is used to define two hemispheres in the event. The leptonic hemisphere is defined as

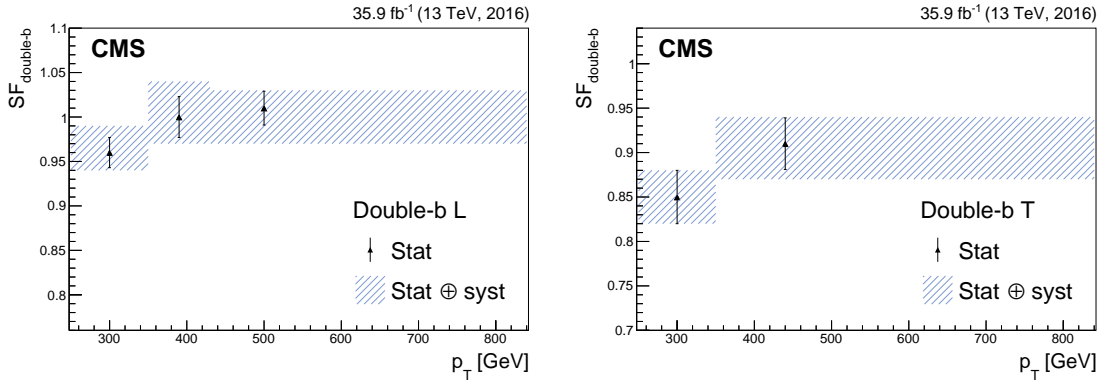

Figure 60. Data-to-simulation scale factors for correctly identifying two b jets in an AK8 jet as a function of the jet p_T for the loose (left) and tight (right) working points of the double-b tagger. The hatched band around the scale factors represents the overall statistical and systematic uncertainty in the measurement. Jets with $p_T > 840$ GeV are included in the last p_T bin.

$|\phi_{\text{jet}} - \phi_{\mu}| < \frac{2}{3}\pi$, and the hadronic hemisphere is its complement. At least one AK4 jet is required in each hemisphere, with $p_T > 30$ GeV and within the tracker acceptance. In addition, the AK4 jet in the leptonic hemisphere should pass the loose working point of the CSVv2 algorithm. At least one AK8 jet is required in the hadronic hemisphere with $p_T > 250$ GeV, $|\eta| < 2.4$, and a pruned jet mass between 50 and 200 GeV. The N-subjettiness parameters τ_1 and τ_2 (section 6) should satisfy the condition $\tau_2/\tau_1 < 0.6$. If more than one such jet is present, the one with the highest p_T is considered. The aforementioned selection is referred to as the “2-prong” selection.

After the event selection, the simulated events are normalized to the yield observed in the data. Figure 61 shows the distribution of the double-b discriminator and the pruned jet mass for the selected 2-prong events. The purity of the sample is high and the AK8 jet mass distribution is consistent with the decay of the W boson to quarks.

Figure 61. Distribution of the double-b tagger discriminator (left) and pruned jet mass (right) for AK8 jets passing the 2-prong event selection as described in the text. The simulation is normalized to the observed number of events.

The probability to misidentify a boosted top quark jet in data is obtained as follows:

$$\varepsilon_{\text{top}} = \frac{N_{\text{bb-tagged}}^{\text{data}} - N_{\text{bb-tagged}}^{\text{bkg,MC}}}{N^{\text{data}} - N^{\text{bkg,MC}}}, \quad (9.1)$$

where $N_{\text{bb-tagged}}^{\text{data}}$ and N^{data} are the number of events with a tagged AK8 jet in data and the total number of events in data, respectively. Similarly, $N_{\text{bb-tagged}}^{\text{bkg,MC}}$ and $N^{\text{bkg,MC}}$ are the simulated number of background events with a tagged AK8 jet and the number of simulated background events before applying the working point of the double-b tagger, respectively. The data-to-simulation scale factors are measured both inclusively and in bins of the AK8 jet p_T . The main systematic effect arises from the normalization of the background processes. An uncertainty of 30% is assigned to the cross section of each background contribution. An additional systematic uncertainty is related to the reweighting of the top quark p_T spectrum. The shape of the p_T distribution for top quarks in data is observed to be softer than in the simulation [77, 78]. For the nominal scale factor measurements, a reweighting procedure is applied to correct for the observed difference. To assess the size of any systematic effect due to the reweighting, the uncertainty is obtained as the difference between the nominal scale factor values and the scale factors obtained when repeating the measurement without applying the reweighting procedure. The systematic uncertainty is found to be 1–2%.

The data-to-simulation scale factors for the misidentification of boosted top quark jets for two of the working points of the double-b tagger are shown as a function of the jet p_T in figure 62. The scale factors are positioned at the average jet p_T value of the jets populating that bin.

Figure 62. Data-to-simulation scale factors for misidentifying a top quark jet as a function of the jet p_T for the loose (left) and tight (right) working points of the double-b tagger. The hatched band around the scale factors represents the overall statistical and systematic uncertainty in the measurement. Jets with $p_T > 840$ GeV are included in the last p_T bin.

10 Summary

A variety of discriminating variables and algorithms used by the CMS experiment for the identification of heavy-flavour (charm and bottom) jets in proton-proton collisions at 13 TeV have been reviewed. Detailed simulation studies have allowed the reoptimization of existing b tagging algorithms and, in addition, new algorithms have been developed for the first time to identify c jets,

as well as $b\bar{b}$ jets in events with boosted topologies. The performance of these heavy-flavour jet identification algorithms has been studied with simulations of different final states with heavy- and light-flavour quarks. The efficiency to correctly identify b jets in resolved $t\bar{t}$ events is 68% at a misidentification probability for light-flavour jets of 1%, which is an improvement of 15% in relative efficiency compared to the best performing algorithm used during LHC Run 1.

The variables and discriminators have been also compared to the data collected by the CMS experiment in 2016 for various event topologies enriched in heavy- or light-flavour jets. Various methods have been presented to determine the data-to-simulation scale factors for the heavy-flavour jet identification efficiency, as well as for the probability to misidentify light-flavour jets. A precision of a few per cent is obtained in the tagging efficiency for b jets with $30 < p_T < 300$ GeV. For b jets with $p_T > 500$ GeV, the precision is of the order of 5%. For scale factors measured in boosted topologies and for c jets in resolved topologies, the total uncertainty is 5–10%, and the statistical uncertainty in the tagging efficiency dominates over the full jet p_T range.

With the increasing integrated luminosity delivered by the LHC, the precision of the data-to-simulation scale factors for the specified topologies, jet flavours, and p_T ranges will increase further. Differential studies of the heavy-flavour identification performances as a function of jet pseudorapidity, and of the number of multiple proton-proton interactions in the same bunch crossing, will also become viable.

Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centres and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: the Austrian Federal Ministry of Science, Research and Economy and the Austrian Science Fund; the Belgian Fonds de la Recherche Scientifique, and Fonds voor Wetenschappelijk Onderzoek; the Brazilian Funding Agencies (CNPq, CAPES, FAPERJ, and FAPESP); the Bulgarian Ministry of Education and Science; CERN; the Chinese Academy of Sciences, Ministry of Science and Technology, and National Natural Science Foundation of China; the Colombian Funding Agency (COLCIENCIAS); the Croatian Ministry of Science, Education and Sport, and the Croatian Science Foundation; the Research Promotion Foundation, Cyprus; the Secretariat for Higher Education, Science, Technology and Innovation, Ecuador; the Ministry of Education and Research, Estonian Research Council via IUT23-4 and IUT23-6 and European Regional Development Fund, Estonia; the Academy of Finland, Finnish Ministry of Education and Culture, and Helsinki Institute of Physics; the Institut National de Physique Nucléaire et de Physique des Particules / CNRS, and Commissariat à l'Énergie Atomique et aux Énergies Alternatives / CEA, France; the Bundesministerium für Bildung und Forschung, Deutsche Forschungsgemeinschaft, and Helmholtz-Gemeinschaft Deutscher Forschungszentren, Germany; the General Secretariat for Research and Technology, Greece; the National Scientific Research Foundation, and National Innovation Office, Hungary; the Department of Atomic Energy and the Department of Science

and Technology, India; the Institute for Studies in Theoretical Physics and Mathematics, Iran; the Science Foundation, Ireland; the Istituto Nazionale di Fisica Nucleare, Italy; the Ministry of Science, ICT and Future Planning, and National Research Foundation (NRF), Republic of Korea; the Lithuanian Academy of Sciences; the Ministry of Education, and University of Malaya (Malaysia); the Mexican Funding Agencies (BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI); the Ministry of Business, Innovation and Employment, New Zealand; the Pakistan Atomic Energy Commission; the Ministry of Science and Higher Education and the National Science Centre, Poland; the Fundação para a Ciência e a Tecnologia, Portugal; JINR, Dubna; the Ministry of Education and Science of the Russian Federation, the Federal Agency of Atomic Energy of the Russian Federation, Russian Academy of Sciences, the Russian Foundation for Basic Research and the Russian Competitiveness Program of NRNU “MEPhI”; the Ministry of Education, Science and Technological Development of Serbia; the Secretaría de Estado de Investigación, Desarrollo e Innovación, Programa Consolider-Ingenio 2010, Plan de Ciencia, Tecnología e Innovación 2013-2017 del Principado de Asturias and Fondo Europeo de Desarrollo Regional, Spain; the Swiss Funding Agencies (ETH Board, ETH Zurich, PSI, SNF, UniZH, Canton Zurich, and SER); the Ministry of Science and Technology, Taipei; the Thailand Center of Excellence in Physics, the Institute for the Promotion of Teaching Science and Technology of Thailand, Special Task Force for Activating Research and the National Science and Technology Development Agency of Thailand; the Scientific and Technical Research Council of Turkey, and Turkish Atomic Energy Authority; the National Academy of Sciences of Ukraine, and State Fund for Fundamental Researches, Ukraine; the Science and Technology Facilities Council, UK; the US Department of Energy, and the US National Science Foundation.

A Parameterization of the efficiency

To facilitate phenomenological studies relying on b jet identification, we provide the b jet identification efficiency as a function of the jet p_T for the three operating points of the DeepCSV algorithm.

The efficiency is obtained using jets with $p_T > 20$ GeV in a simulated $t\bar{t}$ sample and is multiplied by the data-to-simulation scale factor to obtain the tagging efficiency expected in data. This efficiency is shown in figure 63 for the three jet flavours. Polynomial functions are used to fit the dependence of the efficiency on the jet p_T for jets with $20 < p_T < 1000$ GeV. It is worth noting that the parameterization of the fitted functions is not reliable outside this jet p_T range. The parameterizations are summarized in table 6.

Figure 63. Efficiency for b tagging jets for the three different working points of the DeepCSV algorithm multiplied by the measured data-to-simulation scale factor. The efficiencies are shown as a function of the jet p_T using jets with $p_T > 20$ GeV in $t\bar{t}$ events for b jets (upper), c jets (middle), and light-flavour jets (lower). The solid lines represents the functions used to fit the dependence on the jet p_T . The last bin includes the overflow.

Table 6. Polynomial functions used to fit the efficiency of the three working points of the DeepCSV algorithm for the three jet flavours as a function of the jet p_T for jets with $20 < p_T < 1000$ GeV.

Abstract

The limited knowledge of atmospheric parameters like humidity, pressure, temperature, and the index of refraction has been one of the important systematic uncertainties in reconstructing the depth of the shower maximum from the radio emission of air showers. Current air shower Monte Carlo simulation codes like CORSIKA and the radio plug-in CoREAS use various averaged parameterized atmospheres. However, time-dependent and location-specific atmospheric models are needed for the cosmic ray analysis method used for LOFAR data. There, dedicated simulation sets are used for each detected cosmic ray, to take into account the actual atmospheric conditions at the time of the measurement. Using the Global Data Assimilation System (GDAS), a global atmospheric model, we have implemented time-dependent, realistic atmospheric profiles in CORSIKA and CoREAS. We have produced realistic event-specific atmospheres for all air showers measured with LOFAR, an event set spanning several years and many different weather conditions. A complete re-analysis of our data set shows that for the majority of data, our previous correction factor performed rather well; we found only a small systematic shift of 2 g/cm^2 in the reconstructed X_{max} . However, under extreme weather conditions, for example, very low air pressure, the shift can be up to 15 g/cm^2 . We provide a correction formula to determine the shift in X_{max} resulting from a comparison of simulations done using the US-Std atmosphere and the GDAS-based atmosphere.

Keywords: LOFAR, Cosmic Ray, EAS, Radio detection technique, Atmosphere, GDAS, Index of refraction, Effects of humidity, X_{\max} reconstruction

1. Introduction

In recent years, the field of radio detection of air showers has advanced quite rapidly [1, 2]. Estimating the depth of the shower maximum, X_{\max} , with improved accuracy is of great interest for the study of the primary particle composition [3, 4]. The development of the air shower induced by a cosmic ray is governed by the interactions and decays of the secondary particles. The secondary electrons and positrons in the air shower undergo charge separation as they travel through the magnetic field of the Earth. This leads to a time-varying transverse current, producing radio emission. There is another small contribution to the radiation from the excess of negative charge accumulated at the shower front, known as the ‘Askaryan effect’ [5]. The emission reaches the ground as a short pulse on the order of 10 to 100 ns with a specific lateral intensity distribution, or footprint, that depends on X_{\max} ; X_{\max} is calculated in terms of total atmospheric matter traversed by the air shower from the top of the atmosphere to the point where the particle number reaches the maximum. It is therefore important to know the altitude-dependent air density. Another atmospheric parameter that plays a crucial role in the radio emission is the refractive index of air. If for a given emission region along the shower axis an observer is located at the corresponding Cherenkov angle, radiation emitted from all along this region arrives simultaneously. This results in a highly compressed signal in time, forming a ring-like structure on the ground [6, 7]. The refractive index determines the propagation velocity of the radio signal at different altitudes and influences the time compression [8, 9]. For observers located on the Cherenkov ring, pulses are coherent up to GHz frequencies [10]. The angle at which Cherenkov emission is emitted is inversely proportional to the refractive index. At higher frequencies pulses are more sensitive to the refractive index. In general, at all frequencies, the variations in the refractive index lead to changes in the radio intensity footprint [11]. Both the density and the refractive index of air are dependent on air temperature, humidity and pressure. Thus, having a good understanding of these atmospheric variables is crucial.

The radio detection technique can be used in combination with established techniques such as fluorescence detection and surface detection with scintillators and water Cherenkov detectors. Dense antenna arrays like the core of the LOFAR radio telescope [12] provide the opportunity to investigate the radio footprint, i.e. the lateral intensity distribution, in close detail and enable the measurement of X_{\max} up to a precision of < 20 g/cm². The precision is sensitive to the choice of an atmospheric model included in the Monte Carlo air shower simulation codes. There are several parameterized atmospheric models incorporated in the CORSIKA air shower simulation code, based on averaged profiles: U.S. standard

atmosphere parameterized according to J. Linsley [13], parameterized atmospheres for the Pierre Auger Observatory near Malargüe (Argentina) by M. Will and B. Keilhauer [14], South Pole atmospheres parameterized by P. Lipari and D. Chirkin etc. So far, the US standard atmosphere has been used in LOFAR analyses, through CORSIKA simulations [13] and the CoREAS extension [13] which is used to calculate the radio emission of the air showers.

A first order linear correction to the US standard atmosphere has been applied to account for the fact that the US-standard atmosphere does not reflect the realistic atmospheric conditions at a given time. It is preferable to integrate a realistic atmosphere directly into the simulations. In particular, the reconstruction of X_{\max} depends on the refractive index of air, and so a realistic refractive index profile needs to be included.

The effects of the refractive index, n , on the reconstructed X_{\max} have been previously reported in Ref.[15] and Ref.[11], using different simulation codes. In Ref.[11], CoREAS was used to simulate two ensembles of showers, one with a globally higher refractivity $N = (n - 1) 10^6$, another with standard values. A Monte Carlo based approach was taken to study the systematic shift in reconstructed X_{\max} by comparing the set of simulations with higher refractivity to the standard ones. The shift in the reconstructed X_{\max} from the default value was found to be proportional to the geometric distance to X_{\max} . The effect was stronger in the high frequency band of 120–250 MHz than in the 30–80 MHz band. In Ref.[15], a more realistic profile of the refractivity was constructed for one particular day using information from the Global Data Assimilation System, GDAS, a global weather database. The differences between this atmosphere and default atmospheres were studied using the SELFAS radio emission simulation code [16]. The results showed that correcting for the realistic density is the most important factor in the accurate reconstruction of X_{\max} , causing about 30 g/cm² bias in X_{\max} . And the second most important correction was through the inclusion of the high frequency refractivity formula, applicable at radio frequencies, contributing about 5 g/cm² bias in X_{\max} . The effects of the increased refractivity on the time traces and the lateral distribution function (LDF) were also reported. In the 20–80 MHz frequency band, relatively small differences in the amplitude of the electric field and LDF were found, whereas considerable differences were found studying the high frequency band between 120–250 MHz. These results were in agreement with Ref.[11]. While both works paved the way for the understanding of atmospheric effects on radio simulations, a direct application to real data using simulations with realistic atmospheric conditions was not addressed.

In this work, for the first time, GDAS-based atmospheric profiles, automatically included in CoREAS simulations are applied to LOFAR data. The effects of atmospheric parameters like pressure and humidity on the reconstructed X_{\max} are studied and compared to the results of previously used linear corrections. A new GDAS-based correction is introduced and compared to previous methods. Furthermore, a tool is developed to extract GDAS atmospheric parameters which are then interfaced with CORSIKA. The utility of this tool is not only limited to LOFAR. This code, called ‘gdastool’, has been available for public use since the release of CORSIKA version 7.6300. It is flexible and ready to be adapted by the users to obtain parameterized atmospheric profiles for user-specified time and location.

Sections 2 and 3 describe the processing of GDAS data to extract the atmospheric state variables and examples of atmospheric profiles at the LOFAR site, respectively. Section 4 covers the details of the implementation of GDAS in CORSIKA. In sections 5 and 6, LOFAR cosmic ray data are evaluated with the GDAS atmospheric profiles, the GDAS-correction factor is introduced and the explicit effects of humidity on shower parameters are discussed.

2. Extracting atmospheric variables from GDAS data

The Global Data Assimilation System (GDAS) developed at NOAA's¹ National Centers for Environmental Prediction (NCEP) is a tool used to describe the global atmosphere. It is run four times a day (0, 6, 12, and 18 UTC) and provides a 3-, 6- and 9-hour forecast based on the interpolation of meteorological measurements from all over the world including weather stations on land, ships and airplanes as well as radiosondes and weather satellites [17]. The three hourly data are available at 23 constant pressure levels, from 1000 hPa (roughly sea level) to 20 hPa (≈ 26 km) on a global 1° spaced latitude-longitude grid (180° by 360°). Each data set is complemented by data at the surface level. The data are stored in weekly files and made available online. In order to model a realistic atmosphere one needs to obtain the suitable atmospheric parameters from GDAS. Parameters like temperature (K), height (m) relative humidity (H) and pressure (hPa) can be directly extracted from the database. In the GDAS data, the altitude is in geopotential units with respect to a geoid (mean sea level). This is an adjustment to geometric height or elevation above mean sea level using the variation of gravity with latitude and elevation. To convert from geopotential height h (m) to standard geometric altitude z (m) we use the formula

$$z(h, \Phi) = (1 + 0.002644 \cdot \cos(2\Phi)) \cdot h + (1 + 0.0089 \cdot \cos(2\Phi)) \left(\frac{h^2}{6245000} \right) \quad (1)$$

where Φ is the geometric latitude [18]. To calculate the air density, the relative humidity is to be converted into water vapor pressure. The following approximation of the empirical Magnus formula is used to calculate the water vapor pressure (hPa) in terms of humidity and temperature [18]:

$$e = \frac{H}{100\%} \times 6.1064 \times \exp\left(\frac{21.88 t}{265.5 + t}\right) \quad \text{for } t \leq 0^\circ C \quad (2)$$

and

$$e = \frac{H}{100\%} \times 6.1070 \times \exp\left(\frac{17.15 t}{234.9 + t}\right) \quad \text{for } t \geq 0^\circ C. \quad (3)$$

The density can be calculated from the ideal gas law as

$$\rho = \frac{P M_{\text{air}}}{R T} \quad (4)$$

¹National Oceanic and Atmospheric Administration.

where P is the atmospheric pressure in Pa, T is temperature in K and R is the universal gas constant, having a value of $8.31451 \text{ J K}^{-1} \text{ mol}^{-1}$ and M_{air} is the molar mass of air. Moist air can be decomposed into three components to calculate its molar mass: dry air, water vapor and carbon dioxide. The molar mass of humid air is the sum of the molar masses of the components, weighted with the volume percentage ϕ_i of that component [18],

$$M_{air} = M_{dry} \cdot \phi_{dry} + M_{water} \cdot \phi_{water} + M_{CO_2} \cdot \phi_{CO_2}. \quad (5)$$

The molar masses of dry air, water vapor and CO_2 are 0.02897 , 0.04401 and $0.01802 \text{ kg-mol}^{-1}$ respectively. The volume percentage of CO_2 is taken as 385 ppmv , the percentage of water ϕ_{water} is the partial pressure of water vapor divided by the pressure P ; the dry air makes up the rest.

The refractivity, defined as $N = (n - 1) 10^6$, is a function of humidity, pressure and temperature can be expressed as

$$N = 77.6890 \text{ K hPa}^{-1} \frac{p_d}{T} + 71.2952 \text{ K hPa}^{-1} \frac{p_w}{T} + 375 463 \text{ K}^2 \text{ hPa}^{-1} \frac{p_w}{T^2} \quad (6)$$

with p_w , p_d and T being the partial water vapor pressure ($p_w = e \times 100 \text{ Pa}$), partial dry air pressure and temperature respectively [19]. The effect of humidity is important for our study as it tends to increase the refractivity in comparison to that of dry air at the radio frequencies. There are differences between the refractivities obtained in radio and the ones in the visible, near the infrared and UV ranges as described in [18]. To account for the uncertainties in GDAS data one needs to perform in situ measurements with weather balloons. Since this is beyond the scope of this work and we refer to [18], which provides a comparison between GDAS data and weather balloon measurements in Argentina. Since global atmospheric models are typically more precise in the Northern hemisphere where more weather data is available we assume that the intrinsic uncertainty of GDAS at the LOFAR site is similar to that in Argentina. Various relevant uncertainties are: $\pm 0.5 \text{ }^\circ\text{C}$ for temperature, 0.5 hPa for pressure, and 0.05 hPa for water vapor pressure and less than 1 g/cm^2 in atmospheric depth over the altitude range from 3 to 6 km . The uncertainty in water vapor pressure translates to $2 - 7\%$ uncertainty in humidity. The resulting relative uncertainty in N due to these parameters is around 0.5% at the same altitude range. The GDAS data have a resolution of 1° by 1° in latitude longitude. This can be roughly approximated as a distance of 100 km between two adjacent grid points. For highly inclined showers the distance to the region of shower development from the observation site can be larger than the distance between two grid points. For air showers coming from 70° zenith this distance is around 70 km and for zenith $> 75^\circ$ it is about 100 km . In these cases, the choice of an exact grid point becomes complicated. Also at this point, for zenith angles $> 70^\circ$ the correction due to curved atmosphere becomes important. This does not occur for LOFAR as the detected cosmic rays are limited to within a $< 55^\circ$ zenith angle due to the particle detectors used for triggering. In this regime the GDAS model works well.

3. GDAS atmospheric profiles at the LOFAR site

In this section several GDAS atmospheric profiles extracted at the LOFAR site are discussed. Fig-1 (**left**) shows humidity as a function of altitude for 5 arbitrary atmospheric profiles for different days in the year 2011, between June and November. A significant day-to-day fluctuation is seen. The red solid and blue dashed lines indicate two very different weather conditions; the red solid line having high saturating humidity between 5 – 8 km suggests higher cloud coverage and the blue dashed line with low humidity in that range indicates low cloud coverage. Fig-1 (**right**) shows the difference in atmospheric depth profile between the US standard atmosphere and the GDAS atmospheres at LOFAR for 8 profiles over the years 2011 – 2016. The GDAS atmospheres vary significantly from the US atmosphere. Atmospheric profiles with similar atmospheric depth at ground can evolve differently higher in the atmosphere. This is important for calculating the correct distance to the shower maximum. Fig-2 shows the mean profile for the relative difference in refractivity $\Delta N_{\text{relative}}$ between GDAS and the US standard atmosphere as a function of altitude for over 3 years for 100 cosmic rays recorded at LOFAR. It is defined as $\Delta N_{\text{relative}} = (N_{\text{GDAS}} - N_{\text{US}})/N_{\text{US}}$, where N_{GDAS} is calculated from Eq-6 using GDAS atmospheres at LOFAR. N_{US} is obtained from the linear relation $N_{\text{US}} = \frac{\rho_{\text{us}}}{\rho_{\text{sealevel}}} N_{\text{sealevel}}$, with $N_{\text{sealevel}} = 292$. This is the default option for calculating refractivity in CoREAS as well.

The absolute value of the mean $\Delta N_{\text{relative}}$ is around 10% near ground and around 3 – 8% between 3 to 10 km of altitude, the region important for shower development.

Approximately 75% of the atmospheric matter and 99% of the total mass of water vapor and aerosols are contained within the troposphere, the lowest layer of Earth’s atmosphere. Within the troposphere the temperature drops with altitude, reaching a constant value in the tropopause, the boundary region between troposphere and stratosphere. In the U.S standard atmosphere the troposphere ends at 11 km and tropopause extends to an altitude of 20 km. For the local GDAS atmospheres these boundaries are not sharply defined. The flat part in the mean $\Delta N_{\text{relative}} > 10$ km in Fig-2 is the result of constant temperature in the tropopause. However contribution from this region to the radio emission is minimal. To consider the effects of refractive index in the propagation time of radio signal it is important to calculate the effective N [1, 8]. This is defined as

$$N_{\text{eff}} = \frac{\int N(h)dh}{D} \quad (7)$$

where D is the distance between the line of emission and observer. The values of relative effective refractivity $\Delta N_{\text{relative}}^{\text{eff}}$ between the GDAS and US standard atmosphere are around 7 – 10 % in the range of altitude mentioned above, for observers within < 100 m of the shower axis.

4. Implementation in CORSIKA/CoREAS

To incorporate the atmospheric parameters extracted from GDAS in CORSIKA and CoREAS we have developed a program named ‘gdastool’ that downloads the required GDAS

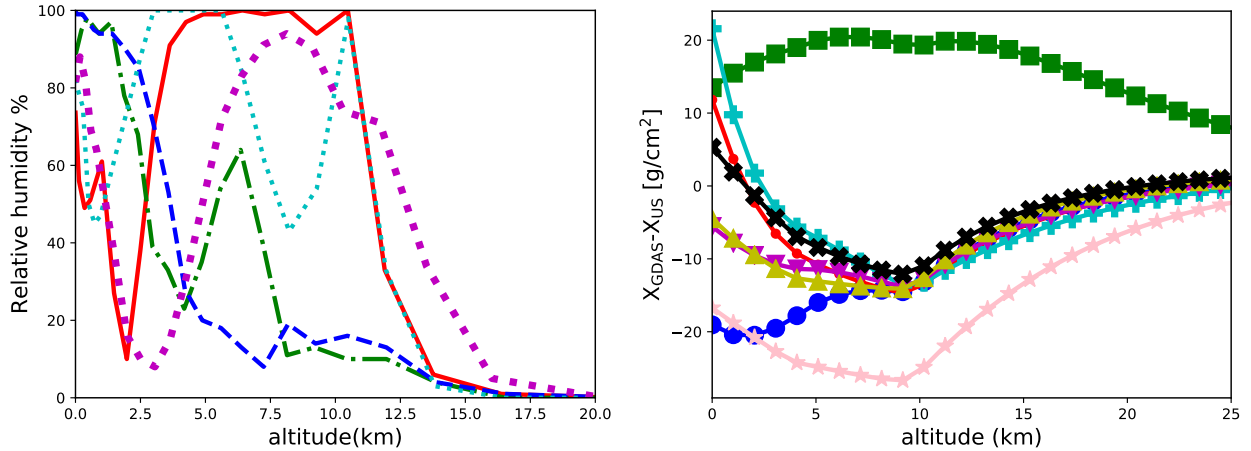

Figure 1: Atmospheric profiles at LOFAR. **Left:** Example of 5 humidity profiles between June to November during the year 2011. **Right:** 8 profiles for the difference in atmospheric depth between US standard atmosphere and GDAS atmospheres as a function of altitude between the years 2011 – 2016.

Figure 2: Mean relative refractivity, defined as $\Delta N_{\text{relative}} = \frac{N_{\text{GDAS}} - N_{\text{US}}}{N_{\text{US}}}$; profiles for 100 recorded cosmic rays at LOFAR spanning over the years 2011 to 2014. The black solid line denotes the mean profile and the blue dashed lines show the standard deviations.

file given the time and location of observation of the event and returns refractive indices between ground and the highest GDAS level. It also fits the density profile according to the standard 5 layer atmospheric model used in CORSIKA [13]. In this model the density $\rho(h)$ has an exponential dependence on the altitude leading to the functional form of mass overburden $T(h)$ which is the density integrated over height (km) as

$$T(h) = a_i + b_i e^{-10^5 h/c_i} \quad i = 1, \dots, 4. \quad (8)$$

Thus, the density is

$$\rho(h) = b_i/c_i e^{-10^5 h/c_i} \quad i = 1, \dots, 4. \quad (9)$$

In the fifth layer the overburden is assumed to decrease linearly with height. The parameters a_i , b_i and c_i are obtained in a manner such that the function $T(h)$ is continuous at the layer boundaries and can be differentiated continuously. The first three layers constitute of the 24 density points obtained from GDAS data. The first layer consists of 10 points, second layer of 7 points and the third layer of 7 points. Since GDAS provides data on constant pressure levels, not of constant heights, the layer boundaries vary slightly between different atmospheric profiles. The mean values of the boundaries for the conditions of 100 cosmic ray events are 3.56 ± 0.11 km, 9.09 ± 0.23 km, 26.27 ± 0.56 km from boundary 1 to 3, respectively.

Next, we fit the data to Eq- 9 in the following way:

For layer 1 the density profile is fitted with two free parameters. Then the density ρ_1 at boundary 1 is calculated using Eq- 9 with the obtained parameters b_1 , c_1 . The condition that the density has to be continuous at the boundaries reduces the number of free parameters to 1 which is the parameter c . Thus the parameter b_2 for second layer can be expressed as a function of ρ_1 and c_2 with c_2 being the only free parameter. The same fitting procedure is repeated for the third layer. The fourth layer ranges from the highest GDAS altitude to 100 km. At these altitudes there are no physical GDAS data. The parameter c_4 is obtained by fitting the last GDAS point and the density at 100 km from US standard atmosphere. At these altitudes the mass overburden is less than 0.1% of the value at ground. The important factor is to satisfy the boundary conditions throughout the atmosphere. Along with density the continuity of mass overburden is also preserved. For that, once a smooth profile for the density is obtained, the parameter a in Eq- 8 is solved for analytically, using the boundary conditions for the mass overburden. The parameterization for the fifth layer was adapted from the US standard atmosphere [13]. The ‘gdastool’ also returns a density profile plot with the best fit parameters as a function of altitude and the rms of the relative density difference between data and fit. The relative density is defined as $\frac{\rho_{\text{fit}} - \rho_{\text{data}}}{\rho_{\text{fit}}}$. Fig-3 (**left**) and its rms is used as a goodness of fit. Fig-3 (**left**) shows the example of a density profile between the fitted model and GDAS. The mean relative error in density for 100 profiles as a function of altitude is presented in Fig-3 (**right**). At lower altitudes the model fits the data very well; deviations $> 2\%$ start at altitudes higher than 15 km which are not so important for the shower development. A bump in the profile at 10 km is observed, this can be explained by the change in the atmosphere at the troposphere boundary as discussed in the previous section. There will be an error on the atmospheric depth introduced by the fitted model in Eq- 8. It is on the order of 2 g/cm^2 on average between the altitude range mentioned above with a variance of $4 - 5 \text{ g/cm}^2$.

The ‘gdastool’ can be executed as a stand alone script within CORSIKA. Given the coordinate and UTC time stamp as input parameters it downloads the required GDAS files and extracts atmospheric data. It then returns an output file that contains fitted mass overburden parameters and tabulated refractive indices interpolated to 1 m intervals. This output file can be invoked through the CORSIKA steering file. When called, it replaces the default atmospheric parameters in CORSIKA with the new ones and the on-the-fly refractive index calculation in CoREAS with the look-up table.

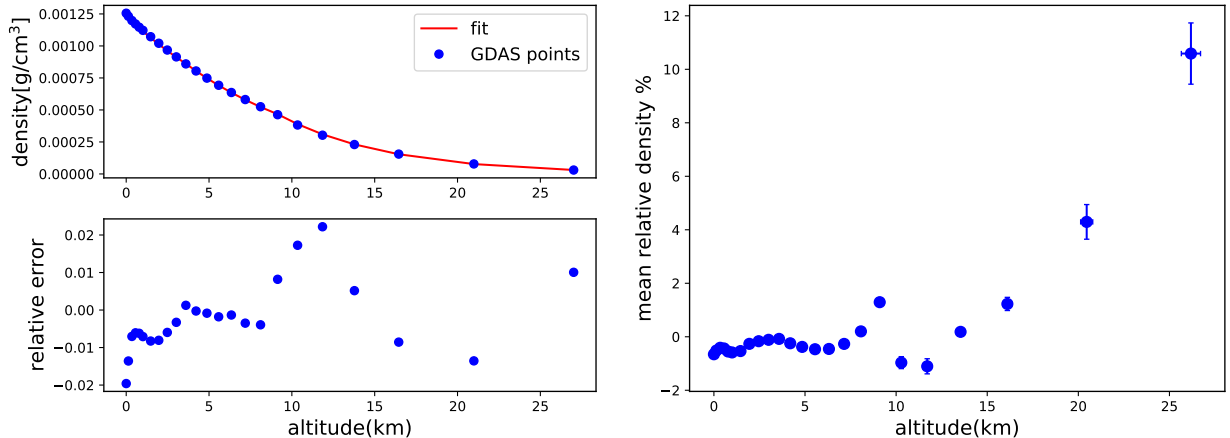

Figure 3: **Left:** Example of one density profile, GDAS and the fitted 5-layered atmospheric model. The bottom panel shows the relative error defined as $\frac{\rho_{\text{fit}} - \rho_{\text{data}}}{\rho_{\text{fit}}}$. **Right:** Mean relative error in density for 100 different atmospheric profiles. The mean is calculated at each of the 24 GDAS points for all the profiles. The error bars indicate the standard deviation.

5. Effects on the reconstruction of the depth of the shower maximum

The highest precision for the determination of X_{max} with the radio technique is currently achieved with the LOFAR radio telescope. Situated in the north of the Netherlands, the dense core of LOFAR consists of 288 low-band dipole antennas within a circle with a diameter of 320 meters, known as the Superterp. The radio emission from air showers in the frequency range 30–80 MHz is recorded by the LOFAR low-band antennas [12, 20]. An array of particle detectors installed on the Superterp provides the trigger for the detection of the air showers [21].

The X_{max} reconstruction technique used at LOFAR is based on the production of dedicated simulation sets for each detected air shower. The number of simulations needed to reconstruct the shower maximum is optimized with CONEX [22]. A set of full CORSIKA simulations with proton and iron primaries is produced for each detected cosmic ray. The radio emission is simulated in a star-shaped pattern for antenna positions in the shower plane using CoREAS. An antenna model is applied to the simulated electric fields and compared to the measured signal in the dipole antennas [23]. The time integrated pulse power is calculated in a 55 ns window centered around the pulse maximum, summed over both polarizations. Finally, a two-dimensional map of the time integrated power is created by interpolating the star-shaped pattern [24]. In the previous analysis a hybrid fitting technique was used in which both the radio and particle data were fitted to the two-dimensional radiation map and the one-dimensional particle lateral distribution function simultaneously. In this work instead of the combined fit we fit only the radio data to the radio simulation. The advantage of switching to the radio only fitting method is that it results in reduced systematic uncertainties.

Fig-4 shows the fit quality for an air shower detected with LOFAR as a function of X_{max}

Figure 4: Quality of fit as a function of simulated X_{\max} for a LOFAR event of energy 1.4×10^8 GeV, with a zenith angle of 38° . **Left:** simulated with default US standard atmosphere, reconstructed $X_{\max} = 675.8$ g/cm 2 . Applying the linear first order atmospheric correction, the resulting $X_{\max} = 658$ g/cm 2 . **Right:** simulated with GDAS atmosphere, reconstructed $X_{\max} = 638.3$ g/cm 2 , the reconstructed X_{\max} in both the cases is indicated by solid black lines.

simulated with two different atmospheres - one with the corresponding GDAS atmosphere and the other with the US standard atmosphere. The reconstructed value of X_{\max} is found from the minimum of the fitted parabola around the best fitted points. We chose a LOFAR event for which the ground pressure was much lower than the US standard atmosphere, by 20 hPa. The atmospheric profile for this particular event is represented by the blue line with circles in Fig-1 (**right**). The reconstructed X_{\max} with the US atmosphere corresponds to a much higher mass overburden than the reconstructed X_{\max} using much thinner GDAS atmosphere. In this example this translates to a difference of around 37.5 g/cm 2 in the reconstructed X_{\max} between the two cases. This large deviation is attributed to the extreme weather condition for the shower chosen in the example. In the previous LOFAR analysis a correction factor to the US atmosphere was used to account for the real atmosphere [3, 24]. The simulations that are produced with US standard atmosphere would approximately yield the correct geometrical altitude to the shower maximum. Then the corrected X_{\max} is calculated by integrating the GDAS density profile obtained at LOFAR, from the top of the atmosphere to the geometric altitude of X_{\max} in the following way:

$$X(h) = \frac{1}{\cos \theta} \int_h^\infty \rho_{\text{gdas}}(h) dh. \quad (10)$$

The corrected X_{\max} for this particular example is 658 g/cm 2 and the difference between the corrected and new X_{\max} is about 20 g/cm 2 .

Using the same approach described above we have studied 123 air showers recorded with LOFAR with three simulation sets:

Figure 5: Difference in mean X_{\max} as a function of ground pressure. The total sample contains 123 air showers recorded at LOFAR. The black line denotes the U.S standard atmospheric pressure.

- **Set A**—the showers were simulated with CORSIKA v-7.6300 and GDAS atmosphere.
- **Set B**—the showers were simulated with CORSIKA v-7.4385 and US standard atmosphere.
- **Set C**—this set is identical to **Set B** but with the additional atmospheric correction factor to it as described above.

The effect of using different CORSIKA versions on the reconstructed X_{\max} , irrespective of the atmospheric model, was probed. The difference in X_{\max} found using CORSIKA versions 7.6300 and 7.4385 was found to be very small, around 1.4 g/cm^2 . This confirms that the differences between Set-A, Set-B and Set-C are due to different atmospheric models, not any artifact arising from different versions of CORSIKA.

In Fig-5 the difference in mean reconstructed X_{\max} between the various simulation sets mentioned above is plotted against ground pressure bins obtained from GDAS. Both the blue circles and red squares converge to zero where GDAS pressure approaches the US standard pressure at 1013 hPa. The red squares have large ΔX_{\max} in general. This is expected as there is no atmospheric correction involved in Set-B. The blue circles however show a higher deviation both at low and high pressure values. This suggests that the linear first order correction added to the standard US atmosphere implemented in Set-C is not sufficient. As the refractive index effects can not be included in the linear first order correction, one needs full GDAS-based atmospheric profiles for more extreme atmospheric conditions.

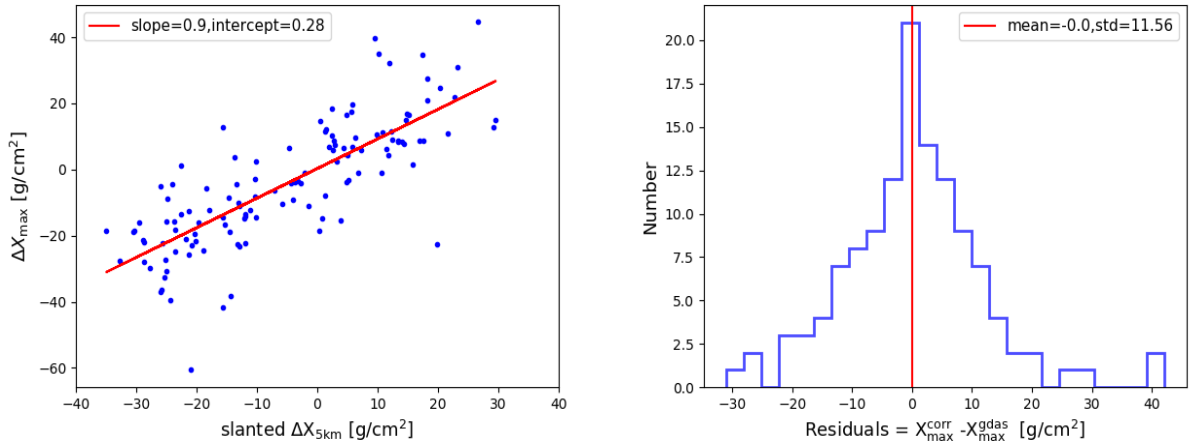

Figure 6: **Left:** scatter plot of $\Delta X_{\max} = X_{\max}^{\text{gdas}} - X_{\max}^{\text{us}}$ vs difference in slanted mass overburden $\Delta X_{5\text{km}} = X_{5\text{km}}^{\text{gdas}} - X_{5\text{km}}^{\text{us}}$. The red line is a linear fit to the profile. **Right:** Histogram shows the residual of fitted and actual X_{\max} ; residual = $X_{\max}^{\text{corr}} - X_{\max}^{\text{gdas}}$.

Here, we study the possibility to introduce a new global correction factor to the reconstructed X_{\max} with US standard atmosphere to correct for realistic atmospheres without having to run full GDAS-based CoREAS simulations. To achieve this we studied the correlation between X_{\max} , refractivity, and slanted mass overburden which is defined as the integrated density from the edge of the atmosphere to a given height at the slant of zenith angle, at different altitudes. It was seen that both the correlation between X_{\max} and refractivity and between X_{\max} and slanted mass overburden correlation are poor at ground and at lower altitudes. At the higher altitudes, between 4 - 6 km, X_{\max} and mass overburden show a higher correlation which is not prominent in X_{\max} vs refractivity profiles at these altitudes. We have found the strongest correlation at an altitude of 5 km. Fig-6 (left) shows the scatter plot of ΔX_{\max} defined as $X_{\max}^{\text{gdas}} - X_{\max}^{\text{us}}$ and difference in the slanted mass overburden $\Delta X_{5\text{km}} = X_{5\text{km}}^{\text{gdas}} - X_{5\text{km}}^{\text{us}}$. The precise correlation suggests the profile can be fit with a straight line and is used as a parameterization of global correction factor, provided by the equation:

$$X_{\max}^{\text{corr}} - X_{\max}^{\text{us}} = 0.9 \left(X_{5\text{km}}^{\text{us}} - X_{5\text{km}}^{\text{gdas}} \right) + 0.28. \quad (11)$$

The histogram in Fig-6 (right) shows the residual of the X_{\max}^{corr} from X_{\max}^{gdas} . The profile is symmetric with mean 0 g/cm^2 and standard deviation 11.56 g/cm^2 . The fluctuations are within the typical systematic uncertainty of the reconstructed X_{\max} with LOFAR, which is around 17 g/cm^2 [24]. This correction factor can be used as a rule of thumb for the estimation of reconstructed X_{\max} with the following caveats. It is specific to LOFAR, as simulations were performed involving weather conditions, observation level, and magnetic field particular to LOFAR. Corresponding correction equations for other experiments can be constructed in the same manner and can yield different results depending on atmospheric parameters.

However, while this global correction factor is very useful when a fast reconstruction is

needed, we will use the full Monte Carlo approach in a future composition analysis. Simulations with event specific GDAS atmospheres are always more accurate than the correction factor. The correction factor might also introduce biases related to the mass of the primary particles. Proton primaries on average generate showers that reach maximum lower in the atmosphere than iron; these kind of effects are not taken into account.

6. Effects of humidity

As described in section 2, in the radio frequency regime, humidity increases the refractive index. For this study, two sets of simulations were produced. In one set the showers were simulated with the respective GDAS atmosphere and in the other with a GDAS atmosphere with vanishing humidity. This was achieved by hard-coding the partial water vapor pressure in Eq-3 to negligible values. For the GDAS atmosphere an extremely humid weather condition at the LOFAR site was chosen. The same atmospheric parameters are used in both cases to ensure that the particles evolve in a similar way in the atmosphere and produce same shower maximum. In this way the inclusion of humidity only influences the simulated radio pulses. The difference in the refractive index manifests in terms of propagation effects on the pulse arrival time and power. The pulse propagating through an atmosphere with higher refractive index will have a lower velocity compared to dry air. This results in a delayed arrival time of the signal, as seen in Fig-7. The difference in peak arrival time is less than 1 ns for an observer at 150 m. The effect is found to be less prominent for observers further away from the axis. The lateral distribution of the energy fluence, the time-integrated power per unit area, for different observer positions is also studied for different frequency bands for these two cases, as shown in Fig-8. In the low frequency band of 30–80 MHz relevant for LOFAR the difference in the fluence between the two sets is small, from around 4% closer to shower axis to 2% at a distance of 100 m from the axis. In the high frequency band of 50–350 MHz the values are larger, being around 8% at 100 m from the core. In the higher frequency band the Cherenkov-like effects become stronger and the signal is compressed along the Cherenkov ring [25]. A rough estimate of the radius of the ring can be obtained from the projection of a cone with an opening angle given by the Cherenkov angle starting from the shower maximum. The opening angle is strongly dependent on the index of refraction. This explains the higher difference in power in Fig-8. Similar effects in high and low frequency bands were also reported in [15] by studying the LDF of the electric field profiles. Inside the Cherenkov radius pulses are stretched due to refractive index effects. For higher refractive indices this will lead to lower pulse power which explains the negative sign in the relative fluence for observer distances close to the core.

The radiation energy is the total energy contained in the radio signal. It scales quadratically with the cosmic ray energy, thus can be used as a cosmic ray energy estimator [26, 27]. The surface integral over the radio LDF mentioned above yields the radiation energy. The relative difference in the integrated LDF between the humid and non-humid profiles for both the low and high frequency regimes is smaller than 1%. This indicates that humidity has almost no effect on the estimated cosmic ray energy as determined from the radiation energy which was also concluded in [28].

Figure 7: Unfiltered electric field components of a CoREAS pulse in time for two different refractive index profiles for a 10^{17} eV proton shower with a zenith angle of 45° coming from east for an observer at 150 m from the axis. The solid and dashed lines represent the profiles with lower and higher refractive indices respectively.

Next, to investigate the effect of humidity on X_{\max} measurements we have performed a Monte Carlo comparison study between two sets of simulations that deals with the atmospheres in a similar way as described in the beginning of this section. For each of these cases we have used a set of 40 simulated events with different energy, zenith and azimuth angles. Each of these sets consist of an ensemble of proton and iron initiated showers based on CONEX selection criteria. One shower from the set with higher humidity is taken as reference and all the simulated showers from the set with zero humidity are used to perform the reconstruction. This yields a reconstructed X_{reco} that can be compared to the actual X_{real} of the reference shower. The same method is repeated for all the showers in the set with higher humidity. Showers with extreme values of X_{\max} were not included in the fit. The range of the fit was taken as ± 50 g/cm 2 of the actual X_{\max} for the test shower.

The difference $X_{\text{reco}} - X_{\text{real}}$ estimates the effect of humidity on the reconstructed X_{\max} . We do not observe any significant shift in X_{\max} in this study. This indicates that these effects are most likely smaller than the overall resolution in reconstructed X_{\max} in the LOFAR frequency band. We also performed the same study in a higher frequency band between 50 and 350 MHz, corresponding to the SKA-low band. There, an overall shift of 6.8 g/cm 2 in the reconstructed X_{\max} was observed. These results, shown in Fig-9, are in line with the LDF studies described earlier in this section.

In Ref.[11], larger shifts of about 10 to 22 g/cm 2 in reconstructed X_{\max} in the high frequency band of 120–250 MHz for 4% higher refractivity and 3.5 to 11 g/cm 2 in the low frequency band of 30–80 MHz were reported. A toy model was used to describe the effects. The toy

Figure 8: LDF profiles for a 10^{17} eV proton shower coming from zenith 45° with $X_{\max} = 593\text{g/cm}^2$. Observers are located to the west of the shower axis. **Left:** low frequency band between 30–80 MHz, **Right:** high frequency band between 50–350 MHz. The upper panel shows the LDF of total fluence for the humid and non-humid sets, the lower panel shows the relative difference between these two.

Figure 9: Histogram for the $\Delta X_{\max} = X_{\text{reco}} - X_{\text{real}}$ between the reconstructed and true value of the X_{\max} obtained from the Monte Carlo study between the humid and non-humid simulation sets. **Left:** for the low frequency band of 30–80 MHz. **Right:** for the high frequency band of 50–350 MHz. The shift in the X_{\max} is significant at 2σ level.

model was based on the assumptions that the size of the radio footprint on the ground would be proportional to the geometric distance to X_{\max} and to the Cherenkov angle at the altitude of X_{\max} . The effect of constant higher refractivity would correspond to a higher Cherenkov

angle resulting in an underestimation of X_{\max} . This then leads to a clear linear relation between shift in X_{\max} and distance to X_{\max} . Without having prior knowledge of individual atmospheric conditions, an overall scaling of the refractivity profile had to suffice. However, the realistic scenario is quite different. There are strong interplays between humidity, pressure, and temperature which are reflected in refractivity. The relative refractivity profile in Fig-2 shows that the shift is not a constant, but is altitude dependent. From near ground to higher altitudes it switches from being a higher value than US standard atmosphere to a lower value. This makes an one-to-one comparison to Ref.[11] hard. However, we can argue that qualitatively same trait in the high and low frequency band has been found in both the works.

The effects of different zenith angles, true X_{\max} and energy were probed for the shift in X_{\max} for both the frequency bins. The simulation set was divided in two groups, each group belonging to high and low values of the parameters mentioned above. No significant effect was seen.

Frequency band	Zenith	ΔX_{\max} (g/cm ²)
50–350 MHz	low < 30°	-6.24±0.30
50–350 MHz	high > 30°	-6.19± 0.37
30–80 MHz	low < 30°	0.10±0.50
30–80 MHz	high > 30°	-0.05±0.46
Frequency band	True X_{\max} (g/cm ²)	ΔX_{\max} (g/cm ²)
50–350 MHz	low < 624	-6.78±0.41
50–350 MHz	high > 624	-6.30± 0.32
30–80 MHz	low < 624	-0.61±0.51
30–80 MHz	high > 624	0.51±0.46
Frequency band	Energy(GeV)	ΔX_{\max} (g/cm ²)
50–350 MHz	low < 2.18×10^8	-6.86±0.35
50–350 MHz	high > 2.18×10^8	-6.92± 0.38
30–80 MHz	low < 2.18×10^8	-0.48±0.48
30–80 MHz	high > 2.18×10^8	0.±0.49

Table 1: Shift in X_{\max} for different zenith, energy and X_{\max} bins for different frequency bands.

7. Conclusion and discussion

Simulating air showers with realistic atmospheres is important for the precise reconstruction of X_{\max} with the radio technique. The GDAS database is a useful platform to extract atmospheric parameters for a given time and location. Atmospheric effects on radio simulations were previously studied in Refs. [11] and [15]. The studies demonstrated the role of correct description of atmospheric density and refractive index when included in the radio simulation codes. However, the application of simulations with realistic atmospheres to real data was not addressed.

We report, for the first time, the application of GDAS-based atmospheric profiles, automated in CoREAS simulation to cosmic ray data. By systematically performing GDAS-based CoREAS simulations for the LOFAR dataset, we have done comparison between GDAS-based atmospheres a linear geometrical first order correction to the US standard atmosphere on X_{\max} . While the linear correction is sufficient for the bulk of the events, it becomes indispensable to use full GDAS based atmospheres for extreme values of the air pressure. When the air pressure at ground level differs by less than 10 hPa from the US standard atmosphere value, the reconstructed X_{\max} value including the linear correction agrees with the full GDAS-based reconstruction value within 2 g/cm². However, when the ground pressure is more than 10 hPa from the US standard atmosphere, this difference grows significantly up to 15 g/cm².

We have also introduced a GDAS-based correction factor for X_{\max} reconstructed with US standard atmosphere without having to run full GDAS-based CoREAS simulations. It is specific to LOFAR, but similar relations can be worked out for other experiments as well. The uncertainty on the predicted X_{\max} using the correction factor is about 12 g/cm²; this is within the typical X_{\max} reconstruction uncertainty with LOFAR, around 17 g/cm².

We have probed the effects of humidity on the lateral distribution of radio power by comparing two profiles with high and low humidity. We performed this study for different frequency bands. In the LOFAR frequency band of 30–80 MHz the relative difference in power is small. For a higher frequency band of 50–350 MHz the same effects are comparatively larger, up to 10%. We also estimated the radiation energy from the LDF profiles to see the effects of humidity on the reconstructed energy. No significant difference was found for either frequency regime which indicates that humidity does not influence the estimated energy. A Monte Carlo study on the reconstructed X_{\max} was also done for these frequency bands. No significant effect of humidity is found on the reconstructed X_{\max} for the low frequency band relevant for LOFAR; for the higher frequency band a mean difference on the order of 7 g/cm² is observed. This could be important for the high precision X_{\max} measurements for the cosmic ray detection with the SKA experiment [29].

In the process of implementing GDAS-based parameterized density and refractive index profile in CORSIKA/CoREAS, we have developed a tool, called ‘gdastool’, which has been available for public use since the release of CORSIKA version 7.6300, and is already being used by other experiments in the community around the globe.

In the previous LOFAR analysis the effects of refractive index were included within the systematic uncertainties on the reconstructed X_{\max} . The improved atmospheric correction will lead to a reduced systematic uncertainty. An update on the mass composition results is not within the scope of this study. It will be discussed in a future publication, which involves, along with atmospheric corrections, improved calibration of the radio antennas, energy scale, and new X_{\max} reconstruction techniques.

8. Acknowledgement

The LOFAR cosmic ray key science project acknowledges funding from an Advanced Grant of the European Research Council (FP/2007-2013)/ERC Grant Agreement no 227610. The project has also received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No 640130). We furthermore acknowledge financial support from FOM, (FOM-project 12PR304). AN is supported by the DFG (Emmy-Noether grant NE 2031/2-1). LOFAR, the Low Frequency Array designed and constructed by ASTRON, has facilities in several countries, that are owned by various parties (each with their own funding sources), and that are collectively operated by the International LOFAR Telescope foundation under a joint scientific policy. We sincerely thank the CORSIKA developers for their assistance regarding the implementation of our work in CORSIKA modules.

ABSTRACT

Motivated by the recent high-precision measurements of cosmic rays by several new-generation experiments, we have carried out a detailed study to understand the observed energy spectrum and composition of cosmic rays with energies up to about 10^{18} eV. Our study shows that a single Galactic component with subsequent energy cut-offs in the individual spectra of different elements, optimised to explain the observed elemental spectra below $\sim 10^{14}$ eV and the ‘knee’ in the all-particle spectrum, cannot explain the observed all-particle spectrum above $\sim 2 \times 10^{16}$ eV. We discuss two approaches for a second component of Galactic cosmic rays – re-acceleration at a Galactic wind termination shock, and supernova explosions of Wolf-Rayet stars, and show that the latter scenario can explain almost all observed features in the all-particle spectrum and the composition up to $\sim 10^{18}$ eV, when combined with a canonical extra-galactic spectrum expected from strong radio galaxies or a source population with similar cosmological evolution. In this two-component Galactic model, the knee at $\sim 3 \times 10^{15}$ eV and the ‘second knee’ at $\sim 10^{17}$ eV in the all-particle spectrum are due to the cut-offs in the first and second components, respectively. We also discuss several variations of the extra-galactic component, from a minimal contribution to scenarios with a significant component below the ‘ankle’ (at $\sim 4 \times 10^{18}$ eV), and find that extra-galactic contributions in excess of regular source evolution are neither indicated nor in conflict with the existing data. We also provide arguments that an extra-galactic contribution is unlikely to dominate at or below the second knee. Our main result is that the second Galactic component predicts a composition of Galactic cosmic rays at and above the second knee that largely consists of helium or a mixture of helium and CNO nuclei, with a weak or essentially vanishing iron fraction, in contrast to most common assumptions. This prediction is in agreement with new measurements from LOFAR and the Pierre Auger Observatory which indicate a strong light component and a rather low iron fraction between $\sim 10^{17}$ and 10^{18} eV.

Key words. Galaxy — cosmic rays — diffusion — ISM: supernova remnants — Stars: winds — Stars: Wolf-Rayet

1. Introduction

Until a decade ago, the cosmic ray spectrum from ~ 10 GeV to $\sim 10^{11}$ GeV was seen as a power law with two main features: a steepening from a spectral index $\gamma \approx -2.7$ to $\gamma \approx -3.1$ at about 3×10^6 GeV, commonly called the ‘knee’, and a flattening back to $\gamma \approx -2.7$ at about 4×10^9 GeV, consequently denoted as the ‘ankle’. Phenomenological explanations for the knee have been given due to propagation effects in the Galaxy (Ptuskin et al. 1993), progressive cut-offs in the spectra of nuclear components from hydrogen to lead (Hörandel 2003a), or re-acceleration at shocks in a Galactic wind (Völk & Zirakashvili 2004), but left open the question of the primary Galactic accelerators producing these particles. Explanations based on source physics have been mostly built on the assumption that supernova remnants, on grounds of energetics known as one of the most promising sources for cosmic rays (Baade & Zwicky 1934), accelerate cosmic rays at shocks ploughing into the interstellar medium to energies up to about 10^{5-6} GeV

(Lagage & Cesarsky 1983; Axford 1994). This may extend to $\sim 10^8$ GeV if they are propagating in fast and highly magnetised stellar winds (Völk & Biermann 1988; Biermann & Cassinelli 1993), or if non-linear effects in the acceleration process are considered (Bell & Lucek 2001). The combination of such components could eventually explain cosmic rays below and above the knee as a superposition of components of different nuclei, as shown, for example by Stanev et al. (1993). At energies above 10^9 GeV this steep component was assumed to merge into a flatter extra-galactic component (Rachen et al. 1993; Berezhinsky et al. 2004), explaining the ankle in the spectrum. For this extra-galactic component, sources on all scales have been proposed: From clusters of galaxies (Kang et al. 1996) through radio galaxies (Rachen & Biermann 1993), compact AGN jets (Mannheim et al. 2001) to gamma-ray bursts (Waxman 1995). It was commonly assumed to be dominated by protons. Eventually, at $\sim 10^{11}$ GeV the cosmic ray spectrum was believed to terminate in the so-called GZK cutoff (Greisen 1966; Zatsepin & Kuzmin 1996) due to interaction with cosmic microwave background (CMB) photons.

* E-mail: satyendra.thoudam@lnu.se

Recent measurements of cosmic rays by several new generation experiments have severely challenged this simple view. At low energies, below $\sim 10^6$ GeV, satellite and balloon-borne experiments such as ATIC-2 (Panov et al. 2007), CREAM (Yoon et al. 2011), TRACER (Obermeier et al. 2011), PAMELA (Adriani et al. 2014), AMS-02 (Aguilar et al. 2014, 2015a,b), and *Fermi*-LAT (Abdo et al. 2009) have measured the energy spectra of various elements of cosmic rays ranging from protons to heavier nuclei such as iron as well as the leptonic component of cosmic rays, and anti-particles such as positrons and anti-protons. Some of their results, for example the rise of the positron fraction above ~ 10 GeV (Aguilar et al. 2013), the harder energy spectrum of helium nuclei with respect to the proton spectrum (Adriani et al. 2011), and the spectral hardening of both the proton and helium nuclei at TeV energies (Yoon et al. 2011), are difficult to explain using standard models of cosmic-ray acceleration in supernova remnants and their subsequent propagation in the Galaxy. At high energies, that is above $\sim 10^6$ GeV, ground-based experiments such as KASCADE-Grande (Apel et al. 2013), the Tibet III array (Amenomori et al. 2008), IceTop (Aartsen et al. 2013), the Pierre Auger Observatory (Ghia et al. 2015) and the Telescope Array (Abu-Zayyad et al. 2013) have carried out detailed measurements of the all-particle energy spectrum and the composition of cosmic rays. First, they confirm a third major break in the spectrum, a steepening to $\gamma \approx -3.3$ above about 10^8 GeV, which has been suggested before both by the Fly’s Eye stereo energy spectrum (Bird et al. 1994) and theoretical arguments about the structure of the ankle (Berezinsky & Grigorieva 1988; Rachen et al. 1993). It has anatomically been named the ‘second knee’ (Hörandel 2006). While this still fits with the original view, the cosmic-ray composition measurements at these energies pose a severe challenge: Instead of gradually becoming heavier as expected, the data show that the composition reaches a maximum mean mass at energies around 6×10^7 GeV, and then becomes gradually lighter again up to the ankle. Finally, above the ankle the composition becomes heavier again. It has been shown that the observed spectrum and composition at the highest energies can be explained by a mixed-composition extra-galactic source spectrum with progressive cutoffs at $\sim Z \times 5 \times 10^9$ GeV, where Z is the nuclear charge (Aloisio et al. 2014). This would imply that there is no significant impact of the GZK effect in cosmic ray propagation except through photo-disintegration of nuclei. In addition, the measurement of an ankle-like feature in the light component of cosmic rays at $\sim 10^8$ GeV by the KASCADE-Grande experiment (Apel et al. 2013), and the new revelation of a strong light component and a very small iron component by the LOFAR measurements between $\sim (1 - 4) \times 10^8$ GeV (Buitink et al. 2016), and by the Pierre Auger Observatory above $\sim 7 \times 10^8$ GeV (Aab et al. 2014) add further challenges to the standard model.

The new data have led to a number of theoretical modifications of the standard model. The spectral hardening at TeV energies has been explained as due to the hardening in the source spectrum of cosmic rays (Biermann et al. 2010a; Ohira et al. 2011; Yuan et al. 2011; Ptuskin et al. 2013), as a propagation effect (Tomassetti 2012; Blasi et al. 2012), the effect of re-acceleration by weak shocks (Thoudam & Hörandel 2014) or the effect of nearby sources (Thoudam & Hörandel 2012, 2013;

Erlykin & Wolfendale 2012). At high energies, the increasing mean mass around the knee still fits well the idea of progressive cut-offs (Hörandel 2003a), if the nuclear species are constrained to masses up to iron and thus limited to energies below about 3×10^7 GeV. The light composition around the ankle revived interest in the so-called ‘proton dip model’, which explains the ankle feature as due to an extra-galactic propagation effect of protons producing electron-positron pairs at the CMB (Berezinsky & Grigorieva 1988; Berezinsky et al. 2006). This would imply that the cosmic ray spectrum below the ankle is, at least in part, of extra-galactic origin. While the recent measurement of $\sim 40\%$ proton fraction at the ankle by the Pierre Auger Collaboration (Aab et al. 2014) has raised problems with this approach, as the model is compatible only with more than 80% protons (Berezinsky et al. 2006), a number of new models have been suggested, involving compact sources with significant photo-disintegration of nuclei during acceleration (Globus et al. 2015a; Unger et al. 2015), or as a component with primordial element composition accelerated at clusters of galaxies and limited by pair production losses in the CMB (Rachen 2016). However, with all these new ideas, big questions remain open: How does the cosmic ray component at the knee connect to the one at the second knee to ankle regime, and where is the transition from Galactic to extra-galactic cosmic rays?

In this work, we revisit the basic models of Galactic cosmic-ray production in view of the currently available data. We start by developing a detailed model description for low-energy cosmic rays assuming them to be primarily produced inside supernova remnants (SNRs) present in the interstellar medium (hereafter, these cosmic rays will be referred to as the ‘SNR-CRs’). This model, described in Section 2, has been demonstrated to explain the observed spectral hardening of protons and helium nuclei in the TeV region and, at the same time, explains the observed composition of cosmic rays at low energies (Thoudam & Hörandel 2014). The model prediction will be extended to high energies, and compared with the observed all-particle energy spectrum. It will be shown that SNR-CRs cannot explain the observed energy spectrum above $\sim 10^7$ GeV. We then revisit two possibilities for a second Galactic component in Section 3: (a) The re-acceleration of SNR-CRs escaped into the Galactic halo by the Galactic wind termination shocks (Jokipii & Morfill 1987; Zirakashvili & Völk 2006), and (b) the contribution of cosmic rays from the explosions of Wolf-Rayet stars in the Galaxy (Biermann & Cassinelli 1993). The possibility of a second Galactic component has also been discussed in Hillas (2005) who considered Type II SNRs expanding into a dense wind of their precursor stars. For both the scenarios considered in the present work, we assume the extra-galactic proton component used by Rachen et al. (1993) to obtain proper results for total spectrum and composition at energies just below the ankle in Section 4. In Section 5 we then check the effect of other hypotheses for the extra-galactic component, using (1) a phenomenological ‘minimal model’ derived from composition results measured at the Pierre Auger Observatory (di Matteo et al. 2015), (2) the minimal model plus the ‘primordial cluster component’ introduced by Rachen (2016), and (3) the ‘extra-galactic ankle’ model by Unger et al. (2015). In Section 6, we present a discussion of our results and their implications, and other views on the cosmic rays below 10^9 GeV, followed by our conclusions in Section 7.

2. Cosmic rays from supernova remnants (SNR-CRs)

Although the exact nature of cosmic-ray sources in the Galaxy is not yet firmly established, supernova remnants are considered to be the most plausible candidates both from the theoretical and the observational points of view. It has been theoretically established that shock waves associated with supernova remnants can accelerate particles from the thermal pool to a non-thermal distribution of energetic particles. The underlying acceleration process, commonly referred to as the diffusive shock acceleration process, has been studied quite extensively, and it produces a power-law spectrum of particles with a spectral index close to 2 (Krymskii 1977; Bell 1978; Blandford & Ostriker 1978; Drury 1983; Ptuskin et al. 2010; Caprioli et al. 2011), which is in good agreement with the values inferred from radio observation of supernova remnants (Green 2009). Moreover, the total power of $\sim 10^{42}$ ergs s^{-1} injected by supernova explosions into the Galaxy, considering a supernova explosion energy of $\sim 10^{51}$ ergs and an explosion frequency of $\sim 1/30$ yr $^{-1}$, is more than sufficient to maintain the cosmic-ray energy content of the Galaxy. In addition to the radio measurements, observational evidence for the presence of high-energy particles inside supernova remnants is provided by the detection of non-thermal X-rays (Vink & Laming 2003; Parizot et al. 2006) and TeV gamma rays from a number of supernova remnants (Aharonian et al. 2006, 2008; Albert et al. 2007). For instance, the detection of TeV gamma rays up to energies close to 100 TeV from the supernova remnant RX J1713.7-3946 by the H.E.S.S. Cherenkov telescope array indicates that particles with energies up to ~ 1 PeV can be accelerated inside supernova remnants (Aharonian et al. 2007).

2.1. Transport of SNR-CRs in the Galaxy

After acceleration by strong supernova remnant shock waves, cosmic rays escape from the remnants and undergo diffusive propagation through the Galaxy. During the propagation, some fraction of cosmic rays may further get re-accelerated due to repeated encounters with expanding supernova remnant shock waves in the interstellar medium (Wandel 1988; Berezhko et al. 2003). This re-acceleration is expected to be produced mainly by older remnants, with weaker shocks, because of their bigger sizes. Therefore, the re-acceleration is expected to generate a particle spectrum which is steeper than the initial source spectrum of cosmic rays produced by strong shocks. This model has been described in detail in Thoudam & Hörandel (2014), and it has been shown that the re-accelerated cosmic rays can dominate the GeV energy region while the non-re-accelerated cosmic rays dominate at TeV energies, thereby explaining the observed spectral hardening in the TeV region. Below, we briefly summarise some key features of the model which are important for the present study.

The steady-state transport equation for cosmic-ray nuclei in the Galaxy in the re-acceleration model is described by,

$$\nabla \cdot (D\nabla N) - [\bar{n}v\sigma + \xi] \delta(z)N + \left[\xi s p^{-s} \int_{p_0}^p du N(u) u^{s-1} \right] \delta(z) = -Q\delta(z), \quad (1)$$

where we have adopted a cylindrical geometry for the propagation region described by the radial r and vertical z coordinates with $z = 0$ representing the Galactic plane. We assume the region to have a constant halo boundary at $z = \pm L$, and no boundary in the radial direction. This is a reasonable assumption for cosmic rays at the galactocentric radius of the Sun as the majority of them are produced within a radial distance $\sim L$ from the Sun (Thoudam 2008). Choosing a different (smaller) halo height for the Galactic centre region, as indicated by the observed *WMAP* haze (Biermann et al. 2010b), will not produce significant effects in our present study. $N(r, z, p)$ represents the differential number density of the cosmic-ray nuclei with momentum/nucleon p , and $Q(r, p)\delta(z)$ is the injection rate of cosmic rays per unit volume by supernova remnants in the Galaxy. The diffusive nature of the propagation is represented by the first term in Equation 1. The diffusion coefficient $D(\rho)$ is assumed to be a function of the particle rigidity ρ as, $D(\rho) = D_0\beta(\rho/\rho_0)^a$, where D_0 is the diffusion constant, $\beta = v/c$ with $v(p)$ and c representing the velocity of the particle and the velocity of light respectively, $\rho_0 = 3$ GV is a constant, and a is the diffusion index. The rigidity is defined as $\rho = Apc/Ze$, where A and Z represent the mass number and the charge number of the nuclei respectively, and e is the charge of an electron. The second term in Equation 1 represents the loss of particles during the propagation due to inelastic interaction with the interstellar matter, and also due to re-acceleration to higher energies, where \bar{n} represents the surface density of matter in the Galactic disk, $\sigma(p)$ is the inelastic interaction cross-section, and ξ corresponds to the rate of re-acceleration. We take $\xi = \eta V \bar{v}$, where $V = 4\pi\mathfrak{R}^3/3$ is the volume occupied by a supernova remnant of radius \mathfrak{R} re-accelerating the cosmic rays, η is a correction factor that is introduced to account for the actual unknown size of the remnants, and \bar{v} is the frequency of supernova explosions per unit surface area in the Galactic disk. The term containing the integral in Equation 1 represents the gain in the number of particles due to re-acceleration from lower energies. The effect of Galactic wind and ionisation losses which are important mostly at low energies, below ~ 1 GeV/nucleon, are not included explicitly in the transport equation. Instead, we introduce a low-momentum cut-off, $p_0 \sim 100$ MeV/nucleon, in the particle distribution to account for the effect on the number of low-energy particles available for re-acceleration in the presence of these processes (Wandel et al. 1987). We assume that re-acceleration instantaneously produces a power-law spectrum of particles with spectral index s . The source term $Q(r, p)$ can be expressed as $Q(r, p) = \bar{v}H[R - r]H[p - p_0]Q(p)$, where $H(m) = 1(0)$ for $m > 0(< 0)$ represents a Heaviside step function, and the source spectrum $Q(p)$ is assumed to follow a power-law in total momentum with an exponential cut-off which, in terms of momentum/nucleon, can be written as

$$Q(p) = AQ_0(Ap)^{-q} \exp\left(-\frac{Ap}{Zp_c}\right), \quad (2)$$

where Q_0 is a normalisation constant which is proportional to the amount of energy f channelled into cosmic rays by a single supernova event, q is the spectral index, and p_c is the cut-off momentum for protons. The exponential cut-off in Equation 2 represents a good approximation for particles at the shock produced by the diffusive shock accel-

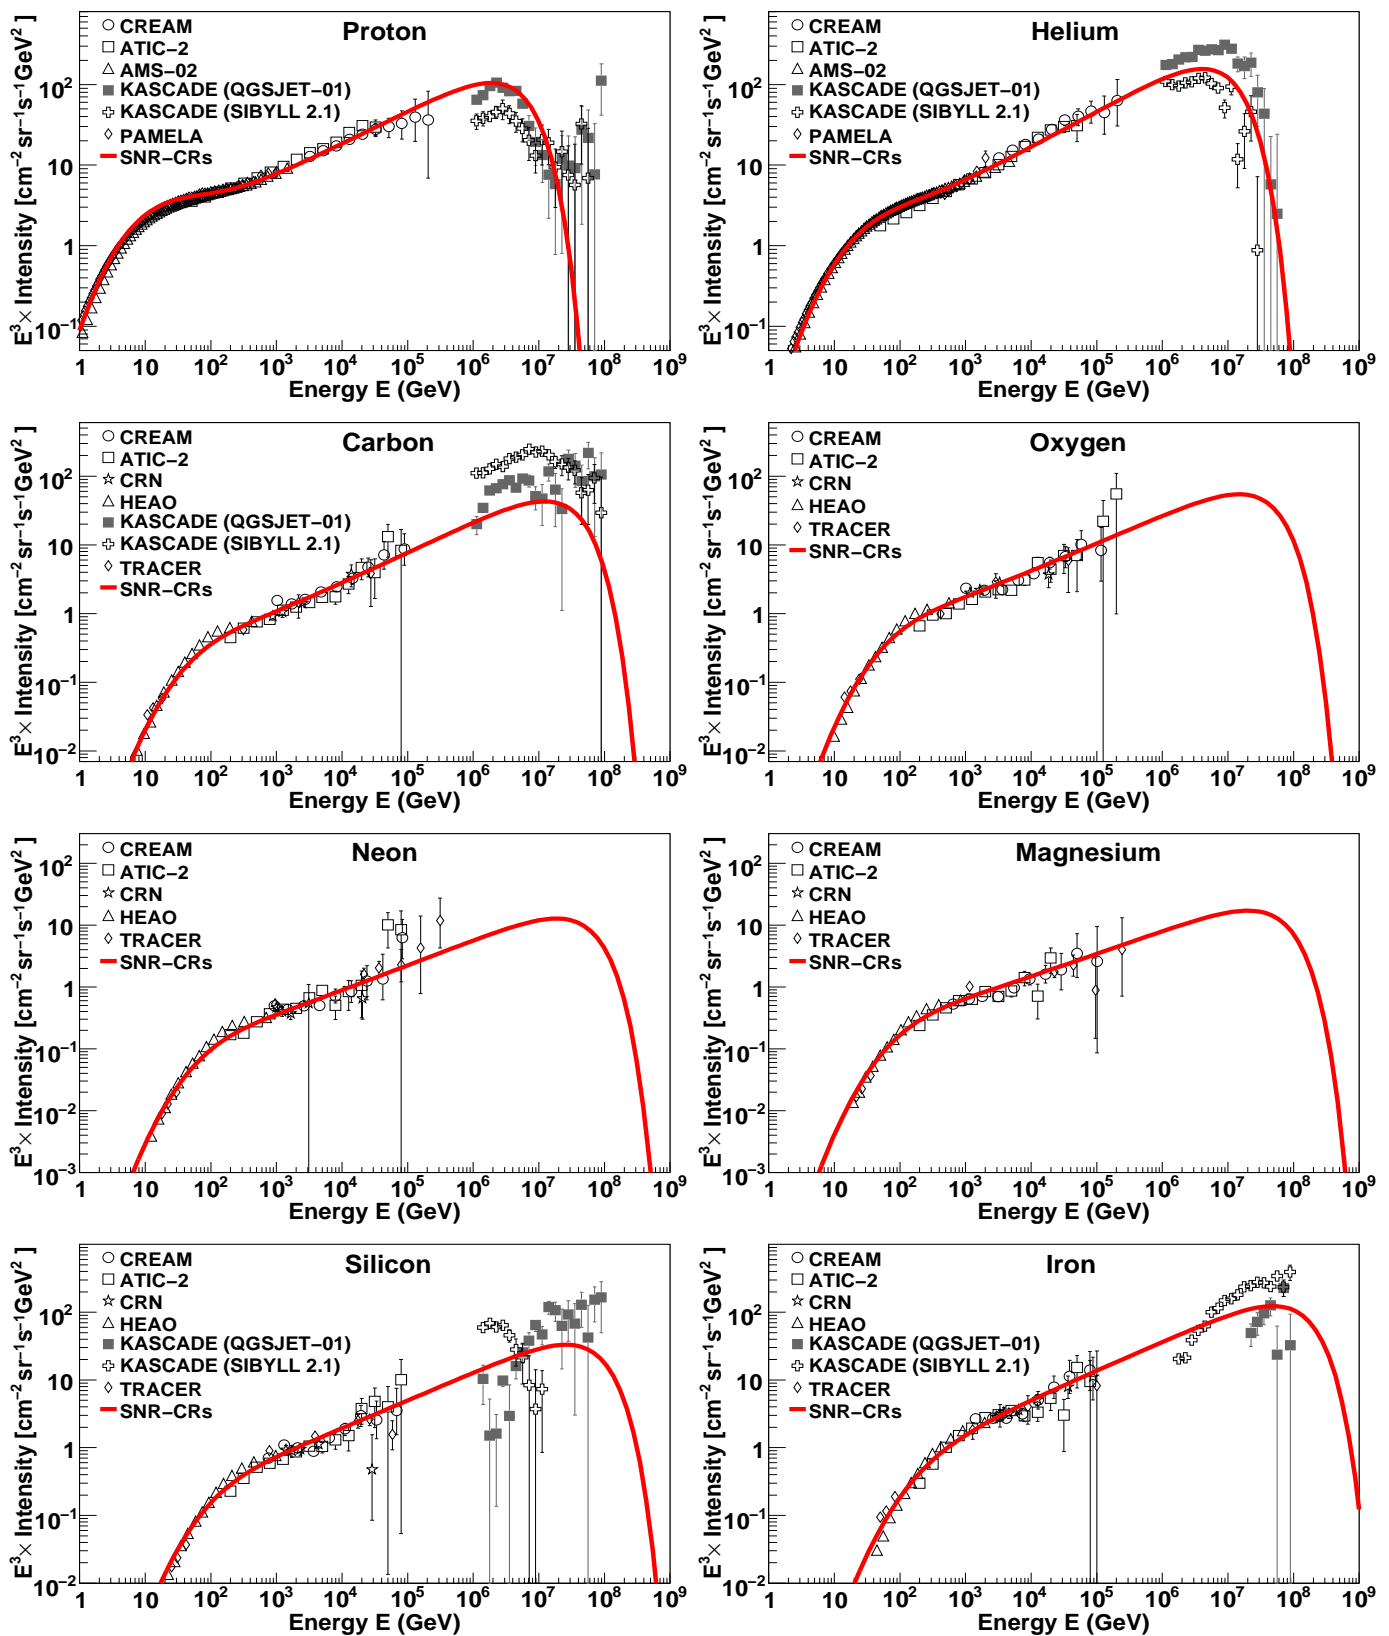

Fig. 1. Energy spectra for different cosmic-ray elements. *Solid line*: Model prediction for the SNR-CRs. *Data*: CREAM (Ahn et al. 2009; Yoon et al. 2011), ATIC-2 (Panov et al. 2007), AMS-02 (Aguilar et al. 2015a,b), PAMELA (Adriani et al. 2011), CRN (Müller et al. 1991; Swordy et al. 1990), HEAO (Engelmann et al. 1990), TRACER (Obermeier et al. 2011), and KASCADE (Antoni et al. 2005). Cosmic-ray source parameters (q, f) used in the calculation are given in Table 1. For the other model parameters (D_0, a, η, s), see text for details.

Table 1. Source spectral indices, q , and energy injected per supernova, f , for the different species of cosmic rays used in the calculation of the SNR-CRs spectra shown in Figures 1 and 2.

Particle type	q	f ($\times 10^{49}$ ergs)
Proton	2.24	6.95
Helium	2.21	0.79
Carbon	2.21	2.42×10^{-2}
Oxygen	2.25	2.52×10^{-2}
Neon	2.25	3.78×10^{-3}
Magnesium	2.29	5.17×10^{-3}
Silicon	2.25	5.01×10^{-3}
Iron	2.25	4.95×10^{-3}

ation mechanism (see e.g. Malkov & Drury 2001). We assume that the maximum energy for cosmic-ray nuclei produced by the supernova shock is Z times the maximum energy for protons. Based on the observed high concentration of supernova remnants and atomic and molecular hydrogen near the Galactic disk, in Equation 1, we assume that both cosmic-ray sources and interstellar matter are distributed in the disk (i.e. at $z = 0$). The distributions are assumed to be uniform, and extended up to a radius R .

Recalling the analytical solution of Equation 1 derived in Thoudam & Hörandel (2014), the cosmic-ray density at the position $r = 0$ for $p > p_0$ follows,

$$N(z, p) = \bar{\nu}R \int_0^\infty dk \frac{\sinh[k(L-z)]}{\sinh(kL)} \times \frac{J_1(kR)}{B(p)} \left\{ Q(p) + \xi s p^{-s} \int_{p_0}^p dp' p'^s Q(p') \mathcal{A}(p') \exp\left(\xi s \int_{p'}^p \mathcal{A}(u) du\right) \right\}, \quad (3)$$

where J_1 is a Bessel function of order 1, and the functions B and \mathcal{A} are given by,

$$B(p) = 2D(p)k \coth(kL) + \bar{n}v(p)\sigma(p) + \xi$$

$$\mathcal{A}(u) = \frac{1}{uB(u)}. \quad (4)$$

From Equation 3, the cosmic-ray density at the Earth can be obtained by taking $z = 0$ considering that our Solar system lies close to the Galactic plane.

2.2. Model prediction for the low-energy measurements

By comparing the abundance ratio of boron-to-carbon nuclei predicted by the model with the measurements, the cosmic-ray propagation parameters (D_0, a) and the re-acceleration parameters (η, s) have been obtained to be, $D_0 = 9 \times 10^{28}$ cm² s⁻¹, $a = 0.33$, $\eta = 1.02$, and $s = 4.5$ (Thoudam & Hörandel 2014). We adopt these values in our present study. The supernova remnant radius is taken to be $\mathfrak{R} = 100$ pc. The inelastic interaction cross-section for protons is taken from Kelner et al. (2006), and for heavier nuclei, the cross-sections are taken from Letaw et al. (1983). The surface matter density is taken as the averaged density in the Galactic disk within a radius equal to the size of the diffusion boundary L . We choose $L = 5$ kpc, which gives an averaged surface density of atomic hydrogen of $\bar{n} = 7.24 \times 10^{20}$ atoms cm⁻² (Thoudam & Hörandel 2013).

An extra 10% is further added to \bar{n} to account for the helium abundance in the interstellar medium. The radial extent of the source distribution is taken as $R = 20$ kpc. Each supernova explosion is assumed to release a total kinetic energy of 10^{51} ergs, and the supernova explosion frequency is taken as $\bar{\nu} = 25$ SNe Myr⁻¹ kpc⁻². The latter corresponds to a rate of ~ 3 supernova explosions per century in the Galaxy.

Using the values of various parameters mentioned above, the energy spectra of SNR-CRs for different elements are calculated. In Figure 1, results for eight elements (proton, helium, carbon, oxygen, neon, magnesium, silicon and iron, which represent the dominant species at low energies) are compared with the measured data at low energies. The source parameters (q, f) for the individual elements are kept free in the calculation, and they are optimised based on the observed individual spectra at low energies. The parameter values that best reproduce the measured data are listed in Table 1. The source spectral indices are in the range of 2.21 – 2.29, and out of the total of 8% of the supernova explosion energy channelled into SNR-CRs, the largest fraction goes into protons at the level of 6.95%, followed by helium nuclei with 0.79%. The calculated spectra reproduce the measured data quite well including the behaviour of spectral hardening at TeV energies observed for protons and helium nuclei. In our model, the absence of such a spectral hardening for heavier nuclei is explained as due to the increasing effect of inelastic collision over re-acceleration with the increase in mass (Thoudam & Hörandel 2014).

2.3. Extrapolation of the SNR-CR spectrum to high energies

In Figure 1, we also show an extrapolation of the model prediction to high energies. For protons, helium, carbon, silicon and iron nuclei, the predictions are compared with the available measurements from the KASCADE experiment above $\sim 10^6$ GeV. The calculation assumes an exponential cut-off for the proton source spectrum at $E_c = 4.5 \times 10^6$ GeV, and for the heavier nuclei at ZE_c . This value of E_c , which is obtained by comparing the predicted all-particle spectrum with the observed all-particle spectrum as shown in Figure 2, represents the maximum E_c value permitted by the measurements. While obtaining the all-particle spectrum shown in Figure 2, we also include contributions from the sub-dominant primary cosmic-ray elements ($Z < 26$), calculated using elemental abundances at 10^3 GeV given in Hörandel (2003a) and a source index of 2.25. Their total contribution amounts up to $\sim 8\%$ of the all-particle spectrum. The predicted all-particle spectrum agrees with the data up to $\sim 2 \times 10^7$ GeV, and reproduces the observed knee at the right position. Choosing E_c values larger than 4.5×10^6 GeV will produce an all-particle spectrum which is inconsistent both with the observed knee position and the intensity above the knee. Although our estimate for the best-fit E_c value does not rely on the proton measurements at high energies, it can be noticed from Figure 1 that both the predicted proton and helium spectra are in good agreement (within systematic uncertainties) with the KASCADE data. For carbon, silicon and iron nuclei, the agreement with the data is less convincing, which may be related to the larger systematic uncertainties in the shapes of the measured spectra.

From Figure 2, it can be observed that, at energies around the knee, the all-particle spectrum is predicted to be

Fig. 2. Contribution of SNR-CRs to the all-particle cosmic-ray spectrum. The thin lines represent spectra for the individual elements, and the thick-solid line represents the total contribution. The calculation assumes an exponential cut-off energy for protons at $E_c = 4.5 \times 10^6$ GeV. Other model parameters, and the low-energy data are the same as in Figure 1. Error bars are shown only for the proton and helium data. High-energy data: KASCADE (Antoni et al. 2005), IceTop (Aartsen et al. 2013), Tibet III (Amenomori et al. 2008), the Pierre Auger Observatory (Schulz et al. 2013), and HiRes II (Abbasi et al. 2009).

dominated by helium nuclei, not by protons. The CREAM measurements have shown that helium nuclei become more abundant than protons at energies $\sim 10^5$ GeV. Such a trend is also consistent with the KASCADE measurements above $\sim 10^6$ GeV (see Figure 1). Based on our prediction, helium nuclei dominate the all-particle spectrum up to $\sim 1.5 \times 10^7$ GeV, while above, iron nuclei dominate. The maximum energy of SNR-CRs, which corresponds to the fall-off energy of iron nuclei, is $26 \times E_c = 1.2 \times 10^8$ GeV. Although this energy is close to the position of the second knee, the predicted intensity is not enough to explain the observed intensity around the second knee. Our result shows that SNR-CRs alone cannot account for the observed cosmic rays above $\sim 2 \times 10^7$ GeV. At 10^8 GeV, they contribute only $\sim 30\%$ of the observed data.

3. Additional component of Galactic cosmic rays

Despite numerous studies, it is not clearly understood at what energy the transition from Galactic to extra-galactic cosmic rays (EG-CRs) occurs. Although it was pointed out soon after the discovery of the CMB and the related GZK effect that it is possible to construct an all-extra-galactic spectrum of cosmic rays containing both the knee and the ankle as features of cosmological propagation (Hillas 1967), the most natural explanation was assumed to be that the transition occurs at the ankle, where a steep Galactic component is taken over by a flatter extra-galactic one. To obtain a sharp feature like the ankle in such a construction, it is necessary to assume a cut-off in the Galactic component to occur immediately below it (Rachen et al. 1993; Axford 1994), thus this scenario is naturally expecting a second knee feature. For a typical Galactic magnetic field

strength of $3 \mu\text{G}$, the Larmor radii for cosmic rays of energy $Z \times 10^8$ GeV is 36 pc, much smaller than the size of the diffusion halo of the Galaxy, which is typically considered to be a few kpc in cosmic-ray propagation studies, keeping cosmic rays around the second knee well confined in the Galaxy. This suggests that the Galactic cut-off at this energy must be intrinsic to a source population or acceleration mechanism different from the standard supernova remnants we have discussed above. In an earlier work, Hillas (2005) considered an additional Galactic component resulting from Type II supernova remnants in the Galaxy expanding into a dense slow wind of the precursor stars. In the following, we discuss two other possible scenarios. The first is the re-acceleration of SNR-CRs by Galactic wind termination shocks in the Galactic halo (Jokipii & Morfill 1987; Zirakashvili & Völk 2006), and the second is the contribution of cosmic rays from the explosions of Wolf-Rayet stars in the Galaxy (Biermann & Cassinelli 1993). Both these ideas have been explored in the past when detailed measurements of the cosmic-ray spectrum and composition at low and high energies were not available. Using new measurements of cosmic rays and astronomical data (like the Wolf-Rayet wind composition), our study can provide a more realistic estimate of the cosmic-ray contribution from these two possible mechanisms. In the following, the re-accelerated cosmic rays from Galactic wind termination shocks will be referred to as ‘GW-CRs’, and cosmic rays from Wolf-Rayet stars as ‘WR-CRs’. Some ramifications of these basic scenarios will be discussed in Section 6, after investigating the effect of different extra-galactic contributions below the ankle in Section 5.

Fig. 3. Contribution of GW-CRs to the all-particle cosmic-ray spectrum. The thin lines represent spectra for the individual elements, and the thick dashed line represents the total contribution. The injection fraction, $k_w = 14.5\%$, and the exponential cut-off energy for protons, $E_{\text{sh}} = 9.5 \times 10^7$ GeV. See text for the other model parameters. Data are the same as in Figure 2.

3.1. Re-acceleration of SNR-CRs by Galactic wind termination shocks (GW-CRs)

The effect of Galactic winds on the transport of cosmic rays in the Galaxy has been discussed quite extensively (Lerche & Schlickeiser 1982a; Bloemen et al. 1993; Strong & Moskalenko 1998; Jones et al. 2001; Breitschwerdt et al. 2002). For cosmic rays produced by sources in the Galactic disk such as the SNR-CRs, the effect of winds on their transport is expected to be negligible above a few GeV as the transport is expected to be dominated mainly by the diffusion process. However, Galactic winds can lead to the production of an additional component of cosmic rays which can dominate at high energies. Galactic winds, which start at a typical velocity of about few km/s near the disk, reach supersonic speeds at distances of a few tens of kpc away from the disk. At about a hundred kpc distance or so, the wind flow terminates resulting into the formation of termination shocks. These shocks can catch the SNR-CRs escaping from the disk into the Galactic halo, and re-accelerate them via the diffusive shock acceleration process. The reaccelerated cosmic rays can return to the disk through diffusive propagation against the Galactic wind outflow. For an energy dependent diffusion process, only the high-energy particles may be effectively able to reach the disk.

To obtain the contribution of GW-CRs, we will first calculate the escape rate of SNR-CRs from the *inner* diffusion boundary, then propagate the escaped cosmic rays through the Galactic wind region, and calculate the cosmic-ray flux injected into the Galactic wind termination shocks. The escaped flux of SNR-CRs from the diffusion boundary, F_{esc} , can be calculated as,

$$F_{\text{esc}} = [D\nabla N]_{z=\pm L} = \left[D \frac{dN}{dz} \right]_{z=\pm L}, \quad (5)$$

where $N(z, p)$ is given by Equation 3. Equation 5 assumes that cosmic rays escape only through the diffusion boundaries located at $z = \pm L$. Under this assumption, the total escape rate of SNR-CRs is given by,

$$Q_{\text{esc}} = F_{\text{esc}} \times 2A_{\text{esc}}, \quad (6)$$

where $A_{\text{esc}} = \pi R^2$ is the surface area of one side of the cylindrical diffusion boundary which is assumed to have the same radius as the Galactic disk, and the factor 2 is to account for the two boundaries at $z = \pm L$. The propagation of the escaped SNR-CRs in the Galactic wind region is governed by the following transport equation:

$$\nabla \cdot (D_w \nabla N_w - \mathbf{V} N_w) + \frac{\partial}{\partial p} \left\{ \frac{\nabla \cdot \mathbf{V}}{3} p N_w \right\} = -Q_{\text{esc}} \delta(\mathbf{r}), \quad (7)$$

where we have assumed a spherically symmetric geometry characterised by the radial variable r , D_w represents the diffusion coefficient of cosmic rays in the wind region which is taken to be spatially constant, $N_w(r, p)$ is the cosmic-ray number density, $\mathbf{V} = \tilde{V} r \hat{r}$ is the wind velocity which is assumed to increase linearly with r and directed radially outwards, \tilde{V} is a constant that denotes the velocity gradient, and $Q_{\text{esc}}(p)$ is given by Equation 6. The exact nature of the Galactic wind is not known. The spatial dependence of the wind velocity considered here is based on the model of magnetohydrodynamic wind driven by cosmic rays, which shows that the wind velocity increases linearly with distance from the Galactic disk until it reaches an asymptotic value at a distance of around 100 kpc (Zirakashvili et al. 1996). The second term on the left-hand side of Equation 7 represents the loss of particles due to advection by the Galactic wind, and the third term represents momentum loss due to the adiabatic expansion of the wind flow which is assumed to be spherically symmetric. In writing Equation 7, considering that the size of the wind region is much larger than the size of the escaping region of the SNR-CRs, we neglect the size of the escaping region and consider Q_{esc} to be a point source located at $r = 0$. By solving Equation 7 analytically, the density of cosmic rays at distance r is given by (see Appendix A),

$$N_w(r, p) = \frac{\sqrt{\tilde{V}} p^2}{8\pi^{3/2}} \int_0^\infty dp' \frac{Q_{\text{esc}}(p')}{\left[\int_p^{p'} u D_w(u) du \right]^{3/2}} \times \exp \left(-\frac{r^2 \tilde{V} p^2}{4 \int_p^{p'} u D_w(u) du} \right). \quad (8)$$

From Equation 8, the cosmic-ray flux with momentum/nucleon p at the termination shock is obtained as,

$$F_w(p) = \left[-D_w \frac{\partial N_w}{\partial r} + \mathbf{V} N_w \right]_{r=R_{\text{sh}}}, \quad (9)$$

where R_{sh} represents the radius of the termination shock. The total rate of cosmic rays injected into the termination shock is given by,

$$Q_{\text{inj}}(p) = F_w(p) \times A_{\text{sh}}, \quad (10)$$

where $A_{\text{sh}} = 4\pi R_{\text{sh}}^2$ is the surface area of the termination shock. Assuming that only a certain fraction, k_{sh} , participates in the re-acceleration process, the cosmic-ray spectrum produced by the termination shock under the test particle approximation can be written as (Drury 1983),

$$Q_{\text{sh}}(p) = \gamma p^{-\gamma} \exp \left(-\frac{Ap}{Zp_{\text{sh}}} \right) \int_{p_0}^p k_{\text{sh}} Q_{\text{inj}}(u) u^{\gamma-1} du, \quad (11)$$

Table 2. Relative abundances of different cosmic-ray species with respect to helium for two different Wolf-Rayet wind compositions used in our model (Pollock et al. 2005).

Particle type	C/He = 0.1	C/He = 0.4
Proton	0	0
Helium	1.0	1.0
Carbon	0.1	0.4
Oxygen	3.19×10^{-2}	7.18×10^{-2}
Neon	0.42×10^{-2}	1.03×10^{-2}
Magnesium	2.63×10^{-4}	6.54×10^{-4}
Silicon	2.34×10^{-4}	5.85×10^{-4}
Iron	0.68×10^{-4}	1.69×10^{-4}

where we have introduced an exponential cut-off in the spectrum at momentum Zp_{sh} with p_{sh} representing the maximum momentum for protons, and γ is the spectral index. In our calculation, p_{sh} and k_{sh} will be kept as model parameters, and their values will be determined based on the measured all-particle spectrum.

After re-acceleration, the transport of cosmic-rays from the termination shock towards the Galactic disk also follows Equation 7. In the absence of adiabatic losses, the density of re-accelerated cosmic rays at the Earth (taken to be at $r = 0$) is given by,

$$N_{\text{GW-CRs}}(p) = \frac{Q_{\text{sh}}}{4\pi D_{\text{w}} R_{\text{sh}}} \exp\left[-\frac{\tilde{V} R_{\text{sh}}^2}{2D_{\text{w}}}\right] \quad (12)$$

The diffusion in the wind region is assumed to be much faster than near the Galactic disk as the level of magnetic turbulence responsible for particle scattering is expected to decrease with the distance away from the Galactic disk. We assume D_{w} to follow the same rigidity dependence as D , and take $D_{\text{w}} = 10D$. For the wind velocity, we take the velocity gradient $\tilde{V} = 15 \text{ km/s/kpc}$. This value of \tilde{V} is within the range predicted in an earlier study using an advection-diffusion propagation model (Bloemen et al. 1993), but slightly larger than the constraint given in Strong & Moskalenko (1998). It may be noted that as long as both D_{w} and \tilde{V} are within a reasonable range, it is not their individual values that is important in determining the flux of GW-CRs, but their ratio \tilde{V}/D_{w} , as can be seen from Equation 12. The larger this ratio, the more the flux will be suppressed, and vice-versa.

The distance to the termination shock can be estimated by balancing the Galactic wind ram pressure, $P_{\text{w}} = \rho V_{\text{t}}^2$, against the intergalactic pressure, P_{IGM} , at the position of the termination shock, where ρ is the mass density of the wind and $V_{\text{t}} = \tilde{V} R_{\text{sh}}$ represents the terminal velocity of the wind. The ram pressure is related to the total mechanical luminosity of the wind at the termination shock as, $L_{\text{w}} = 2\pi R_{\text{sh}}^2 P_{\text{w}} V_{\text{t}}$. Using this, we obtain,

$$R_{\text{sh}} = \left(\frac{L_{\text{w}}}{2\pi P_{\text{IGM}} \tilde{V}}\right)^{1/3}. \quad (13)$$

For Galactic wind driven by cosmic rays (Zirakashvili et al. 1996), the total mechanical luminosity of the wind cannot be larger than the total power of the cosmic rays. From Section 2.2, the total power invested in SNR-CRs (which dominates the overall cosmic-ray energy density in our model)

Fig. 4. Contribution of WR-CRs to the all-particle spectrum. *Top:* C/He = 0.1. *Bottom:* C/He = 0.4. The thin lines represent spectra for the individual elements, and the thick dashed line represents the total contribution. The calculation assumes an exponential energy cut-off for protons at $E_c = 1.8 \times 10^8 \text{ GeV}$ for C/He = 0.1, and $E_c = 1.3 \times 10^8 \text{ GeV}$ for C/He = 0.4. See text for the other model parameters. Data: same as in Figure 2.

is $\sim 8\%$ of the mechanical power injected by supernova explosions in the Galaxy. This corresponds to a total power of $\sim 8 \times 10^{40} \text{ ergs s}^{-1}$ injected into SNR-CRs. Using this, and taking an intergalactic pressure of $P_{\text{IGM}} = 10^{-15} \text{ ergs cm}^{-3}$ (Breitschwerdt et al. 1991), we obtain $R_{\text{sh}} = 96 \text{ kpc}$ from Equation 13. The spectral indices γ are taken to be the same as the source indices of the SNR-CRs listed in Table 1. Having fixed these parameter values, the spectra of the GW-CRs calculated using Equation 12 are shown in Figure 3. Spectra for the individual elements and also the total contribution are shown. The same particle injection fraction of $k_{\text{sh}} = 14.5\%$ is applied to all the elements, and the maximum proton energy corresponding to p_{sh} is taken as $E_{\text{sh}} = 9.5 \times 10^7 \text{ GeV}$. These values are chosen so that the total GW-CR spectrum reasonably agrees with the observed all-particle spectrum between $\sim 10^8$ and 10^9 GeV .

The GW-CRs produce a negligible contribution at low energies. This is due to the increasing effect of advection over diffusion at these energies, preventing particles from reaching the Galactic disk. Higher energy particles, which diffuse relatively faster, can overcome the advection and reach the disk more effectively. The flux suppression at low energies is more significant for heavier nuclei like iron which is due to their slower diffusion relative to lighter nuclei at the same total energy. Adding adiabatic losses to

Fig. 5. Model prediction for the all-particle spectrum using the Galactic wind re-acceleration model. The thick solid blue line represents the total SNR-CRs, the thick dashed line represents GW-CRs, the thick dotted-dashed line represents extra-galactic cosmic rays (EG-RSB93) taken from Rachen et al. (1993), and the thick solid red line represents the total all-particle spectrum. The thin lines represent total spectra for the individual elements. For the SNR-CRs, an exponential energy cut-off for protons at $E_c = 3 \times 10^6$ GeV is assumed. See text for the other model parameters. Data are the same as in Figure 2.

Table 3. Injection energy of SNR-CRs used in the calculation of all-particle spectrum in the WR-CR model (Figure 6).

Particle type	C/He = 0.1 $f(\times 10^{49}$ ergs)	C/He = 0.4 $f(\times 10^{49}$ ergs)
Proton	8.11	8.11
Helium	0.67	0.78
Carbon	2.11×10^{-2}	0.73×10^{-2}
Oxygen	2.94×10^{-2}	2.94×10^{-2}
Neon	4.41×10^{-3}	4.41×10^{-3}
Magnesium	6.03×10^{-3}	6.03×10^{-3}
Silicon	5.84×10^{-3}	5.84×10^{-3}
Iron	5.77×10^{-3}	5.77×10^{-3}

Equation 12 will lead to further suppression of the flux at low energies. But, at energies of our interest, that is above $\sim 10^7$ GeV, the result will not be significantly affected as the particle diffusion time, $t_{\text{dif}} = R_{\text{sh}}^2 / (6D_w)$, is significantly less than the adiabatic energy loss time, $t_{\text{ad}} = 1/\tilde{V} = 6.52 \times 10^7$ yr. The steep spectral cut-offs at high energies are due to the exponential cut-offs introduced in the source spectra.

3.2. Cosmic rays from Wolf-Rayet star explosions (WR-CRs)

While the majority of the supernova explosions in the Galaxy occur in the interstellar medium, a small fraction is expected to occur in the winds of massive progenitors like Wolf-Rayet stars (Gal-Yam et al. 2014). Magnetic fields in the winds of Wolf-Rayet stars can reach of the order of 100 G, and it has been argued that a strong supernova

shock in such a field can lead to particle acceleration of energies up to $\sim 3 \times 10^9$ GeV (Biermann & Cassinelli 1993; Stanev et al. 1993).

Since the distribution of Wolf-Rayet stars in the Galaxy is concentrated close to the Galactic disk (see e.g. Rosslowe & Crowther (2015)), the propagation of WR-CRs can also be described by Equation 1 with the source term replaced by $Q(r, p) = \bar{\nu}_0 H[R - r] H[p - p_0] Q(p)$, where $\bar{\nu}_0$ represents the frequency of Wolf-Rayet supernova explosions per unit surface area in the Galactic disk, and the source spectrum $Q(p)$ follows Equation 2. We assume that each Wolf-Rayet supernova explosion releases a kinetic energy of 10^{51} ergs, same as the normal supernova explosion in the interstellar medium. From the estimated total number of Wolf-Rayet stars of ~ 1200 in the Galaxy and an average lifetime of ~ 0.25 Myr for these stars (Rosslowe & Crowther 2015), we estimate a frequency of ~ 1 Wolf-Rayet explosion in every 210 years. This corresponds to ~ 1 Wolf-Rayet explosion in every 7 supernova explosions occurring in the Galaxy. The source indices of the different cosmic-ray species and the propagation parameters for the WR-CRs are taken to be the same as for the SNR-CRs.

The contribution of WR-CRs to the all-particle spectrum is shown in Figure 4. The results are for two different compositions of the Wolf-Rayet winds available in the literatures: Carbon-to-helium (C/He) ratio of 0.1 (top panel) and 0.4 (bottom panel), given in Pollock et al. (2005). The abundance ratios of different elements with respect to helium for the two different wind compositions are listed in Table 2. In our calculation, these ratios are assumed to be proportional to the relative amount of supernova explosion energy injected into different elements. The overall normalization of the total WR-CR spectrum and the maximum en-

Fig. 6. Model prediction for the all-particle spectrum using the Wolf-Rayet stars model. *Top:* $C/He = 0.1$. *Bottom:* $C/He = 0.4$. The thick solid blue line represents the total SNR-CRs, the thick dashed line represents WR-CRs, the thick dotted-dashed line represents extra-galactic cosmic rays (EG-RSB93) taken from Rachen et al. (1993), and the thick solid red line represents the total all-particle spectrum. The thin lines represent total spectra for the individual elements. For the SNR-CRs, an exponential energy cut-off for protons at $E_c = 4.1 \times 10^6$ GeV is assumed. See text for the other model parameters. Data are the same as in Figure 2.

ergy of the proton source spectrum are taken as free parameters. Their values are determined based on the observed all-particle spectrum between $\sim 10^8$ and 10^9 GeV. For $C/He = 0.1$, we obtain an injection energy of 1.3×10^{49} ergs into helium nuclei from a single supernova explosion and a proton source spectrum cut-off of 1.8×10^8 GeV, while for $C/He = 0.4$, we obtain 9.4×10^{48} ergs and 1.3×10^8 GeV respectively. For both the progenitor wind compositions, the total amount of energy injected into cosmic rays by

a single supernova explosion is approximately 5 times less than the total energy injected into SNR-CRs by a supernova explosion in the Galaxy. The total WR-CR spectrum for the $C/He = 0.1$ case is dominated by helium nuclei up to $\sim 10^9$ GeV, while for the $C/He = 0.4$ case, helium nuclei dominate up to $\sim 2 \times 10^8$ GeV. At higher energies, carbon nuclei dominate. One major difference of the WR-CR spectra from the GW-CR spectrum (Figure 3) is the absence of the proton component, and a very small contribution of the

heavy elements like magnesium, silicon and iron. Another major difference is the much larger flux of WR-CRs than the GW-CRs below $\sim 10^5$ GeV. Below the knee, the total WR-CR spectrum is an order of magnitude less than the total SNR-CRs spectrum (Figure 2).

4. All-particle spectrum and composition of cosmic rays at high energies

The all-particle spectrum obtained by combining the contributions of SNR-CRs, GW-CRs and EG-CRs is compared with the measured data in Figure 5. For the SNR-CRs shown in the figure, we have slightly reduced the value of E_c from 4.5×10^6 GeV (as used in Figure 2) to 3×10^6 GeV in order to reproduce the measurements better around the knee. The extra-galactic contribution, denoted by EG-RSB93 in the figure, is taken from Rachen et al. (1993), which represents a pure proton population with a source spectrum of E^{-2} and an exponential cut-off at 10^{11} GeV as expected from strong radio galaxies or sources with a similar cosmological evolution. Also shown in the figure are the spectra of the individual elements. The model prediction reproduces the observed elemental spectra as well as the observed features in the all-particle spectrum.

The total spectra for the two WR-CR scenarios are shown in Figure 6. For the SNR-CRs, here we take $E_c = 4.1 \times 10^6$ GeV, and a slightly lower value of ν which corresponds to 6 out of every 7 supernova explosions in the Galaxy (assuming a fraction 1/7 going into Wolf-Rayet supernova explosions as deduced in the previous section). The injection energy f for the different elements of the SNR-CRs has been re-adjusted accordingly, so that the sum of SNR-CRs and WR-CRs for the individual elements agree with the measured elemental spectra at low energies. The f values are listed in Table 3. The cosmic-ray propagation parameters are the same as in Figure 2. The predicted all-particle spectra are in good agreement with the measurements. The WR-CR scenarios are found to reproduce the second knee and the ankle better than the GW-CR model.

In Figure 7, we show the elemental fraction at high energies predicted by the GW-CR and WR-CR models. In all the models, the composition consists of a large fraction of helium nuclei over a wide energy range. The maximum helium fraction is found in the case of WR-CR (C/He=0.1) scenario, where the fraction reaches up to $\sim 63\%$ at energy $\sim 2 \times 10^8$ GeV. In contrast to common perceptions, the WR-CR scenarios predict a composition of Galactic cosmic rays dominated mainly by helium (in the C/He = 0.1 case) or carbon nuclei (in the C/He = 0.4) near the transition energy region from Galactic to extra-galactic cosmic rays. The GW-CR model predicts an almost equal contribution of helium and iron nuclei at the transition region.

The cosmic-ray composition at energies above $\sim 3 \times 10^5$ GeV is not quite as well-measured as at lower energies. Above $\sim 10^6$ GeV, KASCADE has provided spectral measurements for groups of elements by measuring the electron and muon numbers of extensive air showers induced by cosmic rays in the Earth's atmosphere. Several other experiments such as LOFAR, TUNKA, and the Pierre Auger Observatory have also provide composition measurements at high energies by measuring the depth of the shower maximum (X_{\max}). Heavier nuclei interact higher in the atmosphere, resulting in smaller values of X_{\max} as compared to

Fig. 7. Elemental fraction predicted by the different models of the additional Galactic component. *Top*: GW-CRs, *middle*: WR-CRs (C/He = 0.1), and *bottom*: WR-CRs (C/He = 0.4).

lighter nuclei. For comparison with theoretical predictions, we often use the mean logarithmic mass, $\langle \ln A \rangle$, of the measured cosmic rays which can be obtained from the measured X_{\max} values using the relation (Hörandel 2003b),

$$\langle \ln A \rangle = \left(\frac{X_{\max} - X_{\max}^{\text{P}}}{X_{\max}^{\text{Fe}} - X_{\max}^{\text{P}}} \right) \times \ln A_{\text{Fe}}, \quad (14)$$

where X_{\max}^{P} and X_{\max}^{Fe} represent the average depths of the shower maximum for protons and iron nuclei respectively given by Monte-Carlo simulations, and A_{Fe} is the mass number of iron nuclei.

In Figure 8, the $\langle \ln A \rangle$ values predicted by the different models are compared with the measurements from different experiments. Although all our model predictions are

Fig. 8. Mean logarithmic mass, $\langle \ln A \rangle$, of cosmic rays predicted using the three different models of the additional Galactic component: WR-CRs ($C/He = 0.1$), WR-CRs ($C/He = 0.4$), and GW-CRs. Data: KASCADE (Antoni et al. 2005), TUNKA (Berezhnev et al. 2013), LOFAR (Buitink et al. 2016), Yakutsk (Knurenko & Sabourov 2010), the Pierre Auger Observatory (Porcelli et al. 2015), and the different optical measurements compiled in Kampert & Unger (2012). The two sets of data points correspond to two different hadronic interaction models (EPOS-LHC and QGSJET-II-04) used to convert X_{\max} values to $\langle \ln A \rangle$.

within the large systematic uncertainties of the measurements, at energies above $\sim 10^7$ GeV, the GW-CR model deviates from the general trend of the observed composition which reaches a maximum mean mass at $\sim 6 \times 10^7$ GeV, and becomes gradually lighter up to the ankle. However, in the narrow energy range of $\sim (1 - 5) \times 10^8$ GeV, the behaviour of the GW-CR model is in good agreement with the measurements from TUNKA, LOFAR and Yakutsk experiments which show a nearly constant composition that is different from the behaviour observed by the Pierre Auger Observatory at these energies. Understanding the systematic differences between the different measurements at these energies will be important for further testing of the GW-CR model. Up to around the ankle, the WR-CR models show an overall better agreement with the measurements than the GW-CR model. At around $(3 - 5) \times 10^7$ GeV, the WR-CR models seem to slightly under predict the KASCADE measurements, and they are more in agreement with the TUNKA measurements. Cosmic-ray composition measured by experiments like KASCADE, which measures the particle content of air showers on the ground, is known to have a large systematic difference from the composition measured with fluorescence and Cherenkov light detectors using X_{\max} measurements (Hörandel 2003b). The large discrepancy between the model predictions and the data above the ankle is due to the absence of heavy elements in the EG-CR model considered in our calculation. The effect of choosing other models of EG-CRs will be discussed in the next section.

5. Test with different models of extra-galactic cosmic rays

Despite of the dominance of the ankle-transition model in the general discussion, it has often been pointed out

that the essential high-energy features of the cosmic ray spectrum, that is the ankle and, in part, even the second knee, can be explained by propagation effects of extra-galactic protons in the cosmologically evolving microwave background (Hillas 1967; Berezhinsky & Grigorieva 1988; Berezhinsky et al. 2006; Hillas 2005; Aloisio et al. 2012, 2014). While the most elegant and also most radical formulation of this hypothesis, the so-called ‘proton dip model’, is meanwhile considered disfavoured by the proton fraction at the ankle measured by the Pierre Auger Observatory (Aab et al. 2014), the light composition below the ankle recently reported by the LOFAR measurement (Buitink et al. 2016) and a potential ‘light ankle’ at about 10^8 GeV found by the KASCADE-Grande experiment (Apel et al. 2013) have reinstated the interest in such models, and led to a number of ramifications, all predicting a more or less significant contribution of extra-galactic cosmic rays below the ankle. As such a component can greatly modify the model parameters, in particular the maximum energy, for the additional Galactic component – if not removing its necessity altogether – we study this effect using the WR-CR models, which show an overall best agreement with the data below the ankle, as a Galactic paradigm.

Before, however, discussing a stronger extra-galactic component below the ankle, we want to think about the *minimal* extra-galactic contribution we can have, if we assume the largely heavy spectrum above the ankle is all extra-galactic and consider their propagation over extra-galactic distances. To construct this ‘minimal model’, we follow di Matteo et al. (2015) and use the Monte-Carlo simulation code CRPropa 3.0 (Batista et al. 2016), which takes into account all important interaction processes undergone by EG-CRs while propagating through the CMB and the extra-galactic background light, and also the energy loss as-

sociated with the cosmological expansion. The effects of uncertainties in the simulations are discussed in Batista et al. (2015). We assume the sources to be uniformly distributed in a comoving volume, and they produce cosmic rays with a spectrum given by (di Matteo et al. 2015),

$$Q_{\text{EG}} = K_0 F_j \left(\frac{E}{E_0} \right)^{-\gamma}, \quad \frac{E}{Z} < R_c$$

$$= K_0 F_j \left(\frac{E}{E_0} \right)^{-\gamma} \exp \left(1 - \frac{E}{ZR_c} \right), \quad \frac{E}{Z} > R_c \quad (15)$$

where K_0 is a normalisation constant, F_j is the injection fraction which depends on the type of the nuclei j , $E_0 = 10^9$ GeV, γ is the source spectral index which is assumed to be the same for the different nuclei, and R_c is the rigidity at which the spectrum deviates from a power law. The model parameters are determined by simultaneously fitting the cosmic-ray energy spectrum, X_{max} and variance of X_{max} above the ankle observed at the Pierre Auger Observatory. We adopt the CTG¹ model for our calculation (di Matteo et al. 2015), and consider that the sources inject protons, helium, nitrogen and iron nuclei. The best-fit model parameters values are $\gamma = 0.73$, $R_c = 3.8 \times 10^9$ GV, $F_{\text{H}} = 0\%$, $F_{\text{He}} = 0\%$, $F_{\text{N}} = 98.69\%$ and $F_{\text{Fe}} = 1.31\%$. In this model, the EG-CR spectrum below $\sim 10^{10}$ GeV is dominated by protons and helium nuclei which are secondary products from the photo-disintegration of heavier nuclei during the propagation. At higher energies up to $\sim 6 \times 10^{10}$ GeV, the spectrum is dominated by the CNO group. Above $\sim 3 \times 10^{10}$ GeV, the spectrum exhibits a steep cut-off which is mostly due to the intrinsic cut-off in the injection spectrum, and not due to the GZK absorption during the propagation. This gives an overall best agreement with the measured data (di Matteo et al. 2015).

The first assumption we consider for an additional component of light particles below the ankle is based on the same physics, that is photo-disintegration of energetic nuclei in photon backgrounds, but considering this effect already in potentially densely photon loaded sources during acceleration. The physical motivation for this scenario is the acceleration of heavy nuclei at external/internal shocks in gamma ray bursts (Murase et al. 2008; Globus et al. 2015b), or in tidal disruption events (Farrar & Gruzinov 2009). Two variants of this assumptions have been recently suggested: the first, by Globus et al. (2015a), assumes that diffusion losses in the source are faster than the photo-disintegration time scale over a large range of energies, leading to a significantly steeper spectrum of the secondary protons than for the escaping residual nuclei, while in the second model by Unger et al. (2015) only the highest energy particles have an escape time which is smaller than the photo-disintegration time. While the predictions of the former model for secondary protons below the ankle are phenomenologically quite similar to the extra-galactic component of Rachen et al. (1993) at these energies, that is an approximate E^{-2} source spectrum with a cosmological evolution $\propto (1+z)^{3.5}$, the second model Unger et al. (2015, hereafter the ‘UFA model’) predicts a strong pure-proton component concentrated only about one order of magnitude in energy below the ankle. Within their fiducial model, they

consider a mix with a pure iron Galactic cosmic-ray component in Unger et al. (2015). For our study, we use results which are optimised for a pure nitrogen Galactic composition², which is closer to our predicted composition for the WR-CR model (C/He = 0.4) around the second knee.

A second assumption for an additional extra-galactic component is based on a universal scaling argument, which links the energetics of extra-galactic cosmic-ray sources on various scales and predicts that a dominant contribution to extra-galactic cosmic rays is expected from clusters of galaxies, accelerating a primordial proton-helium mix at their accretion shocks during cosmological structure formation (Rachen 2016). As it has been shown already by Kang et al. (1997) that, for canonical assumptions on the diffusion coefficient around shocks (e.g. Bohm diffusion), the particle acceleration in this scenario is limited by pair-production losses in the CMB, this extra-galactic component is rather expected not to reach ultra-high energies, except for very optimistic assumptions on the acceleration process, but to be confined to energies *below* the ankle. As so far no detailed Monte-Carlo propagation for this model has been calculated, we use here the analytical approximation developed in Rachen (2016). Assuming that both injection and acceleration of primordial protons and helium nuclei are only dependent on particle rigidity, the model predicts a succession of a proton and helium component with increasing energy, which are fixed in relative normalisation by the known primordial abundances. The more energetic helium component sharply cuts off at the ankle, merging into the cosmic-ray spectrum produced by extra-galactic sources at smaller scales, for which acceleration even in the conservative case is not limited by CMB or other photon interactions, and thus reaches the so-called Hillas limit, $E = ZeBR$, if B is the typical magnetic field, and R the typical size of the accelerator (Hillas 1984). In our treatment, we hereby keep the exact cut-off energy and the total normalisation of this primordial cluster shock component as free parameters and determine them from fitting the all-particle spectrum, where we use the minimal model derived above as the second extra-galactic component extending into ultra-high energies. This model is henceforth denoted as ‘PCS model’.

In Figure 9, we present the all-particle spectrum above 10^6 GeV obtained using the three different EG-CR models – minimal model only, UFA and PCS model. The galactic contributions are from SNR-CRs and WR-CRs (C/He = 0.4). For the SNR-CRs, all the model parameters are the same as in Figure 6 (bottom). For the WR-CRs, the cut-off energy and the normalisation of the source spectrum are re-adjusted in order to produce an overall good fit to the measured spectrum and composition. They are allowed to vary in the three different cases. For the minimal model, the best-fit proton cut-off energy of the WR-CRs is found to be 1.7×10^8 GeV. This is approximately a factor 1.3 larger than the value used in Figure 6. For the PCS and the UFA models, the proton cut-off energies are almost the same at 1.1×10^8 GeV, which are about a factor 1.5 less than that of the minimal model. This relaxation in the cut-off energy is due to the strong contribution of EG-CRs below the ankle in the two models. In the minimal model, the transition from Galactic to extra-galactic components occurs around the ankle, while in the PCS and UFA models, it occurs at

¹ CRPropa with the default TALYS photo-disintegration cross sections and the EBL model of Gilmore et al. (2012)

² Michael Unger, private communication.

$\sim 7 \times 10^8$ GeV. The variation in the injection energy of WR-CRs remain within 6% between the three models. In Figure 9, spectra of five different mass groups are also shown. The elemental fraction of these mass groups are shown in Figure 10.

Fig. 9. All-particle spectrum for the three different models of EG-CRs – Minimal (*Top*), PCS (*middle*), and UFA (*bottom*) – combined with the WR-CR ($C/He = 0.4$) model for the additional Galactic component. SNR-CR spectra shown are the same as in Figure 6 (bottom). Data are the same as in Figure 2. For results using WR-CR ($C/He = 0.1$) model, see Appendix B.

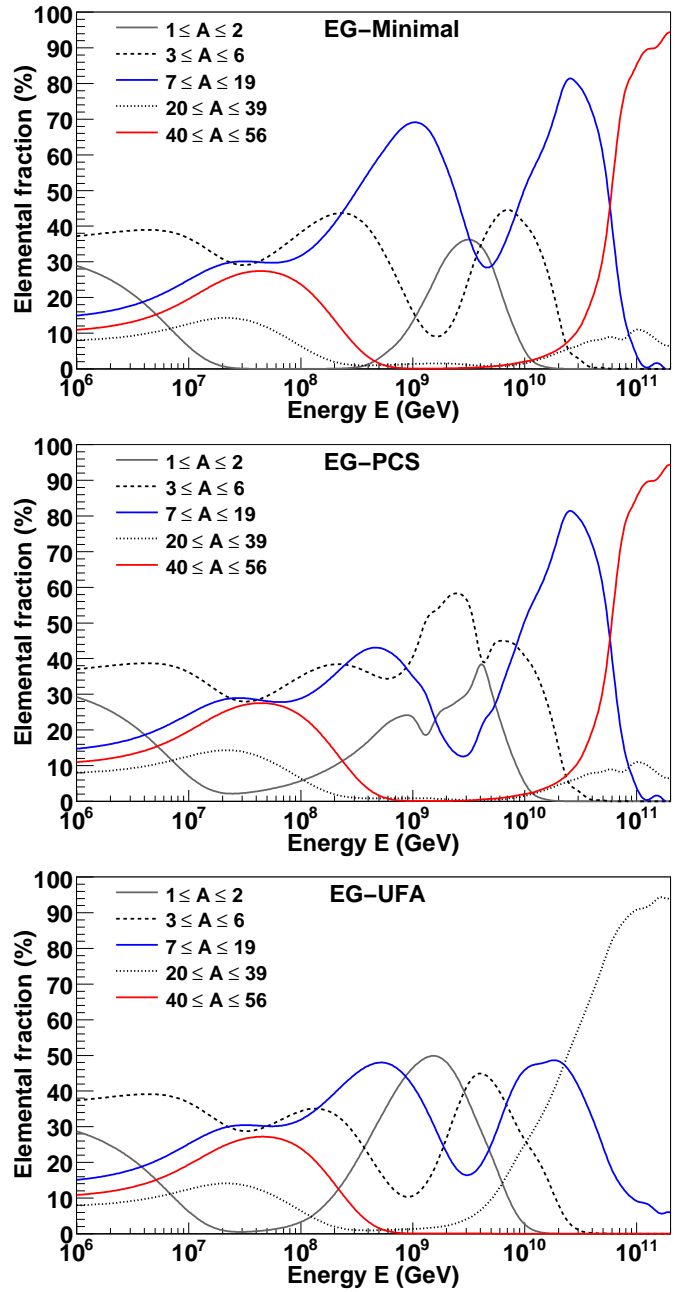

Fig. 10. Elemental fraction of the five different mass groups shown in Figure 9 for the three different EG-CR models: minimal (*top*), PCS (*middle*), and UFA (*bottom*), combined with the WR-CRs ($C/He = 0.4$) model for the additional Galactic component. Results obtained using WR-CR ($C/He = 0.1$) model are given in Appendix B.

In Figure 11, we show $\langle \ln A \rangle$ predicted by the three EG-CRs model after adding the Galactic contribution. At energies between $\sim 3 \times 10^8$ GeV and 3×10^9 GeV, the minimal model shows a bump that follows the trend of LOFAR and the data from other experiments, but contradicts the composition data from the Pierre Auger Observatory at $\sim 10^9$ GeV. The UFA model over predicts the data above the ankle as the model is also tuned to the variance of $\langle \ln A \rangle$, but it is well within the systematic uncertainties (experimental as well as theoretical) as discussed in Unger et al. (2015). The sharp feature present just above 10^9 GeV in the PCS model is due to the dip in the proton spectrum

Fig. 11. Mean logarithmic mass for the three different EG-CR models combined with the WR-CR ($C/He = 0.4$) model. Data are the same as in Figure 8. Results obtained using WR-CR ($C/He = 0.1$) model are shown in Appendix B.

(Figure 9, middle panel, black-thin-solid line) that results from the intersection of the components from galaxy clusters and the minimal model, and is partially an artefact of the simplified propagation approach applied to this model. We expect it to be much smoother for realistic propagation. At energies below $\sim 10^9$ GeV, both the PCS and the UFA models produce similar results which are in better agreement with the observed trend of the composition, but do not introduce a significant improvement over the canonical extra-galactic component used in Section 4. In all the three cases for the EG-CR model, the CNO group dominates the composition of Galactic cosmic rays at the transition region from Galactic to extra-galactic cosmic rays. A clear distinction between the models would be possible from a detailed measurement of the five major mass groups shown in Figure 10, in which they all have their characteristic ‘fingerprint’: for example, around 10^9 GeV the minimal model is dominated by the CNO group, the PCS model by helium, and the UFA model by protons.

Results obtained using the WR-CR ($C/He = 0.1$) scenario are given in Appendix B. The main difference from the results of the $C/He = 0.4$ scenario is the significant dominance of helium up to the transition energy region from Galactic to extra-galactic cosmic rays (see Figures B.1 and B.2). The main results and the parameter values of the different models discussed in the present work are summarised in Table 4.

6. Discussions

Our study has demonstrated that cosmic rays below $\sim 10^9$ GeV can be predominantly of Galactic origin. Above 10^9 GeV, they are most likely to have an extra-galactic origin. We show that both the observed all-particle spectrum and the composition at high energies can be explained if the Galactic contribution consists of two components: (i) SNR-CRs which dominates the spectrum up to $\sim 10^7$ GeV, and

(ii) GW-CRs or preferably WR-CRs which dominates at higher energies up to $\sim 10^9$ GeV. When combined with an extra-galactic component expected from strong radio galaxies or a source population with similar cosmological evolution, the WR-CR scenarios predict a transition from Galactic to extra-galactic cosmic rays at around $(6-8) \times 10^8$ GeV, with a Galactic composition mainly dominated by helium or the CNO group, in contrast to most common assumptions. In the following, we discuss our results for the SNR-CRs, GW-CRs, and WR-CRs in the context of other views on the Galactic cosmic rays below 10^9 GeV, the implication of our results on the strength of magnetic fields in the Galactic halo and Wolf-Rayet stars, and also the case of a steep extra-galactic component extending below the second knee.

6.1. SNR-CRs

The maximum contribution of the SNR-CRs to the all-particle spectrum is obtained at a proton cut-off energy of $\sim 4.5 \times 10^6$ GeV (see Figure 2). Such a high energy is not readily achievable under the standard model of diffusive shock acceleration theory in supernova remnants for magnetic field values typical of that in the interstellar medium (see e.g. Lagage & Cesarsky 1983). However, numerical simulations have shown that the magnetic field near supernova shocks can be amplified considerably up to $\sim 10 - 100$ times the mean interstellar value (Lucek & Bell 2000; Reville & Bell 2012). This is also supported by observations of thin X-ray filaments in supernova remnants which can be explained as due to rapid synchrotron losses of energetic electrons in the presence of strong magnetic fields (Vink & Laming 2003; Parizot et al. 2006). Such strong fields may lead to proton acceleration up to energies close to the cut-off energy obtain in our study (Bell 2004).

The main composition of cosmic rays predicted by the SNR-CRs *alone* looks similar to the prediction of the polygonato model (Hörandel 2003a). Both show a helium domi-

Table 4. Summary of the different models for cosmic rays, and their results presented in this work. In all the models, the Galactic contribution consists of two components: the first component which is produced by regular supernova explosions in the Galaxy (SNR-CRs), and the second component which is considered to be produced either by cosmic-ray re-acceleration by Galactic wind termination shocks (GW-CRs) or by explosions of Wolf-Rayet stars in the Galaxy (WR-CRs). The source spectral indices for the second Galactic component in all the models are assumed to be the same as for the SNR-CRs (see Table 1). For the extra-galactic component, the different models considered are: (a) sources with strong cosmological evolution like strong radio galaxies (EG-RSB93) (b) extra-galactic contribution mainly above the ankle irrespective of the nature of the sources (EG-Minimal), (c) significant photo-disintegration of cosmic-rays in a source region with high photon density (EG-UFA), and (d) cosmic rays accelerated by accretion shocks in clusters of galaxies (EG-PCS). The all-particle spectra predicted by the different combinations of the Galactic and extra-galactic components are quite similar, and show good agreement with the measured spectrum. On the other hand, although the $\langle \ln A \rangle$ predicted by the different models are almost within the range of the different measurements compiled by Kampert & Unger (2012), they show distinctive differences especially in the energy range between the second knee and the ankle. For the model using GW-CRs, the predicted $\langle \ln A \rangle$ also show deviation from the prediction of other models between $\sim 10^7$ and 10^8 GeV. The comments on $\langle \ln A \rangle$ given in the table are with respect to the measurements from TUNKA (Berezhnev et al. 2013), LOFAR (Buitink et al. 2016), Yakutsk (Knurenko & Sabourov 2010), and the Pierre Auger Observatory (Porcelli et al. 2015) between the second knee and the ankle. QGSJET in the table refers to the QGSJET-II-04 model.

Model	Reference sections	Reference figures	Cut-off rigidities (GV)		Composition at: 10 ⁸ GeV, 10 ⁹ GeV (p, He, CNO, Fe)	Extra-galactic contribution at (10 ⁸ , 10 ⁹) GeV	Predicted $\langle \ln A \rangle$ between the second knee and the ankle	
			First Galactic component	Second Galactic component				
GW-CRs	EG-RSB93	3.1 & 4	5, 7 & 8	3.0×10^6	9.5×10^7	(20%, 32%, 12%, 24%), (32%, 2%, 18%, 30%)	(4%, 30%)	Good agreement with TUNKA (QGSJET) and LOFAR/Yakutsk (EPOS-LHC) data, but strong disagreement with Auger data
WR-CRs (C/He=0.1)	EG-RSB93	3.2 & 4	6, 7 & 8	4.1×10^6	1.8×10^8	(6%, 51%, 14%, 24%), (48%, 25%, 26%, 0%)	(6%, 50%)	Moderate agreement with LOFAR and Yakutsk (QGSJET) data, and excellent agreement with Auger (EPOS-LHC) data
WR-CRs (C/He=0.4)	EG-RSB93	3.2 & 4	6, 7 & 8	4.1×10^6	1.3×10^8	(6%, 34%, 30%, 24%), (44%, 6%, 49%, 0%)	(5%, 45%)	Good agreement with LOFAR (QGSJET) data, and moderate agreement with Yakutsk (QGSJET) and Auger (EPOS-LHC) data
WR-CRs (C/He=0.1)	EG-Minimal	5 & B	B.1, B.2 & B.3	4.1×10^6	2.4×10^8	(0%, 57%, 14%, 24%), (15%, 51%, 35%, 0%)	(0%, 16%)	Excellent agreement with LOFAR (QGSJET) and moderate agreement with TUNKA/Yakutsk (QGSJET) data, but strong disagreement with Auger data
WR-CRs (C/He=0.1)	EG-PCS	5 & B	B.1, B.2 & B.3	4.1×10^6	1.5×10^8	(6%, 52%, 13%, 24%), (25%, 53%, 21%, 0%)	(10%, 66%)	Moderate agreement with LOFAR and Yakutsk (QGSJET) data, and good agreement with Auger (EPOS-LHC) data
WR-CRs (C/He=0.1)	EG-UFA	5 & B	B.1, B.2 & B.3	4.1×10^6	1.6×10^8	(4%, 52%, 14%, 24%), (49%, 25%, 25%, 0%)	(3%, 58%)	Moderate agreement with LOFAR (QGSJET) data, and excellent agreement with Auger (EPOS-LHC) data
WR-CRs (C/He=0.4)	EG-Minimal	5	9, 10 & 11	4.1×10^6	1.7×10^8	(0%, 38%, 32%, 24%), (14%, 15%, 69%, 0%)	(0%, 15%)	Good agreement with TUNKA (QGSJET) and LOFAR (EPOS-LHC) data, and moderate agreement with Yakutsk data, but strong disagreement with Auger data
WR-CRs (C/He=0.4)	EG-PCS	5	9, 10 & 11	4.1×10^6	1.1×10^8	(6%, 36%, 29%, 24%), (24%, 42%, 35%, 0%)	(10%, 62%)	Moderate agreement with LOFAR/Yakutsk (QGSJET) and Auger (EPOS-LHC) data
WR-CRs (C/He=0.4)	EG-UFA	5	9, 10 & 11	4.1×10^6	1.1×10^8	(3%, 35%, 32%, 24%), (47%, 10%, 41%, 0%)	(3%, 55%)	Moderate agreement with LOFAR/Yakutsk (QGSJET) data, and good agreement with Auger (EPOS-LHC) data

nance over proton around the knee, and iron taking over at higher energies at $\sim 10^7$ GeV in the SNR-CRs, and at $\sim 6 \times 10^6$ GeV in the poly-gonato model. The helium dominance is more significant in the SNR-CRs than in the poly-gonato model which is due to the flatter spectral index required to reproduce the recent measurements from CREAM and ATIC experiments with the SNR-CRs. The main difference, however, is in the total contribution above $\sim 2 \times 10^7$ GeV. SNR-CRs alone cannot explain the observed all-particle spectrum above $\sim 2 \times 10^7$ GeV. They contribute only $\sim 30\%$ of the observed cosmic rays at $\sim 10^8$ GeV. On the other hand, in the poly-gonato model, the total contribution from elements with $1 \leq Z \leq 28$ can explain the observed spectrum up to energies close to 10^8 GeV. This difference is mainly due to the difference in the shapes of the spectral cut-offs of particles between the two models.

For the SNR-CRs, we consider a power-law with an exponential cut-off, while the poly-gonato model assumes a broken power-law with a smooth break around the cut-off (break) energy. This leads to a higher flux around the cut-off energy in the poly-gonato model. On adding GW-CRs or WR-CRs as an additional Galactic component, the composition above $\sim 10^7$ GeV in our model has a large fraction of helium or a mixture of helium and CNO group, which is quite different from the prediction of the poly-gonato model where the composition is mainly dominated by iron nuclei. Our prediction (in particular, that of the WR-CR scenario) is more in agreement with the X_{\max} measurements from fluorescence and Cherenkov light detectors, while the poly-gonato model is in agreement with data from the measurements of air shower particles on the ground.

Recently, Globus et al. (2015a) claimed that a single Galactic component with rigidity dependent cut-off is sufficient to explain the observed all-particle spectrum when combined with an extra-galactic component. Their claim that an additional Galactic component is not needed does not contradict our claim of having one. It is simply that they assume the particle spectrum as a *broken* power law with an exponential cut-off which leads to an increased flux above the break energy (knee) as in the poly-gonato model. However, we have demonstrated that if one considers a power-law spectrum with an exponential cut-off which is expected for particles produced by diffusive shock acceleration process in supernova remnants (Malkov & Drury 2001), a single component cannot explain the observed spectrum beyond the knee, and a second Galactic component is inevitable. Their single component, which they had not assigned to any specific source class, would correspond to the superposition of multiple components similar to the ones proposed in our model. Based on the physical models of the most plausible sources and the propagation of cosmic rays in the Galaxy, we show that two Galactic components are sufficient to explain the measured spectrum, but do not exclude the existence of more than two components.

6.2. GW-CRs

Assuming that the maximum energy of particles produced by the Galactic wind termination shock is limited by the condition that the particle diffusion length must be less than the size of the shock, the maximum energy under Bohm diffusion can be written as, $E_m \sim 3ZeB(V_s/c)R_s$, where B is the magnetic field, V_s is the shock velocity and R_s is the shock radius. From the GW-CR parameters obtained in our study, we can take $R_s = R_{sh} = 96$ kpc, $V_s = \dot{V}R_s = 1443$ km s⁻¹ which is the terminal wind velocity, and $E_m = 9.5 \times 10^7$ GeV which is the proton cut-off energy. Using these values, the magnetic field strength in the Galactic halo is estimated to be ~ 73 nG. This is approximately a factor 3 less than the value obtained assuming Parker's magnetic field topology for the solar wind (Equation 16).

An intrinsic issue in the case of re-acceleration by Galactic wind termination shock is the difficulty to observe the re-accelerated particles in the Galactic disk because of advection by the wind flow, except for the highest energy particles, as discussed in Section 3.1. As a consequence, the spectrum in the disk may not show a continuous transition between the SNR-CRs and GW-CRs (see e.g. Zirakashvili & Völk 2006). This effect is actually visible in the predicted spectra of the individual elements shown in Figure 5. However, we notice that the superposition of the individual spectra smears out this effect in the all-particle spectrum. Nevertheless, in order to avoid this effect, Zirakashvili & Völk (2006) considered termination shocks which are stronger near the Galactic poles and weaker towards the Galactic equator, unlike in our study where the shocks are considered to have equal strengths in all the directions. In their configuration, the maximum energy of particles decreases from the poles towards the equator, and therefore, the superposition of spectra from different colatitudes produces a continuity in the total spectrum. Another consideration is the particle re-acceleration by spiral shocks in the Galactic wind which are formed

Fig. 12. Elemental fraction for four mass groups obtained using the PCS model of EG-CRs and WR-CRs ($C/He = 0.1$). The proton fraction (not shown in the figure) predicted by the model in the LOFAR energy range is $\sim 10\%$. The grey bands, from top to bottom, represent the best-fit LOFAR measurements of 79% helium, 19% nitrogen and 2% iron nuclei in the energy range of $(1.3 - 4.2) \times 10^8$ GeV (Buitink et al. 2016). At 99% confidence level, the measured proton plus helium fraction can vary in the range of (38–98)%, and the combined nitrogen and iron fraction within (2–62)%.

by the interaction between fast winds originating from the Galactic spiral arms and slow winds from the interarm regions (Völk & Zirakashvili 2004). These shocks, which can be formed at distances of $\sim 50 - 100$ kpc, can accelerate SNR-CRs up to $\sim Z \times 10^8$ GeV. An alternative possibility is the re-acceleration by multiple shock waves in the Galactic wind generated by time dependent outflows of gas from the Galactic disk (Dorfi & Breitschwerdt 2012). These shocks, which are long-lived like the termination shocks, can accelerate particles up to $\sim 10^8 - 10^9$ GeV in the lower Galactic halo. An attractive feature of this model is the advection of particles downstream of the shocks towards the Galactic disk, thereby, resolving the difficulty of observing the re-accelerated particles in the disk. Despite having different features, the cosmic-ray composition predicted by all these different models in the energy range of $\sim 10^7 - 10^9$ GeV are expected to be similar to the result presented here since they consider the same seed particles (cosmic rays from the Galactic disk) for re-acceleration as in our study. Below $\sim 10^7$ GeV where the GW-CRs are significantly suppressed in our case, the other wind models discussed above will give a different result.

6.3. WR-CRs

The prediction of a large helium fraction and a small iron fraction between around 10^8 and 10^9 GeV by the WR-CR ($C/He = 0.1$) model seems to be in agreement with new measurements from the LOFAR radio telescope (Buitink et al. 2016), and the Pierre Auger Observatory (Aab et al. 2014). These measurements have revealed a strong light component, and an almost negligible iron component above $\sim 10^8$ GeV. In Figure 12, the elemental fraction predicted by the WR-CR ($C/He = 0.1$) model combined with the PCS model for the EG-CRs is compared with the best-fit composition of the LOFAR data for four mass groups: $1 \leq A \leq 6$, $7 \leq A \leq 19$, $20 \leq A \leq 39$, and

$40 \leq A \leq 56$. The model predictions are found to show a good agreement with the data.

Using the maximum energy of particles for the WR-CRs, it is possible to estimate the strength of the magnetic field at the surface of Wolf-Rayet stars. Assuming that the magnetic field configuration in the Wolf-Rayet winds follows Parker's model (Parker 1958), the toroidal magnetic field strength near the equatorial plane of the star at the position R_w from the star follows the relation,

$$B = B_0 \frac{\omega R_*^2}{V_w R_w}, \quad (16)$$

where B_0 is the magnetic field at the surface of the star, ω is the angular rotation velocity, R_* is the radius of the star, and V_w is the wind velocity. Using the relation $E_m \sim 3ZeB(V_s/c)R_s$ for the maximum energy as in the case of the GW-CRs, and the proton cut-off energy of $E_m = 1.1 \times 10^8$ GeV for the WR-CRs ($C/He = 0.4$) obtained using the PCS/UFA model, we get $BR_s \sim 1.2 \times 10^{15}$ G cm, where we take the shock velocity $V_s = 0.1 c$ (Soderberg et al. 2012). Using this value of BR_s in Parker's magnetic field configuration (Equation 16) by taking $R_w = R_s$ and other Wolf-Rayet star parameters as $R_* = 3 \times 10^{12}$ cm, $\omega = 10^{-6} \text{ s}^{-1}$, and $V_w = 2000 \text{ km s}^{-1}$ (Berezhko & Völk 2000), we obtain the magnetic field at the surface of the star as $B_0 \sim 1.5 \times 10^4$ G. Such a strong magnetic field was also predicted in an earlier study by Biermann & Cassinelli (1993), and is found to be in agreement with recent magnetic field measurements from Wolf-Rayet stars. Based on an upper limit of 100 G in the observable parts of Wolf-Rayet winds, Chevrotière et al. (2013) estimated an upper limit for the surface magnetic field of ~ 5400 G. An even stronger field in the wind, up to ~ 2000 G, has been reported (Chevrotière et al. 2014), which indicates that the surface magnetic field of these stars can go well above the order of 10^4 G.

From the total energy of 1.4×10^{49} ergs injected into WR-CRs by a single supernova explosion, and the explosion rate of Wolf-Rayet stars in the Galaxy of $1/210 \text{ yr}^{-1}$, we estimate the total power injected into WR-CRs as $2.1 \times 10^{39} \text{ ergs s}^{-1}$. This is approximately a factor 40 less than the power injected into SNR-CRs by supernova explosions in the interstellar medium. The required amount of supernova explosion energy injected into helium nuclei for WR-CRs is about 1.2 – 1.6 times that of the SNR-CRs. This indicates that the average abundance of helium nuclei swept up by supernova shocks in the Wolf-Rayet winds must be higher than the helium abundance present in the interstellar medium if the particle injection fraction and the acceleration efficiency of the shocks are the same for the SNR-CRs and the WR-CRs.

Our results for the WR-CRs are obtained by assuming that the particle injection fraction into the shocks is the same for all the different elements. The injection fraction may depend on the type of the element, and the nature of this dependence is not quite understood. By taking the ratio of the SNR-CRs source spectra (Equation 2) at a fixed rigidity to the known Solar system elemental abundances (Lodders & Palme 2009), we estimate the relative injection fraction of particles for the different elements. Applying these relative injection fractions to the WR-CRs, we find that the composition is significantly dominated by carbon nuclei, in contrast to the results shown in Figure 4 where the composition is mainly dominated by helium or a mixture

helium and carbon nuclei. Thus, the contribution of WR-CRs in this case is strongly constrained by the measured carbon spectrum at low energies. The all-particle spectrum for this case, after adding the contributions of SNR-CRs and EG-CRs, underpredicts the measured data between the second knee and the ankle. This problem might be resolved if we consider that both GW-CRs and WR-CRs contribute at the same time. In future, we will explore the parameter space of this combined scenario.

6.4. Comparison with Hillas's 'Component B'

Bell & Lucek (2001) showed that magnetic field upstream of supernova shock fronts can be amplified non-linearly by cosmic rays up to many times the pre-shock magnetic field. They showed that these highly amplified magnetic fields can facilitate cosmic-ray acceleration up to energies $Z \times 10^8$ GeV for supernova shocks expanding in the interstellar medium, even higher by an order of magnitude for shocks expanding into pre-existing stellar winds. Based on the Bell-Lucek's version of diffusive shock acceleration, Hillas (2005) proposed a second Galactic component 'Component B', produced by Type II supernova remnants in the Galaxy expanding into dense slow winds of the preceding red supergiants, to accommodate for the observed cosmic rays above $\sim 10^7$ GeV. In the Hillas (2005) model, a Galactic component 'Component A', produced by Type Ia supernova remnants in the Galaxy, dominates the all-particle energy spectrum below $\sim 10^7$ GeV. The 'Component A' has a similar composition to the SNR-CRs in our model, but the 'Component B' has a large iron fraction in contrast to the WR-CR component in our model which is dominated mostly by helium or a mixture of helium and CNO group with a small iron fraction. Between $\sim 10^8$ and 10^9 GeV, the predicted all-particle spectrum in Hillas (2005) consists of a significant iron fraction which may be in agreement with the $\langle \ln A \rangle$ data when mixed with a strong extra-galactic proton component, but is in tension with the small iron fraction ($\sim 2 - 10\%$) preferred by the recent measurements of LO-FAR (Buitink et al. 2016) and the Pierre Auger Observatory (Aab et al. 2014). These new measurements disfavour the general view that the Galactic component above the second knee is dominated by heavy (iron) nuclei.

6.5. A steep EG-CR component extending below the second knee

An alternative model that does not require the introduction of an additional Galactic component is to assume that EG-CRs have a significant contribution down to energies below the second knee. Such a scenario would require a steep spectrum of $\sim E^{-3}$ and a strong flux suppression below $\sim 10^8$ GeV (see Hillas 2005 for a brief discussion, and also Muraishi et al. 2005 in the context of the origin of the knee). To explore this scenario, we inject an additional extra-galactic component of pure protons at the position of the Galactic wind termination shocks, and allow them to propagate diffusively towards the Galactic disk in the presence of the Galactic wind outflow. The injection spectrum is assumed to follow $E^{-\gamma} \exp(-E/E_c)$. The propagation is treated exactly the same as the propagation of GW-CRs from the termination shock towards the Galactic disk. All propagation parameters are kept the same, except for the

wind velocity constant \tilde{V} which is treated as a free parameter. The best-fit all-particle spectrum obtained after adding the contribution of SNR-CRs and EG-CRs from the minimal model is shown in Figure 13. The best-fit parameters are $\gamma = 3.3$, $E_c = 4.1 \times 10^6$ GeV for the SNR-CRs protons, $E_c = 1.5 \times 10^9$ GeV for the additional EG-CRs, and $\tilde{V} = 200.5$ km/s/kpc. This value of \tilde{V} gives a wind velocity which is about a factor 13 larger than the wind velocity used in the study of GW-CRs. Such a fast wind is required in order to generate a strong modulation for particles below the second knee so that the predicted flux does not exceed the observed data at low energies. For $\gamma < 3.3$, the required wind velocity is lower, but the model prediction does not fit the observed data very well (see e.g. the case of $\gamma = 3$ in Figure 13). Replacing the additional extra-galactic protons with heavier elements only slightly reduces the required wind velocity. Having a strong Galactic wind can have serious effects on the spectrum and distribution of low-energy cosmic rays in the Galaxy (see e.g. Bloemen et al. 1993). In the presence of a strong wind, cosmic-ray transport will be dominated by advection rather than diffusion, and will produce a cosmic-ray distribution that resembles the distribution of the sources. But, the cosmic-ray distribution inferred from the observations of diffuse gamma-ray emission from the Galaxy indicates a radial gradient weaker than the distribution of supernova remnants or pulsars in the Galaxy. These observations suggest that if supernova remnants are the main sources of cosmic rays in the Galaxy, the propagation of cosmic rays should be dominated by diffusion, not by advection. In addition, if the transport is dominated by advection, the cosmic-ray spectrum is expected to exhibit a break (steepening) at an energy where the advection boundary, $z_c \propto [D(E)/\tilde{V}]^{1/2}$, equals the halo boundary L . Such a break is not observed below the knee, except at ~ 10 GeV which is due to Solar modulation. Attributing the knee to such a break raises issues regarding the cosmic-ray injection index. Below the break, cosmic-ray transport is advection dominated and the spectrum is expected to follow $E^{-(\gamma+a/2)}$, where γ is the source index and a is the diffusion index. For the observed spectral index of ~ 2.7 and $a = 0.33$ used in our study, we get $\gamma = 2.53$. This is incompatible with the prediction of diffusive shock acceleration theory which predicts an index close to 2 for the strong shocks present in supernova remnants (Ptuskin et al. 2010; Caprioli et al. 2011). Choosing $a = 0.6$, as in pure diffusion propagation models, gives $\gamma = 2.4$. This relaxes the tension a bit, but such a high value of a is not favoured by the observed small level of cosmic-ray anisotropy. Another strong constraint on the Galactic wind velocity is provided by the abundance ratio of radioactive secondary to stable secondary. Measurement of $^{10}\text{Be}/^9\text{Be}$ ratio puts a constraint at $\tilde{V} \leq 45$ km/s/kpc (Bloemen et al. 1993). All these arguments pose a serious problem to the alternative scenario of a strong EG-CR component with a steep spectrum extending below the second knee, and modulating by Galactic wind. One possibility, but rather unrealistic, for this scenario to work is if the additional EG-CR component has a spectrum and composition almost similar to that of the GW-CRs produced at the Galactic wind termination shocks.

An alternative to the modulation of EG-CRs by the Galactic wind is the ‘magnetic horizon effect’ (Stanev et al. 2000; Lemoine 2005; Aloisio & Berezhinsky 2005), which

Fig. 13. All-particle energy spectrum for an additional component of EG-CR protons extended down to low energies and modulated by Galactic wind. The numbers within the parentheses denote the injection index for the additional extra-galactic component. For the SNR-CRs, an exponential cut-off energy for protons at 4.1×10^6 GeV is assumed. See text for other details. The EG-Minimal component is the same as in Figure 9 (top). Data: Same as in Figure 2.

leads to a flattening of the extra-galactic spectrum below an energy where the diffusive propagation distance in a partly turbulent extra-galactic magnetic field, over the time scale set by energy losses of the cosmic rays through interactions with ambient photon backgrounds, gets below the average distance of cosmic ray sources. Assuming a relatively strong ($\gtrsim 1$ nG) extra-galactic field with a constant coherence length extending over the entire universe, this effect could set in at around 10^9 GeV, effectively cutting off the extra-galactic component at lower energies slightly below the ankle (Aloisio et al. 2012), or even above (Mollerach & Roulet 2013). However, more detailed treatments in the context of large scale structure formation (Kotera & Lemoine 2008), have indicated that this effect is much less efficient due to the large voids in the universe which are essentially free of magnetic fields. As shown recently in detailed simulations, the magnetic horizon effect should play virtually no role above the second knee for any type of nuclei, and for protons in some extra-galactic magnetic field scenarios, not even above the knee (Batista & Sigl 2014).

We point out that neither the Galactic wind nor the magnetic horizon effects discussed above prevent a hard extra-galactic component, like the light component with $\gamma = 2.7$ as indicated by the KASCADE-Grande measurements above $\sim 10^8$ GeV (Apel et al. 2013), from contributing around the second knee as such a hard component will be already consistent with the measured data at low energies. Even if such a hard extra-galactic component is present, an additional Galactic component will still be required as the extra-galactic component will remain subdominant in the all-particle spectrum below 10^8 GeV.

An additional problem for EG-CRs with an overall spectrum steeper than $E^{-2.7}$ is that, if one assumes that they fill the extra-galactic space homogeneously with energies from ~ 1 GeV to 10^9 GeV, it contains more energy than the gravitational binding energy released in the universe during structure formation (Rachen 2016). Using realistic

cally low efficiencies for this energy – which is, besides the lower overall nuclear binding energy released in fusion by all primordial baryonic matter going into stars, the only fundamental energy budget present in the late universe – to be converted into cosmic rays, one can conclude that spectral indices as discussed here for a dominant extra-galactic component below the second knee cannot easily be reconciled with this energy budget, no matter which kind of sources one proposes. Mainly on the basis of this argument, together with the difficulties of a sufficient spectral modification at low energies discussed above, we consider a dominantly extra-galactic explanation of cosmic rays below 10^8 GeV as implausible.

7. Conclusions

We have demonstrated that a single Galactic component with progressive energy cut-offs in the individual spectra of different elements, and describing the low-energy measurements below $\sim 10^6$ GeV from balloon and satellite-borne experiments, cannot explain simultaneously the knee and the second knee observed in the all-particle spectrum. We show that a two-component Galactic model, the first component dominating up to $\sim 5 \times 10^7$ GeV and the second component dominating in the range of $\sim 5 \times 10^7 - 10^9$ GeV, can explain almost all observed features in the all-particle spectrum and composition when combined with an extra-galactic component dominating above $\sim 10^9$ GeV. Discussing two different scenarios for the second Galactic component, we find that a contribution of Wolf-Rayet supernovae explain best both the measured energy spectrum and composition. Our main result is that this component predicts a Galactic contribution at and above the second knee which is mainly dominated by helium or a mixture of helium and CNO nuclei, and is consistent with a ‘regular’ extra-galactic contribution from sources with a flat spectral index and a cosmological evolution typical for AGNs or star formation. Using re-acceleration at the Galactic wind termination shock as a second Galactic component also allows to fit the all-particle energy spectrum, but not the observed composition very well. Tests of the two-component Galactic model using different hypotheses for a significant extra-galactic cosmic-ray component below the ankle, do neither significantly improve nor deteriorate this result, mostly because *both* the Galactic and extra-galactic components have a rather light composition, and contain little or no heavy nuclei like iron, in contrast to common assumptions. In all cases, the transition from Galactic to extra-galactic cosmic rays occurs between the second knee and the ankle, and we see neither the need nor a theoretical case for an extra-galactic component significantly contributing at or below 10^8 GeV. Our findings are in agreement with recent measurements from LOFAR and the Pierre Auger Observatory, which have revealed a strong light component and a rather low iron fraction between $\sim 10^8$ and 10^9 GeV. A clear distinction of the various discussed Galactic and extra-galactic scenarios would be possible if we could separately measure the spectra of at least four major mass groups, that is protons, helium, CNO, and heavier, at energies between the second knee and the ankle.

Acknowledgements

We wish to thank Michael Unger, Glennys Farrar and Luis Anchordoqui, for their comments on the manuscript, and for providing us results for the UFA model. We also thank Peter Biermann for his insightful comments, and Torsten Enßlin and Christoph Pfrommer for helping to improve the manuscript during a discussion at the meeting of ‘International Team 323’ at the International Space Science Institute in Bern. ST wishes to thank Onno Pols for discussions on Wolf-Rayet stars. AvV acknowledges financial support from the NWO Astroparticle physics grant WARP. We furthermore acknowledge financial support from an Advanced Grant of the European Research Council (grant agreement no. 227610), European Union’s Horizon 2020 research and innovation programme (grant agreement no. 640130), the NWO TOP grant (grant agreement no. 614.001.454), and the Crafoord Foundation (grant no. 20140718).

Appendix A: Derivation of Equation 8

The Green's function, $G(\mathbf{r}, \mathbf{r}', p, p')$, of Equation 7 satisfies,

$$\nabla \cdot (D_w \nabla G - \mathbf{V}G) + \frac{\partial}{\partial p} \left\{ \frac{\nabla \cdot \mathbf{V}}{3} pG \right\} = -\delta(\mathbf{r} - \mathbf{r}')\delta(p - p'). \quad (\text{A.1})$$

In rectangular coordinates, the above equation can be written as,

$$\begin{aligned} D_w \frac{\partial^2 G}{\partial x^2} + D_w \frac{\partial^2 G}{\partial y^2} + D_w \frac{\partial^2 G}{\partial z^2} - \tilde{V} \frac{\partial}{\partial x}(xG) - \tilde{V} \frac{\partial}{\partial y}(yG) \\ - \tilde{V} \frac{\partial}{\partial z}(zG) + \frac{\partial}{\partial p}(\tilde{V}pN) = -\delta(x - x')\delta(y - y')\delta(z)\delta(p - p'), \end{aligned} \quad (\text{A.2})$$

where we have written $\mathbf{V} = \tilde{V}(x\hat{i} + y\hat{j} + z\hat{k})$ with \hat{i} , \hat{j} and \hat{k} representing the unit vectors along the x , y and z directions. Following a similar procedure adopted in Lerche & Schlickeiser (1982b), we express,

$$\begin{aligned} G(x, x', y, y', z, z', p, p') = \\ \int_{-\infty}^{\infty} dk_x \int_{-\infty}^{\infty} dk_y \int_{-\infty}^{\infty} dk_z \bar{G}(k_x, x', k_y, y', k_z, z', p, p') \\ \times e^{ik_x(x-x')} e^{ik_y(y-y')} e^{ik_z(z-z')}, \end{aligned} \quad (\text{A.3})$$

and,

$$\begin{aligned} \delta(x - x') &= \frac{1}{2\pi} \int_{-\infty}^{\infty} dk_x e^{ik_x(x-x')}, \\ \delta(y - y') &= \frac{1}{2\pi} \int_{-\infty}^{\infty} dk_y e^{ik_y(y-y')}, \\ \delta(z - z') &= \frac{1}{2\pi} \int_{-\infty}^{\infty} dk_z e^{ik_z(z-z')}. \end{aligned} \quad (\text{A.4})$$

Inserting Equations A.3 and A.4 into Equation A.2, we get,

$$\begin{aligned}
& -D_w (k_x^2 + k_y^2 + k_z^2) \bar{G} - i\tilde{V} (k_x x' + k_y y' + k_z z') \bar{G} \\
& + \tilde{V} \left(k_x \frac{\partial \bar{G}}{\partial k_x} + k_y \frac{\partial \bar{G}}{\partial k_y} + k_z \frac{\partial \bar{G}}{\partial k_z} \right) + \tilde{V} p \frac{\partial \bar{G}}{\partial p} + \tilde{V} \bar{G} \\
& = -\frac{1}{8\pi^3} \delta(p - p'). \tag{A.5}
\end{aligned}$$

We now introduce variables ψ_x , ψ_y and ψ_z such that $k_x = \psi_x F(p)$, $k_y = \psi_y F(p)$ and $k_z = \psi_z F(p)$, where

$$F(p) = \exp \left(\tilde{V} \int^p du \frac{1}{\tilde{V}u} \right). \tag{A.6}$$

This reduces Equation A.5 to

$$\tilde{V} p \frac{\partial \bar{G}}{\partial p} + B(p) \bar{G} = -\frac{1}{8\pi^3} \delta(p - p'), \tag{A.7}$$

where,

$$\begin{aligned}
B(p) = & -D_w(p) (\psi_x^2 + \psi_y^2 + \psi_z^2) F^2(p) \\
& - i (\psi_x x' + \psi_y y' + \psi_z z') F \tilde{V} + \tilde{V}. \tag{A.8}
\end{aligned}$$

The solution of Equation A.7 is given by,

$$\begin{aligned}
\bar{G}(k_x, x', k_y, y', k_z, z', p, p') = & \frac{1 - H[p - p']}{8\pi^3 \tilde{V} p'} \\
& \times \exp \left[\int_{E'}^E du \frac{B(u)}{\tilde{V}u} \right], \tag{A.9}
\end{aligned}$$

where the Heaviside step function $H[p - p'] = 1(0)$ for $p > p' (< p')$. Taking inverse Fourier transform of \bar{G} , we obtain the required Green's function as,

$$\begin{aligned}
G(x, x', y, y', z, z', p, p') = & \frac{1 - H[p - p']}{8\pi^3 \tilde{V} p} \left(\frac{\pi}{I_{p,p'}} \right)^{3/2} \\
& \times \exp \left[-\frac{(C_{x,x'}^2 + C_{y,y'}^2 + C_{z,z'}^2)}{4I_{p,p'}} \right] \tag{A.10}
\end{aligned}$$

where,

$$\begin{aligned}
C_{x,x'} = & \tilde{V} x' \int_{p'}^p du \frac{1}{\tilde{V}u} \frac{F(u)}{F(p)} - x' + x, \\
C_{y,y'} = & \tilde{V} y' \int_{p'}^p du \frac{1}{\tilde{V}u} \frac{F(u)}{F(p)} - y' + y, \\
C_{z,z'} = & \tilde{V} z' \int_{p'}^p du \frac{1}{\tilde{V}u} \frac{F(u)}{F(p)} - z' + z, \tag{A.11}
\end{aligned}$$

and,

$$I_{p,p'} = \int_p^{p'} du \frac{D_w(u)}{\tilde{V}u} \left(\frac{F(u)}{F(p)} \right)^2. \tag{A.12}$$

Then, for a given cosmic-ray source characterised by $q(x', y', z', p')$, the differential number density of particles with momentum p at a distance (x, y, z) is given by,

$$\begin{aligned}
N(x, y, z, p) = & \int_0^\infty dx' \int_0^\infty dy' \int_0^\infty dz' \int_0^\infty dp' \\
& \times G(x, x', y, y', z, z', p, p') q(x', y', z', p'). \tag{A.13}
\end{aligned}$$

For any point source located at $(0, 0, 0)$ and emitting $q(p)$ spectrum of particles, that is $q(x', y', z', p') = \delta(x') \delta(y') \delta(z') q(p')$, the solution becomes,

$$\begin{aligned}
N(x, y, z, p) = & \frac{1}{8\pi^3 \tilde{V} p} \int_p^\infty dp' q(p') \left(\frac{\pi}{I_{p,p'}} \right)^{3/2} \\
& \times \exp \left[-\frac{(x^2 + y^2 + z^2)}{4I_{p,p'}} \right]. \tag{A.14}
\end{aligned}$$

From Equation A.6, since $F(p)$ reduces to p , and so also $F(u)$ to u , by writing $(x^2 + y^2 + z^2) = r^2$ in spherical coordinates and replacing $q(p)$ by $Q_{\text{esc}}(p)$ as given by Equation 6, Equation A.14 can be reduced in the form of Equation 8:

$$\begin{aligned}
N(r, p) = & \frac{\sqrt{\tilde{V}} p^2}{8\pi^{3/2}} \int_0^\infty dp' \frac{Q_{\text{esc}}(p')}{\left[\int_p^{p'} u D_w(u) du \right]^{3/2}} \\
& \times \exp \left(-\frac{r^2 \tilde{V} p^2}{4 \int_p^{p'} u D_w(u) du} \right). \tag{A.15}
\end{aligned}$$

Appendix B: All-particle spectrum and composition of cosmic rays obtained using different EG-CR models and WR-CRs (C/He = 0.1)

The predicted all-particle spectrum, elemental fraction and $\langle \ln A \rangle$ obtained for the three different models of EG-CRs (the minimal, PCS and UFA), combined with the WR-CR (C/He = 0.1) scenario for the additional Galactic component, are shown in Figures B.1, B.2, and B.3, respectively. The proton cut-off energies for the WR-CRs required to produce a good-fit to the measured spectrum are 2.4×10^8 GeV for the minimal model, 1.5×10^8 GeV for the PCS model, and 1.6×10^8 GeV for the UFA model. These values are about a factor 1.4 larger than the cut-off energies obtained in the case of C/He = 0.4. The variation in the injection energy of WR-CRs between the three cases remain within 6% as in the C/He = 0.4 scenario.

The predicted composition is dominated by helium nuclei up to around the second knee for the minimal and the UFA models, while for the PCS model, helium dominates up to around 10^{10} GeV. The Galactic component at the transition energy region from Galactic to extra-galactic cosmic rays is dominated by helium, unlike in the case of C/He = 0.4, where it is dominated by a mixture of helium and CNO group.

Fig. B.1. All-particle spectrum for the three different EG-CR models: minimal (*top*), PCS (*middle*), and UFA (*bottom*), obtained using WR-CRs ($C/He = 0.1$) as the additional Galactic component. The proton cut-off energies for the WR-CRs used in the calculation are 2.4×10^8 GeV for the minimal model, 1.5×10^8 GeV for the PCS model, and 1.6×10^8 GeV for the UFA model. The injection energy of the WR-CRs varies within 6% between the three models. SNR-CR spectra are the same as in Figure 6 (*top*). Data are the same as in Figure 2.

The $\langle \ln A \rangle$ predicted by the minimal model shows some deviation from the general trend of the measurements be-

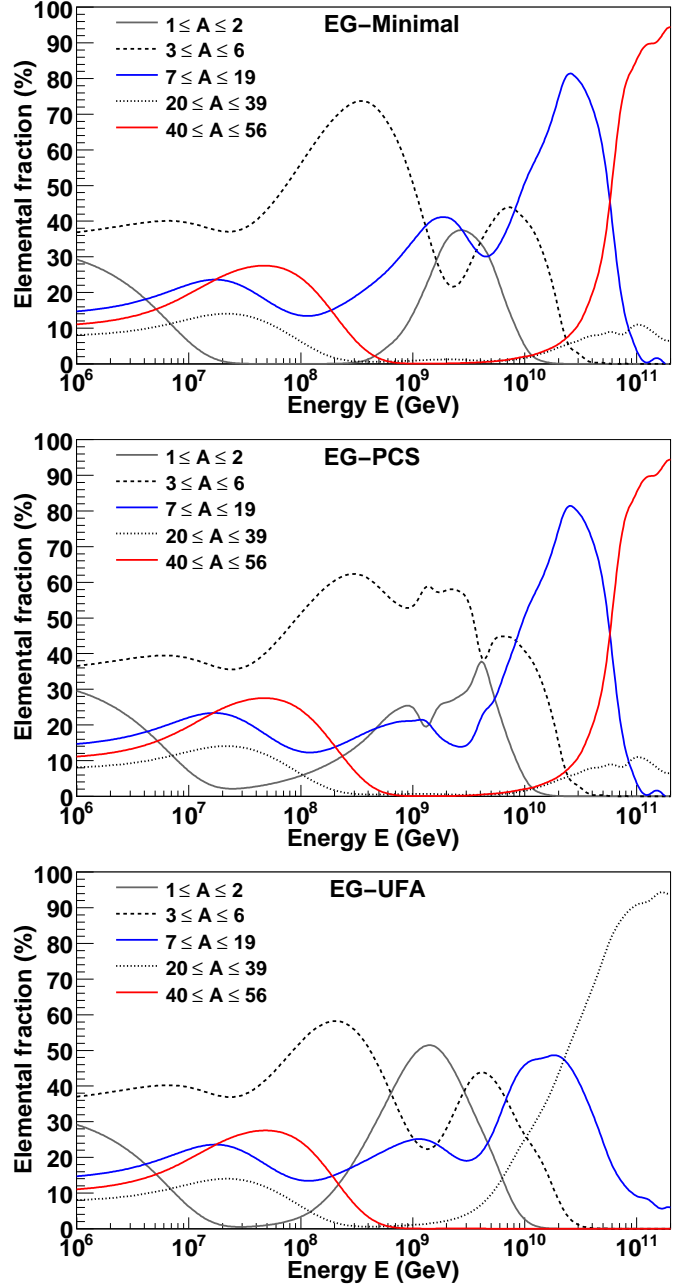

Fig. B.2. Elemental fraction of the five different mass groups shown in Figure B.1 for the three different EG-CR models: minimal (*top*), PCS (*middle*), and UFA (*bottom*), obtained using WR-CRs ($C/He = 0.1$) as the additional Galactic component.

tween $\sim 10^8$ and 5×10^9 GeV, although the discrepancy is less than that observed in the $C/He = 0.4$ scenario. The predictions of both the PCS and the UFA models show better agreement with the data below $\sim 10^9$ GeV. Between around 10^7 and 10^9 GeV, they predict a mean mass lighter than the prediction of the $C/He = 0.4$ case, and show a better agreement with the data (EPOS-LHC) from the Pierre Auger Observatory in the $10^8 - 10^9$ GeV energy range, but slightly under predict the available measurements at around $\sim 10^8$ GeV. The two WR-CR scenarios should be possible to differentiate by accurate measurements of the elemental composition between 10^7 and 10^9 GeV.

Fig. B.3. Mean logarithmic mass of cosmic rays for the minimal, PCS and UFA models of EG-CRs obtained using WR-CRs ($C/He = 0.1$) as the additional Galactic component. Data are the same as in Figure 8.

Abstract. Cosmic rays are routinely measured at LOFAR, both with a dense array of antennas and with the LOFAR Radboud air shower Array (LORA) which is an array of plastic scintillators. In this paper, we present two results relating to the cosmic-ray energy scale of LOFAR. First, we present the reconstruction of cosmic-ray energy using radio and particle techniques along with a discussion of the event-by-event and absolute scale uncertainties. The resulting energies reconstructed with each method are shown to be in good agreement, and because the radio-based reconstructed energy has smaller uncertainty on an event-to-event basis, LOFAR analyses will use that technique in the future. Second, we present the radiation energy of air showers measured at LOFAR and demonstrate how radiation energy can be used to compare the energy scales of different experiments. The radiation energy scales quadratically with the electromagnetic energy in an air shower, which can in turn be related to the energy of the primary particle. Once the local magnetic field is accounted for, the radiation energy allows for a direct comparison between the LORA particle-based energy scale and that of the Pierre Auger Observatory. They are shown to agree to within $(6\pm 20)\%$ for a radiation energy of 1 MeV, where the uncertainty on the comparison is dominated by the antenna calibrations of each experiment. This study motivates the development of a portable radio array which will be used to cross-calibrate the energy scales of different experiments using radiation energy and the same antennas, thereby significantly reducing the uncertainty on the comparison.

1 Introduction

One of the main challenges in the field of cosmic-ray astrophysics is accurately determining the energy of detected cosmic rays. Experiments use different detection, calibration, and reconstruction techniques, resulting in different energy scales. Currently, it is necessary to shift the energy scales of different experiments in order to align them to produce an overall spectral fit [1, 2]. Understanding an experiment’s energy scale is critical for comparing the spectrum and composition measurements of different experiments and for building global models of cosmic-ray sources, acceleration and propagation [3, 4].

An important factor that influences an experiment’s energy scale and the associated uncertainties is the way in which cosmic rays are detected. Above roughly 100 TeV, cosmic rays are detected indirectly, via the air shower that is generated when the primary cosmic ray interacts in the atmosphere. Air shower particles that reach the Earth’s surface can be sampled with detectors on the ground and used to estimate the energy in the air shower [5, 6]. However, this method only captures a snapshot of the shower development and relies heavily on hadronic interaction models for the interpretation of data, which introduce large systematic uncertainties at high energies [7]. An alternative approach is to measure the energy deposition from the electromagnetic part of the air shower during its longitudinal development, which eliminates most of the dependency on hadronic interaction models. This can be done, for example, by measuring the fluorescence light emitted by air molecules that have been excited by the shower particles. The fluorescence detection method provides a calorimetric energy measurement, but can only be done during dark nights and requires good knowledge of atmospheric conditions [8–11].

Air showers are also detected using the broadband radio emission that is generated as the shower develops [12–16]. The dominant contribution to the radio emission comes from

the geomagnetically induced, time-varying transverse current that develops as the shower propagates [17, 18]. The strength of this emission scales with the absolute value of the geomagnetic field and the sine of the angle between the shower velocity and the geomagnetic field. A secondary contribution comes from emission that results from the development of a charge excess in the shower front [19]. Radio emission is produced primarily by the electromagnetic components of the shower, and is calculated from first principles using classical electrodynamics [20]. The measured radio signal is integrated over the whole air shower, and so measurements can be used to perform complete calorimetric energy reconstructions without having to consider absorption or scattering [21, 22]. Furthermore, the total energy radiated by the air shower in the form of radio emission, or radiation energy, of the shower can be determined by integrating the radio energy fluence (energy per unit area) footprint on the ground. Once the radiation energy is corrected for the strength of the local magnetic field and second order effects such as the effect of atmospheric density on the shower development and the relative charge excess contribution, it becomes a universal quantity. If the radiation energy from an air shower is found in conjunction with the shower energy, determined using an independent method, it can be used to compare the energy of cosmic rays detected at different locations. The radio measurement technique also allows for the precise reconstruction of the atmospheric depth of shower maximum, X_{\max} [23, 24]. The interpretation of this parameter relies on having an accurate energy determination.

The LOw Frequency ARray (LOFAR) is a distributed radio telescope with a dense antenna array in the Netherlands [25]. An in-situ particle detector array, the LOFAR Radboud Air Shower Array (LORA), is used to trigger antenna readout [26]. Each event is simultaneously sampled by the LOFAR antennas, which measure emission in the 30 – 80 MHz band, and LORA scintillators which detect particles reaching ground level. Features of the primary cosmic ray are reconstructed with high precision [14, 27]. In this paper we present two results related to the cosmic-ray energy scale of LOFAR.

First, we present energy reconstruction techniques using the radio emission measured with the LOFAR antennas and particle data measured with the LORA scintillators. The techniques are based on CoREAS and CORSIKA simulations, respectively, and provide unique energy reconstructions. We establish that the energies reconstructed with both methods are consistent. Until recently, within LOFAR, shower properties like X_{\max} and energy were reconstructed using a hybrid method that included both particle and radio data, with the particle data determining the absolute energy. In general, the event-by-event uncertainties on radio-based energy reconstructions are smaller than those of particle-based energy reconstructions, and so with this work we move to using radio measurements to set the LOFAR energy scale [28].

Second, we determine the radiation energy of each LOFAR event using a relation derived from CoREAS simulations [22, 29] and demonstrate how radiation energy can be used to compare the energy scales of different experiments. Radiation energy is measured by the Auger Engineering Radio Array (AERA) [21, 30] in conjunction with traditional cosmic-ray measurements made at the Pierre Auger Observatory. This allows us to compare the LORA and Auger energy scales via the radiation energy measured at each location.

This paper is organized as follows. In Section 2.1 the LOFAR telescope and cosmic-ray data processing techniques are introduced. In Section 2.2 both the radio-based and particle-based energy reconstruction methods and experimental uncertainties are described. In Section 2.3 a comparison is made of the energy reconstructions resulting from each method. In Section 3.1 we find the radiation energy for events measured at LOFAR. Finally, in Sec-

tion 3.2, the LORA and Auger energy scales are compared using the radiation energy, and a new technique is introduced that will be used to compare energy scales between experiments in the future.

2 The cosmic-ray energy scale of LOFAR

This section contains a discussion of the cosmic-ray measurements made at the LOFAR telescope. Radio and particle-based energy reconstruction techniques are described, and a comparison is made between the two.

2.1 Cosmic-ray measurements with LOFAR

LOFAR is a radio telescope with antenna stations distributed across northern Europe. A dense core of 24 stations is located in the North of the Netherlands [25]. At the center is the “Superterp,” consisting of six stations located within a 160 m radius. Each station consists of 96 dual-polarized Low Band Antennas (LBAs) that operate in the 30 – 80 MHz band as well as High Band Antennas which are not used in this analysis. The 96 LBAs are organized in inner and outer sets of 48 each, and at any given time one of the two sets is operational. Each antenna is digitized at 200 mega-samples per second and the data are stored in a 5 s ring buffer. Also on the Superterp is LORA, a particle detector array consisting of 20 plastic scintillators. LORA detects showers above 10^{16} eV and acts as a trigger for radio readout. When a cosmic ray is detected, the ring buffers are frozen and 2.1 ms of data are saved. Data from the LBAs are processed offline [14] where radio frequency interference (RFI) is removed and the data are calibrated [31]. The arrival direction of the event is found using the timing of arrival of the radio signal. The voltage at each antenna position is integrated over a 55 ns time window centered at the pulse peak, resulting in what will be referred to as “measured energy,” ε .

The interpretation of both radio and particle data depends on the detector calibration, or in other words, how the measured signals in analog-digital conversion (ADC) units are translated into a quantity with physical meaning. This requires comparing measured data to a known source. The LOFAR system response, including the antennas and signal chain, is calibrated using Galactic emission as a source, as it is the primary contributor to the background in the antenna signals. However, there is a secondary contribution to the signal from electronic noise introduced in the signal chain. In order to estimate this contribution, modeled Galactic emission is propagated through the antenna and signal chain component by component, including frequency dependent gains and losses in the system and electronic noise where it enters the system. The electronic noise is not known a priori, and is determined using a fitting procedure that makes use of the variation of the Galactic emission measured by the LOFAR antennas as a function of local sidereal time. The calibration can then be found by comparing measured background signals to the predicted Galactic and electronic noise signals. The resulting calibration has an uncertainty of 13%, which is dominated by the uncertainty on the underlying models used to predict the Galactic emission. Details of the LOFAR system response calibration are given in [31].

The energy deposited by the shower particles in the scintillators is determined by calibrating the scintillators using single muons [26]. The scintillators are operated in a mode with a low trigger setting, so that singly charged particles trigger the detector readout. In order to calculate the total signal produced by a single muon, which corresponds to the total energy deposit, the ADC time trace is integrated in a time window of $(-75, +875)$ ns around

the peak of the signal. By collecting many muons, we build a distribution of energy deposits from which the most probable value can be determined. This procedure can be done in the field, so that the scintillators are calibrated under realistic operating conditions. Energy deposits from single muons are also simulated with GEANT4 [32], using an all-sky $\cos^2(\theta)$ zenith angle distribution of arrival directions and a realistic description of the detector. This provides a distribution of simulated energy deposits from which we determine the most probable value. By comparing the peak of the measured muon distribution to the simulated muon distribution, we arrive at a calibration factor for the LORA scintillators. More details on the scintillator calibration are provided in Appendix A.

A preliminary radio-based energy estimate is made using a two dimensional LDF that makes use of the asymmetry in the radio footprint due to the interference of geomagnetic and charge excess components [33]. The radio fluence at the position of each antenna is determined, and the LDF is fit using a minimization procedure. This results in initial estimates for energy, X_{\max} , and core position. These values are the starting points for the final shower reconstruction which is described in the following section.

2.2 Energy reconstruction

The LOFAR energy reconstruction is based on CORSIKA [34] and CoREAS [29] simulations. CORSIKA 7.7100 is used with hadronic interaction models FLUKA [35] and QGSJETII-04 [36]. A thinning method, where only a sub-sample of particles are tracked to make large simulations more feasible, is applied at the 10^{-6} level with optimized weight limitation [37]. A GEANT4 [32] simulation of the scintillator panels is used to derive the energy deposit from the CORSIKA-simulated particles at ground level as a function of radius from shower core, which is then used to determine the simulated energy deposit at the position of the LORA scintillators. The ‘gdastool’ CORSIKA plug-in is used to simulate each event with a realistic atmosphere [38]. The CORSIKA “STEPFC” parameter, which controls the electron multiple scattering length used in the EGS4 package (which handles electromagnetic interactions), is set to its default value of 1. This value was shown to produce radiation energy 11% lower than an optimized value of STEPFC=0.05 [39]. In order to correct for this, we increase the simulated radiation energy by 11%. Details of the simulation procedure can be found in [27].

A set of simulations is generated for each shower using the initial energy estimate and the direction determined from radio signal arrival times as input parameters. The set contains both iron nuclei and protons as primaries and X_{\max} values spanning the natural range. Antenna positions are simulated in a star-shaped pattern with 8 arms of 20 antennas spaced 25 m apart. The pattern is generated in the shower plane and then projected onto the ground plane, so that two arms align with the $\mathbf{v} \times \mathbf{B}$ axis and two with the $\mathbf{v} \times \mathbf{v} \times \mathbf{B}$ axis, where \mathbf{v} is the velocity axis of the shower front and \mathbf{B} is the Earth’s magnetic field.

The simulated electric field traces are converted into voltages by applying the LBA antenna model, and bandpass filtered to 30 – 80 MHz. As is done with measured data, the simulated voltage traces are integrated over a 55 ns time window centered at the pulse peak, resulting in a simulated “measured energy,” ε_{sim} . Radio and particle-based energy reconstructions are then done using χ^2 fitting procedures, which are described in the following subsections.

2.2.1 Radio energy reconstruction

The radio-based energy reconstruction is done by comparing ε_{sim} at each LOFAR antenna position to the detected ε . For this, a two-dimensional radiation map is generated by interpolating ε_{sim} in the antennas simulated in the star-shaped pattern in the shower plane. This way, ε_{sim} at any given antenna position $(x_{\text{ant}}, y_{\text{ant}})$ can be obtained. The map is then fit to LOFAR data using a minimization procedure with free parameters for the core position of the shower and a scale factor for the energy, as

$$\chi_{\text{radio}}^2 = \sum_{\text{antennas}} \left(\frac{\varepsilon - f_r^2 \varepsilon_{\text{sim}}(x_{\text{ant}} - x_0, y_{\text{ant}} - y_0)}{\sigma_{\text{ant}}} \right)^2 \quad (2.1)$$

where σ_{ant} refers to the one sigma level of the time-integrated voltage of measured traces outside the signal window, (x_0, y_0) is the shower core position, and f_r is the energy scaling factor, allowing for deviations from the simulated cosmic-ray energy. A χ^2 fit is done for each simulation in the set. This is similar to the fit procedure that has been used for LOFAR X_{max} analyses in the past [23, 27], the difference being that here there is no particle data information included in the fit. In the case that the scale factor is greater than 2 or less than 0.5, a new set of simulations is run with a new starting energy estimate. The values of f_r , x_0 , and y_0 for the simulation with minimum χ^2 are taken as the reconstructed values for this event, and the radio-based energy is found as

$$E_{\text{radio}} = f_r \times E_{\text{sim}}. \quad (2.2)$$

An example of the best fit ε_{sim} map to measured data is shown in the left panel of Fig. 1. The background color represents the ε_{sim} that would be received by an antenna at each position, and the colors in the white circles represent ε at specific antenna positions. The white cross represents the shower core.

We consider systematic uncertainties, which affect the absolute scale of the reconstructed cosmic-ray energy, and event-by-event uncertainties, both of which are outlined in Table 1. An overview of the uncertainties is given here, and an extended discussion can be found in Appendix A. Event-by-event uncertainties on the radio-based energy include the following. The simulated antenna model predicts the antenna response as a function of direction, which is different for each event. By offsetting the direction of the incoming cosmic ray by $\pm 5^\circ$ in the zenith direction and propagating the effects through the energy reconstruction process, we conservatively estimate that the uncertainties in the antenna response have at most a 5% effect on the reconstructed energy. Change in antenna gain as a function of temperature is found to be negligible. We use realistic atmospheres on an event-by-event basis for our simulations, and so any effects arising from incorrect atmospheric conditions are also negligible. There is uncertainty which comes from the event reconstruction procedure, and is estimated using a Monte Carlo vs. Monte Carlo method. This uncertainty includes the effects of the noise levels and geometry on the reconstruction of a particular event. Values range from 4% to 18%, with a typical value being 9%. Additionally, there is an uncertainty due to the fact that the type of the primary is unknown. Given the same shower geometry and X_{max} , an air shower initiated by a proton primary yields a reconstructed energy consistently 10% lower than an air shower initiated by an iron primary. In the fitting procedure the best-fit simulation that is used to reconstruct the energy is associated either with a proton or an iron primary. Therefore, we add an asymmetric event-by-event uncertainty to each event to account for the unknown primary. The typical total event-by-event uncertainty is then 14%.

Figure 1. Left: Example radio footprint for a LOFAR event, shown in the ground plane, with energy 7.2×10^{17} eV, zenith angle 37° , azimuth angle 41° south of east, and $X_{\max} = 670$ g/cm 2 . The color scale represents measured energy, ϵ , at each position. The background map results from simulations, and the colors in the white circles represent data measured with the LOFAR antennas. Right: Map of the particle energy deposit in LORA scintillators for the same event. The color scale represents the energy deposit per square meter in MeV. The background color comes from simulations, and the filled squares represent energy deposits measured by LORA scintillators.

Systematic uncertainties which affect the absolute radio-based energy scale include the calibration of the antenna and signal chain, the effects of hadronic interaction models, and the choice of radio simulation package, namely, CoREAS [29] or ZHAireS [40]. The system calibration is the dominant factor, at 13% [31]. The choice of simulation package has a 2.6% effect on energy, and the effect of the choice of hadronic interaction model is 3% [39, 41]. Although the radio emission is primarily generated by the electromagnetic component of the air shower, the choice of hadronic interaction model influences how much of the primary particle energy goes into that component.

2.2.2 Particle energy reconstruction

The particle-based energy reconstruction uses the best fit CORSIKA simulation as determined by the radio χ^2 fit. The radio-based measurements are more sensitive to X_{\max} and shower development, and so are more reliable for determining the best simulation. Furthermore, the core position from the radio measurement is used. When the core position falls outside the footprint of the particle detectors, it is difficult to constrain. In this sense, the two reconstructions are not entirely independent, but once the shower geometry is fixed the scale set for the particle-based energy is determined entirely by the scintillator data. A diagram of the radio and particle energy reconstruction procedures is shown in Figure 2.

Because we use results from the radio reconstruction to fix the shower geometry, many of the typical uncertainties associated with particle-based reconstructions are avoided. We take this approach, and do not attempt a completely independent particle-based reconstruction for two reasons. First, in past LOFAR analyses, a hybrid method was used to reconstruct energy which combined radio and particle information. The radio information was primarily used to determine the event geometry, while the energy was set using the particle information. The particle-based method described in this section is consistent with past analyses, and therefore allows us to compare the energy set in past analyses with the new radio-based technique.

Table 1. Summary of the uncertainties in the radio-based energy scale. The \oplus symbol indicates quadratic addition. Details of how these uncertainties are derived can be found in Appendix A.

Uncertainty	Value
Event-by-event	
angular dependence of antenna model	5%
temperature dependence	negligible
reconstruction uncertainty	typically 9%
composition uncertainty	10 %
Total event-by-event	11% \oplus reconstruction uncertainty
Absolute scale	
antenna calibration and system response	13%
hadronic interaction models	3%
radio simulation method	2.6%
Total absolute scale	13.6%

Figure 2. Diagram of the radio and particle energy reconstruction procedures. The radio-based reconstruction is done first, resulting in a best-fit simulation. This is then used in the particle-based reconstruction.

Secondly, because of the small footprint of the scintillator array, independent particle-based reconstructions would suffer from poor core reconstruction, which would severely reduce the number of usable events we have, and furthermore, the resulting uncertainties would be prohibitively large. It should be noted that LORA detects a large number of lower energy air showers that fall within the footprint of the scintillator array but do not have a strong radio signal. In this work we are interested in comparing the radio and particle reconstruction techniques, so these events aren't considered, however they were the source of an independent spectral analysis [42].

With the best simulation known, a particle χ^2 is fit, as

$$\chi_{\text{particle}}^2 = \sum_{\substack{\text{particle} \\ \text{detectors}}} \left(\frac{d_{\text{det}} - f_p d_{\text{sim}}}{\sigma_{\text{det}}} \right)^2 \quad (2.3)$$

where d_{det} is the deposited energy measured by a LORA detector with one standard deviation of background noise level σ_{det} , and d_{sim} is the GEANT4 simulated deposit. The particle scale factor f_p is needed to bring the simulated energy into agreement with the measurements. An example of the particle footprint of the best fit simulation is shown in the right panel of Fig. 1. The background color represents the simulated energy per square meter that would be deposited in a LORA scintillator at each location. On average, one muon deposits 6.5 MeV in a scintillator panel. The squares represent the locations of the scintillators with the color being the measured energy deposit. Again, the white cross represents the shower core. The particle-based energy is then found as

$$\begin{aligned} E_{\text{particle}} &= f_p \times E_{\text{sim}} \\ &= \frac{f_p}{f_r} \times E_{\text{radio}}. \end{aligned} \quad (2.4)$$

The uncertainties on the particle-based energy reconstruction are summarized in Table 2. Event-by-event uncertainties include variation in the detector response, as well as the reconstruction uncertainty for each event. Scintillators have on average a 10% fluctuation in response, but since the fluctuations are not correlated between scintillators, this propagates into a 2.5% uncertainty on the reconstructed energy. The reconstruction uncertainty on the particle-based energy, like the radio-based energy, is determined using a Monte Carlo vs. Monte Carlo method. The reconstruction uncertainty on the particle-based energy is larger than that of the radio-based energy, and extends from 10% up to 50%. The unknown composition of the measured events also contributes a significant uncertainty. Although constraining the shower geometry using information from the radio fit reduces this uncertainty, we find that for events with the same X_{max} and geometry, the reconstructed energies for showers initiated by iron primaries are lower than for proton-initiated showers. This effect is a function of zenith angle, with almost no difference in energy reconstructions for vertical showers, and up to 30% difference at zenith angles around 50° . We have parameterized this effect, and added an asymmetric event-by-event uncertainty accordingly, based on the primary of the best-fit simulation.

Systematic uncertainties include the uncertainty on the scintillator calibration and the effect of the choice of hadronic interaction model used in the simulations. Using a field calibration method, scintillator calibration can be performed at any time and the uncertainty in calibration values propagates into 3% uncertainty in energy. In order to estimate the uncertainty introduced by the choice of hadronic interaction model, we simulated a subset of events using both Sibyll 2.3c and QGSJETII-04 and found an average 7% difference in reconstructed energy between the two. More details about the uncertainties on the particle energy are given in Appendix A.

It is also known that above 10^{16} eV, there is a discrepancy between the number of simulated and measured muons in air showers [43–46], with a 50% deficit in simulated muons at $10^{17.5}$ eV reported by Auger. In order to quantify the effect this has on our reconstructed energy, we ran simulations, artificially inflating the muonic component of the signal at ground

Table 2. Summary of the uncertainties in the particle-based energy scale. The \oplus symbol indicates quadratic addition. Details of how these uncertainties are derived can be found in Appendix A. Note: this technique for reconstructing the energy based on particle information also uses information from the radio reconstruction, such as shower geometry and age, reducing the overall uncertainties.

Uncertainty	Value
Event-by-event	
scintillator response variation	2.5%
reconstruction uncertainty	10 – 50%
composition uncertainty	2 – 30%
Total event-by-event	2.5% \oplus reconstruction uncertainty \oplus composition uncertainty
Absolute scale	
scintillator calibration	3%
hadronic interaction models	7%
Total absolute scale	7.6%

level by 50%. The signal in the scintillators is dominated by the electromagnetic component of the shower, so the muon discrepancy does not have a large effect on the reconstructed energy. For the majority of our events, increasing the simulated muonic component of the air shower by 50% corresponded to a $\sim 5\%$ decrease in reconstructed energy. At zenith angles above 40° , the effects becomes larger, up to $\sim 10\%$.

2.3 Comparison of energy reconstruction techniques

In the past, LOFAR X_{\max} analyses used the scintillator measurements to set the energy scale. With an absolute antenna calibration available [31], and because the event-by-event uncertainties on the energy reconstruction using radio data are significantly lower than for the reconstruction using particle data, LOFAR analyses will move to the radio-only approach from now on [28]. Here, we compare the radio-based and particle-based energy reconstruction of each event to demonstrate the consistency of the results. Fig. 3 shows the relation between energy reconstructed with LOFAR radio data and LORA particle data. The error bars represent the event-by-event uncertainties of each event. For both radio and particle-based energies, these uncertainties are dominated by the uncertainty on the reconstruction technique, discussed in Section 2.2. The data consist of 283 events between 2011 and 2018, where we have chosen events where both radio and particle fits converge, the reconstructed core position has an uncertainty of less than 5 m, and the radio and particle reduced χ^2 of each event are less than 5. We also only consider events with particle-based energy reconstructed above 10^{16} eV. Since the radio signal scales with energy and is thus small at low energies, the detection is biased to upward fluctuations. The diagonal line represents a one-to-one correlation. The inset histogram shows the relative difference between radio-based and particle-based energy reconstructions. The mean of the distribution, found using a Gaussian fit, is -0.07, and the standard deviation is 0.35.

There is a small population of events towards the lower energies where the radio-based reconstructions are higher than the particle-based reconstructions. Some of these events have

Figure 3. Comparison of energy reconstructed using radio and particle-based methods. Error bars indicate event-by-event uncertainties. Inset: Relative difference between particle-based and radio-based reconstructed energy. The mean of the distribution, found using a Gaussian fit, is -0.07 , and the standard deviation 0.35 .

relatively small event-by-event uncertainties compared to their distance from the line. Normally there would be fluctuations on either side of the mean from each method. However, since the radio signal becomes difficult to detect at low energies, it is more probable to have upwards fluctuations of radio-based energy reconstructions than downward fluctuations. This is also evident in the asymmetry of the relative energy histogram. As this effect is insignificant for our analysis, we do not correct for it. We conclude that the radio and energy based reconstructions are consistent within the resolution of the measurements.

3 Using radiation energy to compare energy scales of different experiments

In this section we will demonstrate how radiation energy, S_{RD} , which is the total amount of radio emission emitted by an air shower, can be used to compare the energy scales of different experiments when measured in conjunction with the total shower energy, determined using an independent method.

3.1 Determination of the LOFAR radiation energy

Here, we first describe radiation energy and the corrections needed to make it a universal quantity in a general way. Then, we will lay out how we use the results presented in [22], which are based on CoREAS simulations, to determine the corrected radiation energy for LOFAR events.

The radiation energy contained in an air shower can be found by integrating the energy deposit per unit area, or fluence, over the radio footprint. Since radio waves are not attenuated

in the atmosphere, the altitude of the observation site is inconsequential as long as all the radiation energy in the shower has been released before it reaches the ground. This makes radiation energy an ideal value to compare between different locations. However, it must still be corrected for various factors in order to make it a universal quantity which can be compared between different experiments and events. The corrections outlined here follow those described in [22].

The strength of the local magnetic field influences the strength of the geomagnetic emission. For example, the magnetic field at LOFAR is 0.492 G, which is twice as strong as the 0.243 G magnetic field at Auger. This means for the same event, the radiation energy detected at LOFAR would be larger. To correct for this, the radiation energy is scaled by the ratio of the magnetic field of a reference location and the local magnetic field. Furthermore, when the radiation energy is calculated, the geomagnetic contribution to the radiation energy is corrected to account for the shower geometry, in particular, the angle between the magnetic field and shower axis, α . The charge excess fraction of the radiation energy has been parameterized so that this correction can be made to only the geomagnetic contribution. The radiation energy also depends on the air density in which the air shower develops; showers that develop in a less dense atmosphere have relatively larger radiation energy. In general, one has to consider “clipping” effects when the radiation energy is not yet completely released at the observer height. For LOFAR events, this is not a concern due to the fact that the observation height is close to sea level and that most shower energies are below 10^{18} eV. Making these corrections yields the “corrected radiation energy” which can be compared between different experiments.

The work presented in [22] used CoREAS simulations to derive a relation between the corrected radiation energy in the 30–80 MHz band, $S_{RD,corr}$, and the electromagnetic energy, E_{em} , contained in the air shower. The radiation energy was found by integrating the simulated fluence in the 30–80 MHz band over the radio footprint, and making the corrections discussed above. The magnetic field strength was normalized to the magnetic field strength at Auger. This resulted in the equation

$$S_{RD,corr} = A \times 10^7 \text{eV} (E_{em}/10^{18} \text{eV})^B \quad (3.1)$$

where $A = 1.683 \pm 0.004$, and $B = 2.006 \pm 0.001$.

We use this result to directly find the corrected radiation energy of LOFAR events. In the fitting method described in Section 2.2.1, we determine the CoREAS simulation that best fits the measured radio data. Once this is known the energy contained in the electromagnetic component of the air shower, E_{em} , can be found using the longitudinal profile information provided by the associated CORSIKA simulation, scaled by the radio scale factor f_r found in Section 2.2.1. We then use Eq. 3.1 to determine the corrected radiation energy. Finding $S_{RD,corr}$ this way is only possible because we use a simulation-based reconstruction technique and identify a best fit simulation for each event. This gives us direct access to information about the (simulated) electromagnetic component of the air shower. Alternatively, one can integrate the fluence over the radio footprint of the best-fit simulation and make the corrections described above to determine the corrected radiation energy. We have confirmed that both methods yield the same result. We also note that the fraction of E_{em} to the total cosmic-ray energy depends on the choice of hadronic interaction model, where here we have used QGSJETII-04.

3.2 Comparison of the energy scales of LORA and the Pierre Auger Observatory

Equation 3.1 gives the relation between the corrected radiation energy, $S_{RD,corr}$, and the electromagnetic energy in the shower, E_{em} . In order to compare the energy scales of different experiments using the universal quantity $S_{RD,corr}$, we need a relation between it and the total cosmic-ray energy, E_{CR} . We will use a function of the same form as equation 3.1 to relate $S_{RD,corr}$ and E_{CR} , written generally as $S_{RD,corr} = A' \times 10^7 \text{eV} (E_{CR}/10^{18} \text{eV})^{B'}$. We use the notation A', B' for the parameters in this case to distinguish them from A, B in equation 3.1, and we emphasize that they should not be directly compared because here we relate $S_{RD,corr}$ and E_{CR} , whereas equation 3.1 relates $S_{RD,corr}$ and E_{em} . For reference, in the LOFAR energy range roughly 85% of the total cosmic-ray energy goes into the electromagnetic components of the air shower. The fraction of E_{CR} that goes into E_{em} differs by particle type, with protons generating showers with a higher fraction of electromagnetic particles than iron nuclei. The difference is roughly 4.5% at 10 EeV, and decreases towards higher energies [7, 47]. Since we expect the experiments we want to compare to measure a similar composition, we don't take this difference into account.

Because the radio and particle components of each LOFAR event are measured simultaneously, we can derive the relation between $S_{RD,corr}$ determined using the LOFAR antennas and the particle-based cosmic-ray energy determined using the LORA scintillators, E_{CR}^{LORA} . In order to avoid any biases in detection that occur at lower energies, only events where both the radio and particle-based energies reconstruct to greater than 1.3×10^{17} eV are used. Using an Orthogonal Distance Regression [48] method and fitting the equation

$$S_{RD,corr} = A'_{\text{LORA}} \times 10^7 \text{eV} (E_{CR}^{\text{LORA}}/10^{18} \text{eV})^{B'_{\text{LORA}}} \quad (3.2)$$

results in the parameters $A'_{\text{LORA}} = 1.57 \pm 0.12(\text{stat}) \pm 0.49(\text{sys})$, $B'_{\text{LORA}} = 2.07 \pm 0.06(\text{stat})$, where the statistical uncertainty comes from the fitting procedure. The systematic uncertainty includes both the uncertainties on the radio-based energy scale which propagate into the radiation energy, and the uncertainties on the particle-based energy scale.

Fig. 4 shows the LOFAR corrected radiation energy as a function of LORA cosmic-ray energy. Error bars indicate the event-by-event uncertainties on each point. The resulting best-fit line of the form 3.2 is also shown in purple, with the shaded region indicating the absolute scale uncertainty on the corrected radiation energy.

We compare the energy scales of LORA and Auger by making use of the relation between the corrected radiation energy measured with AERA and the total cosmic-ray energy, E_{CR}^{Auger} , as determined by the Auger surface detectors [49] which are calibrated using the calorimetric energy measurements of the fluorescence detectors [50]. We denote the AERA corrected radiation energy as $S_{RD,corr}^*$, to indicate that in this case corrections are made for the relative strength of the geomagnetic emission, but second order corrections for charge excess fraction and air density in the region of shower development are not included. Derived in [15] and [21], the total corrected radiation energy in the 30 – 80 MHz band can be related to total cosmic-ray energy using

$$S_{RD,corr}^* = \frac{S_{RD}}{\sin^2(\alpha)} = A'_{\text{Auger}} \times 10^7 \text{eV} (E_{CR}^{\text{Auger}}/10^{18} \text{eV})^{B'_{\text{Auger}}} \quad (3.3)$$

where $A'_{\text{Auger}} = 1.58 \pm 0.07(\text{stat}) \pm 0.67(\text{sys})$, $B'_{\text{Auger}} = 1.98 \pm 0.04(\text{stat})$, and α is the angle between magnetic field and shower axis. The systematic uncertainties include both the 16% uncertainty (at $10^{17.5}$ eV) on the Auger energy scale [50], and the 14% uncertainty on the

Figure 4. Relation between the corrected radiation energy measured by the LOFAR antennas and the cosmic-ray energy as determined by the LORA scintillators. The error bars represent event-by-event uncertainties. The purple line shows the best fit line for LOFAR measurements of corrected radiation energy and LORA cosmic-ray energy, and the banded region around the best fit line represents the systematic uncertainties on the corrected radiation energy. The green line shows the best fit line for AERA measurements of corrected radiation energy and Auger cosmic-ray energy [21], and the shaded green region represents the systematic uncertainties on the corrected radiation energy. QGSJETII-04 was used in the simulations on which the LOFAR and LORA energy reconstructions are based.

AERA antenna calibration [30]. Equation 3.1, used to find the corrected radiation energy for LOFAR, already includes a normalization of the local magnetic field to that of Auger. Therefore the parameters $A'_{\text{LORA}}, B'_{\text{LORA}}$ and $A'_{\text{Auger}}, B'_{\text{Auger}}$ and in equations 3.2 and 3.3 are comparable, with the caveat that second order corrections are not made for the Auger radiation energy. Equation 3.3 is also shown in Fig. 4 in green, with the shaded region indicating the absolute scale uncertainties on the radiation energy.

Using equations 3.2 and 3.3, we compare the average energies of LORA and Auger at a corrected radiation energy $S_{RD,corr} = 1$ MeV. This value of $S_{RD,corr}$ was chosen for the comparison because it is close to the average value of the LOFAR corrected radiation energy (determined in log-space). $S_{RD,corr} = 1$ MeV corresponds to a LORA energy of $(2.64 \pm 0.42(\text{sys})) \times 10^{17}$ eV and an Auger energy of $(2.48 \pm 0.52(\text{sys})) \times 10^{17}$ eV. The ratio

between the LORA and Auger energies $E_{\text{CRLORA}}/E_{\text{CRAuger}} = 1.06 \pm 0.20$, meaning that LORA energy is 6% larger, with a 20% combined uncertainty on the comparison. The uncertainty on the comparison includes only the radio-based uncertainties on the radiation energy, namely the uncertainties on the calibration of the AERA antennas and the LOFAR radio-based energy scale. We do not include the uncertainties associated with the Auger or LORA energy scales because we are not making a statement about the absolute energy scale of either experiment, only the comparison between the two. The B'_{LORA} and B'_{Auger} parameters of equations 3.2 and 3.3 are different, so the ratio between LORA and Auger energy changes with energy. At the low end of the LOFAR corrected radiation energy range, $S_{RD,corr} = 0.25$ MeV, $E_{\text{CRLORA}}/E_{\text{CRAuger}} = 1.11 \pm 0.20$. At the high end, $S_{RD,corr} = 10$ MeV, $E_{\text{CRLORA}}/E_{\text{CRAuger}} = 1.01 \pm 0.20$. For all these points, the energy scales of Auger and LORA agree within the comparison uncertainty, although it should be noted that the comparison uncertainty is larger than the absolute uncertainty on either energy scale. The LORA cosmic-ray energy is derived using an approach based on hadronic interaction models. In contrast, the Auger cosmic-ray energy comes from surface detector measurements, which are calibrated using the fluorescence detectors which make model-independent, calorimetric measurements [50]. Nevertheless, this comparison shows that the energy scales of the two experiments are compatible, albeit with a large uncertainty on the comparison.

Radio techniques have previously been used to compare the energy scales of different experiments. The energy scales of Tunka-133 [51] and KASCADE-Grande [52] have been compared using their radio extensions, Tunka-Rex [53] and LOPES [54]. This was done both by comparing the absolute amplitude of the radio measurements 100 m from the shower core at each location with the energies measured by Tunka-133 and KASCADE-Grande, and by using a simulation-based method [55]. This study benefited from the fact that the antennas at each location were calibrated using the same technique, which reduced the uncertainties on the comparison. The remaining uncertainties on the comparison were due to the LOPES antenna model and the fact that the absolute amplitude of the signal at 100 m was compared, rather than radiation energy. This value is harder to compare because it relies on knowledge of the radio footprint at a particular location, and corrections have to be made for observation level and zenith angle. In the study presented here, we have avoided these location and shower-specific uncertainties by using the universal measurement of corrected radiation energy rather than signal amplitude. However, the uncertainties associated with our comparison are large, because for each experiment, the uncertainties on the radiation energy, most notably the antenna calibration, must be included.

Having a method to compare the energy scales of different experiments with minimal uncertainty is necessary in order to make meaningful comparisons of their spectra and composition measurements, which are used to build global models of cosmic-ray sources, acceleration and propagation [1, 2]. We plan to do this by combining the techniques used here and in [55]. A portable array of antennas will be built and deployed at various experiments, measuring radiation energy in conjunction with the host experiment's traditional air shower measurements. The radiation energy can feasibly be reconstructed with only 5 antennas, as AERA has demonstrated [21]. Using radiation energy to compare the energy scales eliminates uncertainties due to measurements being made at different locations, and using the same array eliminates the uncertainties associated with the antennas and calibration. This will allow for a cross-calibration of the energy scales of different experiments with minimal uncertainty.

4 Conclusions

Cosmic-ray air showers are regularly detected at LOFAR, where simultaneous measurements are made with antennas and particle detectors. In this work we compared the reconstructed energies using radio-based and particle-based methods. The reconstruction methods are based on CoREAS and CORSIKA simulations respectively, where simulated radio and particle footprints are fit to measured data using χ^2 minimization processes. In the past, LOFAR analyses have used a hybrid approach in which both radio and particle data were fit simultaneously. The radio information was primarily used to determine the shower geometry, while the energy was set with the particle information. In this work, the energies are fit separately, yielding two unique energy reconstructions. We have shown that both methods of determining energy produce consistent results.

We discussed the uncertainties on both methods, and find a 13.6% systematic uncertainty on radio-based energy and 7.6% on particle-based energy. The event-by-event uncertainties on radio-based energies are around 14%. For particle-based energies the event-by-event uncertainties extend to more than 50%. Both are dominated by the uncertainty in the event reconstruction procedure and unknown composition. Taking into consideration the relative uncertainties, we now move from using the hybrid fitting method to using the radio-based reconstruction method to set the LOFAR energy scale.

We also used the corrected radiation energy in the 30 – 80 MHz band to compare the LORA and Auger energy scales. Radiation energy between experiments can be compared because it represents a calorimetric energy measurement that primarily depends on the local magnetic field, which is a well known quantity and which can be accounted for. Second order corrections can also be made with knowledge of the shower geometry and atmospheric conditions. Using the relations derived in equations 3.2 and 3.3, we determined that for a corrected radiation energy of 1 MeV the difference in LORA and Auger energies is 6% with an uncertainty on the comparison of 20%.

Moving forward, we will use corrected radiation energy to cross-calibrate the energy scales of different experiments. The systematic uncertainties that are relevant for the comparison of the corrected radiation energy between experiments are dominated by the uncertainties associated with antenna and system calibrations, here 14% for AERA antennas and 13% for the LOFAR antenna and system response. By using the same detection system in each location, these uncertainties can be removed from the comparison of relative energies. We plan to build a portable array of antennas which will be used to measure radio emission from air showers in situ at different experiments. The corrected radiation energy will then be used to directly compare the energy scales of the experiments with minimal systematic uncertainties, allowing for the establishment of a universal energy scale.

A Uncertainties

This appendix addresses how the uncertainties on the reconstructed energy of LOFAR events were derived.

A.1 Event-by-event Uncertainties

Radio and Particle: reconstruction uncertainties

The reconstruction uncertainty of each event is derived using a Monte Carlo vs. Monte Carlo method. The simulation set created for each event contains at least 40 showers. One shower is used as mock “data” and the time-integrated power, ε , at the position of each LOFAR antenna is found using the two dimensional ε_{sim} map. Noise is added to the “data” that reflects the noise level in the actual event data. This “event” is then reconstructed using the remaining simulations using the same procedure discussed in Section 2.2.1. The fit produces the scale factor f_r , used to convert the simulated energy E_{sim} to event energy as $E_{\text{radio}} = f_r \times E_{\text{sim}}$. Each shower in the set is simulated at the same energy, so if the fit were perfect the scale factor would always be $f_r = 1$. This procedure is repeated using every simulation in the set as the “event”, yielding a set of scale factors, f_r . The same procedure is also applied to the particle data, yielding a set of reconstructed scale factors f_p . The resulting distributions of scale factors for one event are shown in the histograms in Fig. 5, where the radio scale factors are in the left panel and particle scale factors are in the right panel. One standard deviation of the distribution is taken to be the fit uncertainty for a particular event.

Figure 5. Reconstructed scale factors resulting from a Monte Carlo vs. Monte Carlo study for one event. Radio scale factors are shown in the left panel, and particle scale factors in the right panel. The standard deviation of each distribution is taken as the fit uncertainty for this event.

Fig. 6 shows the distribution of the standard deviation of scale factors for each event, or equivalently, the reconstruction uncertainty, for all events. Again, the radio uncertainty is shown in the left panel, and particle uncertainty in the right. We see that typical values for reconstruction uncertainties on radio-based energy are close to 9% with little spread. The most probable value (MPV) of the particle-based uncertainties is 12%, but they have a much larger spread and extend to 50%.

Radio and Particle: composition uncertainties

Although the radio reconstruction technique discussed in Section 2.2.1 reconstructs X_{max} to within 17 g/cm^2 [27], there is still uncertainty associated with the primary composition. For each event, a best fit simulation is chosen out of a set of more than 40 simulations of both proton and iron primaries. The energy of the event is then found using equations 2.1 and 2.2. The fact that the best fit simulation is associated with either a proton or an iron primary affects the reconstructed energy. In order to quantify this uncertainty, we ran simulations for a subset of events collecting a set of both 15 proton and 15 iron simulations with X_{max} values within 5 g/cm^2 of the reconstructed value of the event. We found that iron-initiated showers

Figure 6. Distribution of fit uncertainties for radio-based energy reconstruction (left), and particle-based energy reconstruction (right).

consistently reconstruct with an radio-based energy 10% higher than proton-initiated showers. This effect is independent of X_{\max} or zenith angle. For each event, we include an asymmetric 10% uncertainty. For example, if the best fit simulation corresponds to a proton primary, the error bar is included in the positive direction. This provides a conservative estimate for the composition uncertainty on the radio-based energy reconstruction.

Likewise, there is a composition uncertainty on the particle-based energy reconstruction. Given the same X_{\max} , proton-initiated showers reconstruct with a higher energy than iron-initiated showers. This effect is amplified with increasing zenith angle. For vertical showers, proton-initiated events reconstruct a few percent higher than iron. At 50° zenith, this difference increases to 30%. We have parameterized the difference between proton and iron energy reconstruction as a function of zenith angle, and added asymmetric error bars accordingly.

Radio: angular dependence of the antenna model

We account for the uncertainty in the angular dependence of the antenna model. The overall calibration of the antenna model is handled separately [31]. Measurements have been made using a reference source attached to an octocopter that showed that the received power as a function of direction, based on the antenna model, is in general agreement with measurements [56]. In order to estimate the remaining uncertainty, we offset the antenna model by $\pm 1^\circ$ and $\pm 5^\circ$ in the zenith direction. Events are then reprocessed with the offset antenna model to determine the effect on reconstructed energy. The ratio between the energy reconstructed with the offset and without the offset for each event is shown in Fig. 7. We take an uncertainty of $\pm 5\%$, which is reflective of the distributions of the energy reconstruction ratio with the model offset 5° . This is a conservative estimate, because in practice, each antenna may have a slightly different offset in different directions, in which case the effect of the antenna model will have less impact on the final energy.

Radio: temperature dependence

There was no apparent seasonal or temperature dependence found in the antenna gain. This was determined by looking at the average power contained in the background of event traces over the course of the year. The dominant contribution to the background radio signal is Galactic noise. While the same sky is visible over 24 hours in local sidereal time, the

Figure 7. The ratio between energy reconstructed with antenna model offsets and the original model. Offsets of $\pm 1^\circ$ and $\pm 5^\circ$ were applied.

portion that is visible during nighttime and daytime hours changes from winter to summer; more Galactic emission is visible at night in the winter. There are more LBA observations in night hours, and so the average power increases in the winter months. The effect is that there is 10% more noise power in the traces, but this effect is simply an offset and not multiplicative, and is handled in the data processing pipeline. We also do not see any degradation in the average antenna signal over time.

Particle: scintillator response variation

The response of the scintillators varies over time. We characterize the variation of each scintillator by looking at the daily average energy deposit. The variation is then determined by taking the standard deviation of average energy deposits. There is no apparent systematic variation with temperature, degradation over time, or correlation between detectors. In order to propagate this uncertainty into the energy reconstruction, we repeat the analysis while adjusting the scintillator calibration, or equivalently, the conversion factor from deposited energy in ADC units into MeV. Since the variation in each scintillator is uncorrelated, the adjustment to each scintillator’s calibration is made by selecting a new value from a Gaussian distribution with the original conversion factor as the mean, and variation as the standard deviation. This process was repeated three times, and the maximum effect on the resulting energy scale was 2.5%.

A.2 Systematic Uncertainties

Radio: antenna calibration

The antenna and signal chain calibration is the dominant systematic uncertainty in the radio-based energy reconstruction at 13%. The calibration is based on modeling the propagation of Galactic noise through the LOFAR signal chain. Details are given in [31]. The dominant contribution to the uncertainty on the calibration is the uncertainty on the underlying models predicting the brightness temperature of the galaxy, which contribute 11%.

Radio: choice of simulation code

The simulated radio emission for this analysis was generated using CoREAS. CoREAS determines radio emission from a given particle track in the cascade by applying the endpoint formalism [29, 41]. There are other methods, including the approach taken in ZHAireS, which implements the ZHS method [57, 58]. The agreement between the two simulation codes was studied in [39], and the effect of choosing one code over the other on the energy scale was determined to be less than 2.6%.

Radio and particle: hadronic interaction model

In order to determine the effect of the choice of hadronic interaction model used in the CORSIKA simulation, ten events, with a minimum of 40 simulations each, were re-analyzed using simulations produced with the Sibyll 2.3c [59] interaction model instead of QGSJETII-04. This changed the resulting radio-based energy by 3% and particle-based energy by 7%.

Particle: scintillator calibration

In order to calibrate the scintillators, or in other words, to find the conversion between charge deposit in ADC counts and MeV, it is necessary to collect single muon events. This is done in the field by setting the trigger threshold very low, and collecting a combination of singly charged particle events (presumably dominated by muons) and noise triggers from a single scintillator. Then, the most probable muon deposit from LORA data can be compared to the most probable energy deposit based on GEANT4 simulated muon events using a realistic detector description and arrival directions following a $\cos(\theta)^2$ zenith angle distribution [32]. The resulting muon energy deposit distributions are shown in Fig. 8. The distribution shown in red comes from simulation, and the blue distribution shows events measured in the field. For the field events, the noise peak is also visible. We also measured the energy deposit of single muon events in a laboratory setting, using a muon tower to ensure the triggered events were exclusively single muons. The resulting distribution is shown in green. The field measurements have a broader distribution due to the environment being less controlled, but the peak of the distribution still represents the most probably muon energy deposit.

There is a systematic uncertainty associated with the calibration of the LORA scintillators. By repeating the field calibration process a number of times, we find the standard deviation of the calibration values for each scintillator. Then, this uncertainty is propagated through the analysis, and new energy reconstructions are obtained. The average standard deviation of the scintillator calibration value is $\pm 3\%$, which propagates into $\pm 3\%$ uncertainty in event energy. This is shown in Fig. 9. The histograms represent the ratio of energy reconstructed with the standard calibration plus 3% (in blue), and minus 3% (in orange) to the original energy reconstruction.

The spatial response of the scintillators was measured at Karlsruhe Institute of Technology (KIT) and using a muon tracking detector which was originally used for muon tracking in the KASCADE experiment [52]. The response is very uniform over the surface of the scintillator, and is now included in LORA simulations [60].

Figure 8. Distributions of energy deposits from single muons. The distribution in red shows the GEANT4 simulated deposits. The green and blue lines represent muon energy deposits measured in the lab and field, respectively.

Figure 9. Ratio of energy reconstructed with the standard calibration plus 3% (in blue), and minus 3% (in orange) to the original energy reconstruction.

Acknowledgments

Cosmic rays are the highest energy particles found in nature. Measurements of the mass composition of cosmic rays between 10^{17} eV and 10^{18} eV are essential to understand whether this energy range is dominated by Galactic or extragalactic sources. It has also been proposed that the astrophysical neutrino signal¹ comes from accelerators capable of producing cosmic rays of these energies². Cosmic rays initiate cascades of secondary particles (air showers) in the atmosphere and their masses are inferred from measurements of the atmospheric depth of the shower maximum, X_{\max} ³, or the composition of shower particles reaching the ground⁴. Current measurements⁵ suffer from either low precision, and/or a low duty cycle. Radio detection of cosmic rays⁶⁻⁸ is a rapidly developing technique⁹, suitable for determination of X_{\max} ^{10,11} with a duty cycle of in principle nearly 100%. The radiation is generated by the separation of relativistic charged particles in the geomagnetic field and a negative charge excess in the shower front^{6,12}. Here we report radio measurements of X_{\max} with a mean precision of 16 g/cm² between $10^{17} - 10^{17.5}$ eV. Because of the high resolution in X_{\max} we can determine the mass spectrum and find a mixed composition, containing a light mass fraction of $\sim 80\%$. Unless the extragalactic component becomes significant already below $10^{17.5}$ eV, our measurements indicate an additional Galactic component dominating at this energy range.

Observations were made with the Low Frequency Array (LOFAR¹³), a radio telescope consisting of thousands of crossed dipoles, with built-in air shower detection capability¹⁴. LOFAR records the radio signals from air showers continuously while running astronomical observations simultaneously. It comprises a scintillator array (LORA), that triggers the readout of buffers, stor-

ing the full waveforms received by all antennas.

We have selected air showers from the period June 2011 - January 2015 with radio pulses in at least 192 antennas. The total uptime was ~ 150 days, limited by construction and commissioning of the telescope. Showers that occurred within an hour from lightning activity, or have a polarisation pattern that is indicative of influences from atmospheric electric fields are excluded from the sample¹⁵.

Radio intensity patterns from air showers are asymmetric due to the interference between geomagnetic and charge excess radiation. They can be reproduced from first principles by summing the radio contributions of all electrons and positrons in the shower. We use the radio simulation code CoREAS¹⁶, a plug-in of CORSIKA¹⁷, which follows this approach.

It has been shown that X_{\max} can be accurately reconstructed from densely sampled radio measurements¹⁸. We use a hybrid approach, simultaneously fitting the radio and particle data. The radio component is very sensitive to X_{\max} , while the particle component is used for the energy measurement.

The fit contains four free parameters: the shower core position (x, y) , and scaling factors for the particle density f_p and the radio power f_r . If f_p deviates significantly from unity, the reconstructed energy does not match the simulation and a new set of simulations is produced. This procedure is repeated until the energies agree within uncertainties. The ratio between f_r and f_p should be the same for all showers and is used to derive the energy resolution of 32% (see Figure

1).

The radio intensity fits have reduced χ^2 -values ranging from 0.9 to 2.9. All features in the data are well reproduced by the simulation (see Extended Data Figs. 1-5), demonstrating that the radiation mechanism is now well-understood. The reduced χ^2 -values exceeding unity may indicate remaining uncertainties in the antenna response, atmospheric properties, or limitations of the simulation software.

Radio detection becomes more efficient for higher-altitude showers that have larger footprints. The particle trigger, however, becomes less efficient since the number of particles reaching the ground decreases. To avoid a bias, we require that *all* the simulations produced for a shower pass the trigger criteria. Above 10^{17} eV this cut removes 4 showers from the sample. At lower energies, this number rapidly increases, and we exclude all showers below 10^{17} eV from this analysis.

Furthermore, we evaluate the reconstructed core positions of all simulated showers. Showers with a mean reconstruction error above 5 m are rejected. This cut does not introduce a composition bias, because it is based on the sets of simulated showers, and not on the data. The final event sample contains 118 showers.

The uncertainty on X_{\max} is determined independently for all showers¹⁸, and has a mean value of 16 g/cm^2 (see Extended Data Figure 6). Figure 2 shows our measurements of the *average* X_{\max} , which are consistent with earlier experiments using different methods, within statistical un-

certainties. The high resolution for X_{\max} *per shower* allows us to derive more information on the composition of cosmic rays, by studying the complete shape of the X_{\max} distribution. For each shower, we calculate:

$$a = \frac{\langle X_{\text{proton}} \rangle - X_{\text{shower}}}{\langle X_{\text{proton}} \rangle - \langle X_{\text{iron}} \rangle} \quad (1)$$

where X_{shower} is the reconstructed X_{\max} , and $\langle X_{\text{proton}} \rangle$ and $\langle X_{\text{iron}} \rangle$ are mean values predicted by the hadronic interaction code QGSJETII.04¹⁹.

The cumulative probability density function (CDF) for all showers is plotted in Fig. 3. First, we fit a 2-component model of proton and iron nuclei, with the mixing ratio as the only free parameter. To calculate the corresponding CDFs we use a parametrisation of the X_{\max} distribution fitted to simulations based on QGSJETII.04. The best fit is found for a proton fraction of 62%, but it describes the data poorly with a p-value of 1.1×10^{-6} .

A better fit is achieved with a four-component model (p+He+N+Fe), yielding a p-value of 0.17. While the best fit is found for a Helium fraction of 80%, the fit quality deteriorates only slowly when replacing helium by protons. This is demonstrated in Figure 4 where the p-value is plotted for four-component fits where the fractions of helium and proton are fixed, and the ratio between N and Fe is left as the only free parameter. The total fraction of light elements (p+He) is in the range [0.38,0.98] at 99% confidence level, with a best fit value of 0.8. The heaviest composition that is allowed within systematic uncertainties still has a best fit p+He fraction of 0.6, and a 99% confidence level interval of [0.18, 0.82]. The online method section contains information about the systematic uncertainties and the statistical analysis.

The abundances of individual elements depend on the hadronic interaction model. The X_{\max} values predicted by EPOS-LHC²⁰ are on average 15-20 g/cm² higher than QGSJETII.04 (see Fig. 2). This coincides with the separation between, for example, protons and deuterium or between helium and beryllium. We therefore prefer to present our result as a total fraction of light elements, instead of placing too much emphasis on individual elements.

Recent results for the Pierre Auger Observatory indicate that the cosmic ray composition at 10¹⁸ eV, just below the ankle, can be fitted with a mixture of protons and either helium (QGSJET.II04) or nitrogen (EPOS-LHC)³. With decreasing energy, their proton fraction drops, while their helium (or nitrogen) fraction rises, down to the threshold energy of $7 \cdot 10^{17}$ eV. An extrapolation of this trend to our mean energy of $3 \cdot 10^{17}$ eV connects smoothly to our best fitting solution in which helium dominates.

KASCADE-Grande has reported an ankle-like feature at 10^{17.1} eV, where the spectral index for light elements changes to $\gamma = -2.79 \pm 0.08^4$. However, they find a light particle (p+He) fraction below 30% at 3×10^{17} eV (based on their Figure 4), considerably lower than our value. In contrast to LOFAR and Auger, their composition measurements are based on the muon/electron ratio. Auger has reported a muon excess compared to all commonly used hadronic interaction models²¹. Inaccurate predictions of muon production, or $\langle X_{\max} \rangle$, can be the cause of the discrepancy in the fraction of light particles between LOFAR and KASCADE-Grande.

If the knee in the all-particle spectrum near 3×10^{15} eV corresponds to the proton or helium cut-off of the main Galactic cosmic-ray population, the corresponding iron cut-off would lie at most

at an energy 26 times larger. If this population still dominates at 10^{17} eV, the mass composition should be dominated by heavy elements at that energy. Therefore, the large component of light elements observed with LOFAR must have another origin.

In principle, it is possible that we observe an extragalactic component. In that case the ankle in the cosmic-ray spectrum, slightly above 10^{18} eV, does not indicate the transition from Galactic to extragalactic origin. Instead, it can be explained as the imprint of pair production on the cosmic microwave background on an extragalactic proton spectrum²². However, since this feature only appears for a proton-dominated flux it is in tension with our data that favours a mixture of light elements.

A second Galactic component, dominating around 10^{17} eV, can be produced by a class of extremely energetic sources (Galactic exatrons), like the explosions of Wolf Rayet stars into their stellar winds²³, or past Galactic gamma-ray bursts²⁴. Alternatively, the original Galactic population could be reaccelerated by the Galactic wind termination shock²⁵. Such scenarios predict mixtures of light elements, consistent with our results.

Figure 1 | Energy resolution. The distribution of f_r/f_p is fitted with a Gaussian, yielding $\sigma = 0.12$ on a logarithmic scale, corresponding to an energy resolution of 32%. This value is actually the quadratic sum of the energy resolution of the radio and particle resolutions. In this analysis, there was no absolute calibration for the received radio power yet, so f_r has an arbitrary scale.

Figure 2 | Measurements of $\langle X_{\max} \rangle$. The mean depth of shower maximum as a function of energy is plotted for LOFAR and earlier experiments based on different techniques^{26–29}. Error bars indicate one-sigma uncertainties. The systematic uncertainties are +14/-10 g/cm² on $\langle X_{\max} \rangle$ and 27% on energy and are indicated with a shaded band. The Pierre Auger Observatory measures the fluorescence light emitted by atmospheric molecules excited by air shower particles. Hires/MIA used a combination of the fluorescence technique and muon detection. The Tunka and Yakutsk arrays use non-imaging Cherenkov detectors. The green (upper) lines indicate the $\langle X_{\max} \rangle$ for proton shower simulated with QGSJETII.04 (solid) and EPOS-LHC (dashed). The blue (lower) lines are for showers initiated by iron nuclei.

Figure 3 | Composition model fits. The cumulative probability density of the parameter a (see Eqn. 2) is plotted for the data (blue line, shading indicates the range where the p -value > 0.01) and several models, based on QGSJETII.04 simulations. A set that contains only proton showers is centered around $a = 0$ and has a large spread, while iron showers give a small spread around $a = 1$. A two-component model of proton and iron yields the best fit for a proton fraction of 62%, but does not describe the data well with a p -value of 1.1×10^{-6} . A four-component model gives the best fit at 0% proton, 79% helium, 19% nitrogen, and 2% iron, with a p -value of 0.17. The uncertainty on these values is explored in Figure 4.

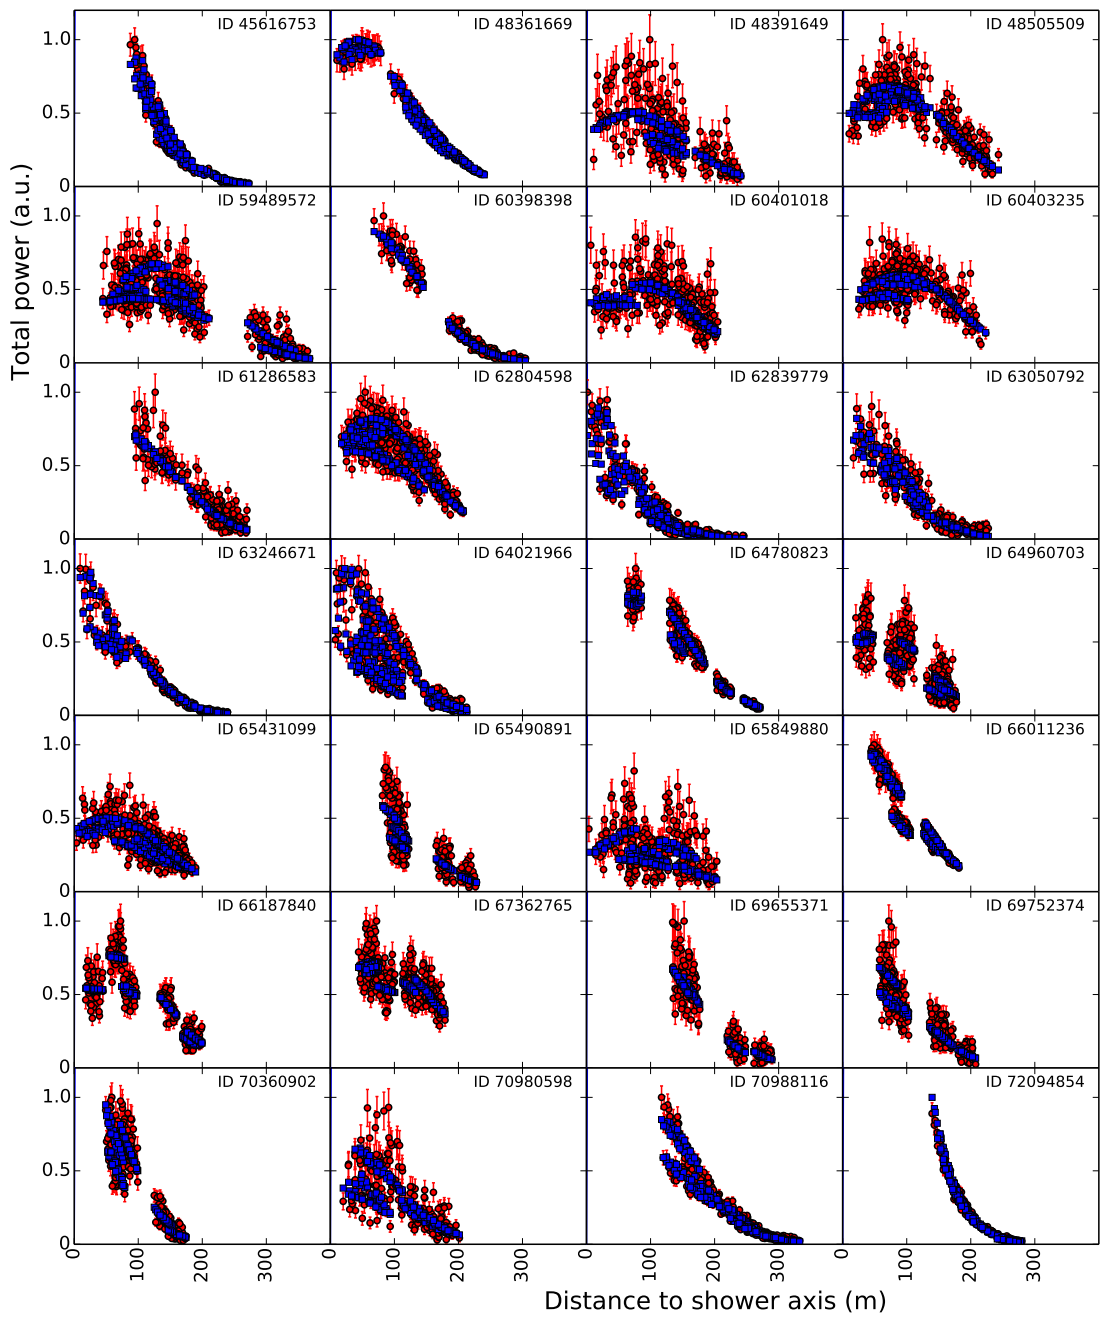

Figure 4 | p-value distribution for four-component model. The four-component model is explored further by keeping the proton and helium fractions fixed at all possible combinations, and solving for the nitrogen/iron ratio. The p-value (see Fig. 3) is plotted as a function of the proton and helium fraction. The optimal fit is found at 0% proton and 79% helium ($p=0.17$), but the deviation only deteriorates slowly when replacing helium with proton. The thick black contour line contains all combinations for which $p > 0.01$. At this significance level the total fraction of light elements (p+He) lies between 0.38 and 0.98.

Methods

Event selection Cosmic ray detection at LOFAR continuously runs in the background during astronomical observations. When 16 out of the 20 scintillator stations of the LORA particle array detect a signal, a trigger is issued and the ring buffers of all active antennas within a ~ 1 km radius are stored for offline analysis¹⁴. Which antennas are active depends on the settings of the astronomical observation. For this analysis we have selected showers that were measured with at least 4 antenna stations (corresponding to at least 192 antennas) in the low band (30 - 80 MHz after filtering)

The trigger and selection criteria introduce a composition bias. This bias is removed with a cut based on dedicated sets of simulations that are produced for each observed shower. These sets contain 50 proton and 25 iron showers, that span the whole range of possible shower depths. A shower is only accepted when *all* simulations in its set pass the triggering and selection criteria. This anti-bias cut removes many showers below 10^{17} eV, but only 4 above that energy. In this analysis, we restrict ourselves to the higher-energy showers and impose a cut on energy $E_{\text{reco}} > 10^{17}$ eV.

The energy cut itself is another potential source of compositional bias, as the reconstructed energy might be dependent on the depth of the shower. However, in our reconstruction approach this effect is very small because energy and X_{max} are fitted simultaneously. Extended Data Figure 7 shows distributions of the ratio between true and reconstructed energy for proton and iron simulations. The systematic offset between the two particle types is of the order of $\sim 1\%$.

We used data from the Royal Netherlands Meteorological Institute to check for lightning storm conditions during our observations. When lightning strikes have been detected in the North of the Netherlands within an hour from a detection, the event is flagged and excluded from the analysis. The presence of electric fields in the clouds can severely alter the radio emission even in the absence of lightning discharges³⁰. The polarisation angle of the radio pulse is very sensitive to the nature of the emission mechanism^{15,31} and is used as an additional veto against strong field conditions.

Finally, a quality cut is imposed on the sample in order to only include showers that have a core position and arrival direction that allows accurate reconstruction. We use the dedicated sets of simulations produced for each shower to derive uncertainties on core position, energy and X_{\max} . These three values are highly correlated, so a single cut on the core uncertainty of $\sigma_{\text{core}} < 5$ m is sufficient.

The quality cut is based on the dedicated sets of simulations. These sets are produced for a specific combination of core position and arrival direction. Therefore, the quality cut is effectively a cut on position and direction, and does not introduce a composition bias.

Furthermore, we stress that there is no cut on the quality of the reconstruction of the actual data. By applying the cuts described above we obtain a sample of 118 showers that are fitted to the simulation yielding reduced χ^2 -values in the range 0.9-2.9. Deviations from unity can be ascribed to uncertainties in antenna response, atmospheric properties like the index of refraction, or limitations of the simulation software.

Reconstruction The energy and X_{\max} of the shower are reconstructed with the technique described in Buitink et al. (2014)¹⁸.

Statistical uncertainty The statistical uncertainty on the power measurements of individual antennas include three contributions. First, there is contribution from the background noise which is a combination of system noise and the Galactic background. Secondly, there is a contribution from uncertainties in the antenna response model. There can be differences between the responses of antennas, either because of antenna properties (e.g. cross-talk between nearby antennas), or because of signal properties (e.g. polarisation). Since these fluctuations are different for each shower core position and arrival direction, they are essentially random and included as a 10% statistical uncertainty on the power. A third contribution is due to the error introduced by interpolating the simulated pulse power. Strictly speaking this is not a measurement uncertainty, but it must be taken into account when fitting the data to simulation. The interpolation error is of the order of 2.5% of the maximum power¹⁸. The three contributions are added in quadrature and produce the one sigma error bars shown in Extended Data Figures 1-5.

The statistical uncertainty on X_{\max} is given by the quadratic sum of the uncertainties due to reconstruction technique and the atmospheric correction. The former is found by applying our analysis to simulated events with added Gaussian noise, where the noise level is determined from the data.

In the CORSIKA simulations the standard US atmosphere model was used. The reconstructed shower depth is corrected for variations in the atmosphere using data from the Global

Data Assimilation System (GDAS) of the NOAA National Climatic Data Center. We follow a procedure developed by the Pierre Auger collaboration³². This typically leads to adjustments of the order of 5–20 g/cm². Remaining uncertainty after correction is of the order of 1 g/cm²

The index of refraction of air is a function of temperature, air pressure, and relative humidity. Using local weather information the final data sample was split in two equal size groups corresponding to conditions with relatively high or low index of refraction. The mean reconstructed X_{\max} of these groups deviate from the mean by ± 5 g/cm², and we adopt this value as an additional statistical uncertainty. Because the refractivity used in simulation corresponds to dry air there is also an associated systematic error (see below).

The total statistical uncertainty on X_{\max} is found by adding above factors in quadrature. A distribution of the uncertainty for the showers in our final sample is shown in Extended Data Figure 6.

The energy resolution is 32% and is found by comparing energy scaling factors of the radio power and particle density fit (see Figure 1).

Systematic effects The data has been subjected to several tests to find the systematic uncertainty on the reconstructed values for X_{\max} :

- **Zenith angle dependence** The final data sample is split into two groups of equal size by selecting showers with a zenith angle below or above 32 degrees. For both groups the mean

reconstructed X_{\max} is calculated, yielding deviations from the mean value of $\pm 8 \text{ g/cm}^2$. This spread is larger than expected from random fluctuations alone and is included as a systematic uncertainty. The dependence on zenith angle may be related with atmospheric uncertainties (see below).

- **Index of refraction of air** As explained above, the index of refraction changes because of differences in atmospheric conditions. Fluctuations on X_{\max} due to changing humidity are of the order of 5 g/cm^2 with respect to the mean. However, the index of refraction that was used in the radio simulations corresponds to dry air, and is a lower bound to the actual value. Therefore, the real value of X_{\max} can be higher than the reconstructed value but not lower, and we adopt an asymmetrical systematic uncertainty of $+10 \text{ g/cm}^2$.
- **Hadronic interaction model** Since the reconstruction technique is based on full Monte Carlo simulations, it is sensitive to the choice of hadronic interaction model that is used. It has been shown with a comparison between QGSJETII.04, SYBILL 2.1, and EPOS-LHC, that the uncertainty due to model dependence is $\sim 5 \text{ g/cm}^2$. Note that the uncertainty on the *composition* due to different models (in other words: on how to interpret the measured X_{\max} values) is of course larger.
- **Radiation code** For this analysis we have used the radiation code CoREAS in which the contributions of all individual charges to radiation field are added together. The advantage of this microscopic approach is that it is completely model-independent and based on first principles. ZHAireS³⁴ is another microscopic code and gives very similar results³⁵. To calculate the emission CoREAS uses the end-point formalism³⁶, while ZHAireS is based on the

ZHS algorithm³⁷. Both formalisms are derived directly from Maxwell's equations and have been shown to be equivalent³⁸. The other difference between CoREAS and ZHAires is that they take the particle distribution from different air shower propagation codes (CORSIKA and AIRES respectively) that internally use different hadronic interaction models. Since the radiation formalisms themselves are equivalent, small differences between CoREAS and ZHAireS are most likely due to differences in the hadronic interaction models used to simulate the particle interactions. The choice of radiation code does therefore not introduce an additional systematic uncertainty on top of the uncertainty to hadronic interaction models that is already included. A comparison study with LOFAR data did also not show any evidence for a systematic offset between the codes and will be published in an upcoming paper.

The remaining small dependence of X_{\max} on zenith angle is possibly related to the index of refraction. Showers with different inclination angles have their shower maximum at different altitudes, and therefore different local air pressure and index of refraction. Therefore, increasing the index of refraction used in simulations will result in a zenith-dependent change in reconstructed X_{\max} . This possibly removes the observed dependence of the composition on zenith angle. Correctly taking into account a complete atmospheric model for the profile of the refractivity of air is subject of further study. Here, we treat the effect conservatively by adding the first two contributions to the uncertainty linearly. The other two contribution are independent and are added in quadrature, yielding a total systematic uncertainty of $+14/ - 10 \text{ g/cm}^2$.

The systematic uncertainty on the energy reconstruction with the LORA particle detector array is 27%, which includes effects due to detector calibration, hadronic interaction models, and the assumed slope of the primary cosmic-ray spectrum in the CORSIKA simulations^{33,39}

Statistical analysis For each observed shower, we calculate:

$$a = \frac{\langle X_{\text{proton}} \rangle - X_{\text{shower}}}{\langle X_{\text{proton}} \rangle - \langle X_{\text{iron}} \rangle} \quad (2)$$

where X_{shower} is the reconstructed X_{max} , and $\langle X_{\text{proton}} \rangle$ and $\langle X_{\text{iron}} \rangle$ are mean values predicted by QGSJETII.04¹⁹. Thus a is an energy-independent parameter that is mass sensitive. A pure proton composition would give a wide distribution of a centered around zero, while a pure iron composition gives a narrower distribution around unity.

From the measurements we construct a cumulative distribution function (CDF) in the following Monte Carlo approach. A realisation of the data is made by taking the measured values for the energy and X_{max} , adding random fluctuations based on the statistical uncertainty of these parameters, and calculating the a parameters and the corresponding CDF. By constructing a large number of realisations with different random fluctuation, we can calculate the mean CDF and the region that contains 99% of all realisations. These are indicated in Figure 3 as the solid blue line and the shaded region respectively.

We fit theoretical CDFs based on composition with two or four mass components to the data. The test statistic in the fit is the maximum deviation between the data and the model CDFs. The p-value is given by the probability of observing this deviation, or a larger one, assuming the fitted

composition model.

We first use a two-component model of proton and iron nuclei, where the mixing ratio is the only free parameter. The best fit is found for a proton fraction of 62%, but it describes the data poorly with a p-value of 1.1×10^{-6} .

A better fit is achieved with a four-component model (p+He+N+Fe), yielding a p-value of 0.17. While the best fit is found for a Helium fraction of 80%, the fit quality deteriorates only slowly when replacing helium by protons. This is demonstrated in Figure 4 where the p-value is plotted for four-component fits where the fractions of helium and proton are fixed, and the ratio between N and Fe is left as the only free parameter. The solid line in this Figure contains the parameter space where $p > 0.01$. We construct a 99% confidence level interval on the total fraction of light elements (p+He) by finding the two extreme values of this fraction that still lie within the $p > 0.01$ region.

The total fraction of light elements (p+He) is in the range [0.38,0.98] at 99% confidence level, with a best fit value of 0.8. The heaviest composition that is allowed within systematic uncertainties (see above) still has a best fit p+He fraction of 0.6, and a 99% confidence level interval of [0.18, 0.82].

Abstract

We present an updated cosmic-ray mass composition analysis in the energy range $10^{16.8}$ to $10^{18.3}$ eV from 334 air showers measured with the LOFAR radio telescope, and selected for minimal bias. In this energy range, the origin of cosmic rays is expected to shift from galactic to extragalactic sources. The analysis is based on an improved method to infer the depth of maximum X_{\max} of extensive air showers from radio measurements and air shower simulations.

We show results of the average and standard deviation of X_{\max} versus primary energy, and analyze the X_{\max} -dataset at distribution level to estimate the cosmic ray mass composition. Our approach uses an unbinned maximum likelihood analysis, making use of existing parametrizations of X_{\max} -distributions per element. The analysis has been repeated for three main models of hadronic interactions.

Results are consistent with a significant light-mass fraction, at best fit 23 to 39% protons plus helium, depending on the choice of hadronic interaction model. The fraction of intermediate-mass nuclei dominates. This confirms earlier results from LOFAR, with systematic uncertainties on X_{\max} now lowered to 7 to 9 g/cm².

We find agreement in mass composition compared to results from Pierre Auger Observatory, within statistical and systematic uncertainties. However, in line with earlier LOFAR results, we find a slightly lower average X_{\max} . The values are in tension with those found at Pierre Auger Observatory, but agree with results from other cosmic ray observatories based in the Northern hemisphere.

Keywords: Cosmic rays, radio detection, composition

1. Introduction

Cosmic rays arrive at the Earth's atmosphere in an energy range from below 10^9 to above 10^{20} eV. Upon interacting in the atmosphere, they produce a cascade of secondary particles called *extensive air shower*,

*Corresponding author

Email address: A.Corstanje@astro.ru.nl (A. Corstanje)

which is measurable in ground-based detector arrays for energies above about 10^{14} eV. At the high end of the energy spectrum, these particles have the highest energy of the known particles in the Universe. Therefore, the questions about their origin and their mass composition have raised considerable interest, and cosmic-ray air showers are measured in observatories around the world. The largest is the Pierre Auger Observatory in Argentina [1, 2], spanning an area of 3000 km^2 .

In this analysis, we study cosmic rays with a primary energy between $10^{16.8}$ and $10^{18.3}$ eV, the energy range where a transition is expected from particles originating from within the Galaxy, to an extragalactic origin. Heavy nuclei from the Galaxy are expected to reach higher energies than protons, as they are more easily magnetically contained due to their higher charge (i.e., the Hillas criterion [3]). Therefore, composition measurements in this energy region are interesting for comparison with models of cosmic-ray sources and propagation. For instance, in [4] it is argued that a secondary Galactic component may (still) dominate around 10^{17} eV. In one scenario where supernovas of Wolf-Rayet stars are the main sources, one expects a rather low proton fraction together with a higher helium and C/N/O fraction, before proton-dominated extragalactic cosmic rays take over around 10^{18} eV.

Along the track of an air shower, the number of secondary particles reaches a maximum, at a depth expressed in g/cm^2 of traversed matter, referred to as X_{max} . This maximum is reached for almost all showers in our energy range, typically at altitudes of 2 to 7 km. At a given primary energy, X_{max} depends on the mass of the primary particle. It is different for protons compared to heavy nuclei, both on average and in distribution. The shift in average X_{max} with respect to protons is approximately proportional to $\ln A$, for particles with atomic mass number A , where protons have the deepest shower maximum on average. Thus, measuring X_{max} for a collection of air showers gives information about their composition, and is the basis for the present analysis.

There are three main techniques for measuring X_{max} : (i) measuring fluorescence light along the trail of the air shower, (ii) measuring Cherenkov light, and (iii) measuring the radio signal using antennas on the ground [5, 6]. Measuring secondary particles on the ground, especially the electron/muon ratio, yields composition information without (explicitly) measuring X_{max} . The radio detection technique has shown substantial development in recent years, leading to a method to determine X_{max} with a resolution about 20 g/cm^2 [7]. The method has been demonstrated using the LOFAR radio telescope, showing that the cosmic rays around 10^{17} eV have a considerable light-mass component [8]. Here, we present a method which has been improved on several points, thus lowering the systematic uncertainties, and an extended dataset.

The method relies on air shower simulations tracking individual particles, and summing up their contributions to the radio signal measured on the ground. For this, the CORSIKA [9] simulation program has been used, with its plugin CoREAS [10] for computing the radio signal. For an ensemble of simulated air showers, their lateral intensity distribution or ‘radio footprint’ is fitted to the measurements, from which X_{max} and the energy of the measured shower are reconstructed.

The X_{max} -distributions for the different elements have substantial overlap. Achieving low systematic uncertainties on X_{max} is therefore a crucial point for composition measurements, besides a good X_{max} -resolution per shower. This is done by a fiducial sample selection based on the CoREAS simulations per shower, and lowering known contributions to systematic uncertainties where possible. For example, in [11] it was shown that accurately representing local atmospheric conditions (refractive index) at the time of the air shower, removes a systematic error of 4 to 11 g/cm^2 .

Other improvements to the analysis include a radio-only reconstruction of both X_{max} and energy, the latter using a new calibration based on Galactic emission [12] which halves the systematic energy uncertainty compared to the earlier particle-based treatment. Using a fast pre-computation of shower simulations with CONEX [13] streamlines the reconstruction, as showers can be pre-selected for their X_{max} . The selection criteria to obtain a bias-free X_{max} sample have been improved, and a refined statistical analysis has been done. All these increase the accuracy of the composition analysis, by lowering systematic and/or statistical uncertainties.

The Low Frequency Array (LOFAR) [14] is a radio telescope consisting of many separate antennas. The core region in the north of the Netherlands has a high density of antennas. The antennas are grouped in stations, each of which in the Netherlands contains 96 low-band antennas (LBA), working in the 10 to 90 MHz range, and 48 high-band antennas (HBA) operating at 110 – 240 MHz. The center of LOFAR is a circular

area of 320 m diameter, with six of those stations. In a core region of about 6 km², there are 18 more stations. LOFAR uses ring buffers to store up to 5 seconds of the raw measured signals at each antenna, which are used to measure the radio signals of air showers. For air shower measurements, we use signals from the low-band antennas, filtered to 30 to 80 MHz.

To trigger a buffer readout when an air shower arrives, a particle detector array called LORA (LOFAR Radboud Air shower Array) [15] is located inside the innermost ring of LOFAR. With 20 scintillator detectors monitored in real time, a trigger is sent to LOFAR when a threshold of 13 coincident detections is reached, a level which is optimal for our purposes.

The paper is organized as follows: in Sect. 2, we present the method of fitting air shower simulations to measured data to infer X_{\max} . Furthermore, we discuss the selection criteria used to obtain a bias-free sample of showers. In Sect. 3, the statistical analysis to infer particle composition from the X_{\max} values is explained. The results are split into two sections, Sect. 4 for the X_{\max} distribution from our dataset, and Sect. 5 for the composition results. A summary is given in Sect. 6.

2. Method

The discussion of the methods is split into five sections. After an introduction to the use of CORSIKA and CoREAS simulations, we give a brief review of the procedure to infer X_{\max} for individual measured air showers. A more detailed explanation is found in [7]; the details that have changed in this version are given below. The method to estimate the primary energy, and its uncertainties, are discussed in Sect. 2.3. We show how including the local atmospheric conditions into the simulations leads to improved accuracy. Finally, we explain our method to select showers in order to create an unbiased sample.

2.1. CORSIKA/CoREAS simulations

For the reconstruction of LOFAR-measured air showers, we use CORSIKA (version 7.7100) to simulate air showers, with its plugin CoREAS which calculates the radio emission from the particle showers. The simulation uses a ‘microscopic’ approach: it simulates individual particles and their contribution to radio emission, as they are produced along the evolution of the shower. Air showers are simulated from a Monte Carlo approach to particle interactions, and applying classical electrodynamics (Maxwell’s equations) to obtain the radio signal at the antennas. For the particle part, three main models of hadronic interactions have been considered: QGSJetII-04 [16], EPOS-LHC [17], and Sibyll-2.3d [18] [19]. Their differences represent the intrinsic (systematic) uncertainty on hadronic interactions at the high energy levels of cosmic rays in our energy range and beyond.

The radio signals are calculated from first principles, i.e., without free parameters other than those from discretization approaches, which are set to values fine enough to reach convergence in results. This is important for accuracy in reconstructing X_{\max} . Calculations are based on the ‘endpoint formalism’ presented in [20]. In particular, there is no distinction between separate emission mechanisms such as geomagnetic and charge-excess contributions (see e.g. [21]), as these are naturally included. The radio signals at ground level are a (coherent) superposition of contributions from particles along the shower track, propagated geometrically to the antennas. Therefore, one reconstructs essentially the (geometric) distance to X_{\max} from the radio signals.

When fitting simulated air showers to LOFAR measurements, close agreement is found, for pulse energy [8] as well as for detailed measurements such as circular polarization [22]. Comparisons of results from Corsika/CoREAS with another simulation program based on the same principles, ZHAireS [23], show close agreement [6, 24, 25], and remaining differences are ascribed to details in the simulation of particle interactions. The given detailed and, where possible, parameter-free approach, together with agreement between different extensively developed simulation codes, gives a solid basis for accurate air shower reconstructions.

2.2. Using CoREAS simulations to estimate X_{\max} of measured air showers

Starting point is a set of air showers measured with LOFAR. When an event is triggered by the particle detector array LORA, its radio dataset is passed through our analysis pipeline [26]. Its primary output

parameter for this analysis is pulse ‘energy’, defined as the square of the measured voltage in an antenna, integrated over a time window of 55 ns (11 samples) around the pulse maximum. When reconstruction quality criteria are passed, a dataset consists of pulse energy, including its uncertainty, per antenna in at least 3 LOFAR stations, an accurate measurement of the incoming direction, and an initial estimate of X_{\max} and primary energy from fitting a (parametrized) lateral distribution function [27]. The initial estimates are used as a starting point for the simulations. Simulations are iterated if the initial parameters are found to be inaccurate. Therefore, the final estimates do not depend on them.

For each shower measured with LOFAR, we produce an ensemble of CoREAS showers, spanning the natural range of X_{\max} for protons and for iron nuclei. We use the QGSJetII-04 hadronic interaction model [16] to produce the particle showers with CORSIKA. As simulation energy we use an estimate from fitting an analytic description of the radio footprint [27], or an estimate from the particle detectors when the fit failed to converge.

As a pre-computation stage we produce 600 showers with the fast simulation method CONEX, version 4.3700 [13], of which 150 have an iron primary while the others start from a proton. This is suitable to select those random number seeds to span the natural range of X_{\max} roughly uniformly with about 15 showers. The same random number seeds are used in the full CORSIKA (version 7.7100) simulations. The number of CONEX showers is high enough to sample into the tails of the X_{\max} -distributions at a level corresponding to the size of our final dataset ($N = 334$). The aim is twofold, to have simulated showers covering the entire range of X_{\max} , which is important for the selection criteria for a bias-free sample (see Sect. 2.5), and to have a region around the best-fitting X_{\max} with extra dense coverage, to improve precision.

Therefore, ten additional showers are simulated in a region of ± 20 g/cm² around the first X_{\max} estimate, aiming to have a high density of simulations close to the reconstructed X_{\max} . The total number of simulated showers is around 30 per measured shower. If the reconstructed X_{\max} deviates from the initial fit, extra showers are simulated to match the dense region with the reconstructed X_{\max} . An example is shown in the middle panel of Fig. 1; existing showers with $X_{\max} > 700$ fall outside the plotted vertical range.

The radio signal of each simulated shower is passed through our antenna model for the LOFAR LBA antennas [26], and through the bandpass filter used in the data analysis, to be able to compare with LOFAR data. The signal energy for each simulated shower is then matched per antenna to the LOFAR measurements. In this fit, the core position and an overall scaling factor are free parameters. This gives a chi-squared value for each shower:

$$\chi_{\text{radio}}^2 = \sum_{\text{antennas}} \left(\frac{P_{\text{ant}} - f_r^2 P_{\text{sim}}(x_{\text{ant}} - x_0, y_{\text{ant}} - y_0)}{\sigma_{\text{ant}}} \right)^2, \quad (1)$$

where P_{ant} and σ_{ant} denote the measured signal energy and its uncertainty, and P_{sim} is the simulated pulse energy. The overall scaling factor is f_r^2 , and (x_0, y_0) is the fitted shower core position. In contrast to the method in [7], we perform the fit based on the radio signals only, making the radio reconstruction self-sufficient. In the previous analysis, the fit included both radio and particle detector data. As a consequence, showers for which the reconstruction cannot be done accurately without the particle detector signals are now (automatically) discarded.

The result of the fitting procedure for one of our measured showers is shown in Fig. 1. In the left panel, the best-fitting simulated shower is shown (background color) together with the measurements (colored circles). The colored circles blend in well with the background color, indicating a good fit. This is confirmed by the middle plot, showing a reduced χ^2 of 1.3 for the best fit, and a clear minimum as a function of X_{\max} . The right panel shows a one-dimensional representation of the simulated and measured intensities per antenna.

We employ a Monte Carlo procedure, using the simulated ensemble of showers to infer the uncertainties on X_{\max} , the energy and the shower core position. For each simulated shower in our ensemble we create three mock datasets as they would have been measured, i.e., adding the noise level found in each LOFAR antenna. They represent three different realisations of the random noise, at a fixed shower core position. This simulated shower is then reconstructed through the above procedure, using the ensemble of all other simulations. Statistically comparing the reconstructions with the real X_{\max} , core position, and radio scale factor, which are known in simulations, yields their uncertainties. The uncertainties thus found are calculated

Figure 1: An example of fitted CoREAS showers to a LOFAR-measured shower. The left panel shows simulated signal energy along with the measurements, in the shower plane, for the best-fitting shower. The lateral intensity (and pulse energy) distribution is not rotationally symmetric. The middle panel shows the reduced χ^2 as a function of X_{\max} , with a parabolic fit through the lower envelope denoted by the magenta line. The right panel shows a 1-D lateral distribution function, where red points with uncertainties denote the measurements, and blue points denote the simulated intensities.

from the entire simulated ensemble, and are applicable to the measured shower as well as to each simulated shower; this is important in the bias-free sample selection procedure explained in Sect. 2.5. This procedure, relying on the reconstruction method described above, now also uses only the radio signals.

2.3. Estimate of the primary particle energy

We estimate the energy of the primary particle by comparing the pulse energy of the measured radio signal with the predicted radio signal from CoREAS, which was produced at a given simulation energy obtained from the initial fit. The intensity, and measured pulse energy, of the radio signal scale quadratically with the primary energy [28, 29, 30]. Fitting CoREAS radio signal energy to LOFAR data produces an overall scale factor. The square root of this is taken as a correction to the simulation energy, giving an estimate of the primary particle energy. Moreover, following [24] we apply a correction factor of 11% to the simulated pulse intensities. This accounts for a finite step size (electron multiple scattering length) in tracking the particle cascade in the simulation.

This procedure of matching simulated and measured pulse energy relies on an accurate absolute calibration of the radio antennas at LOFAR. The calibration has been improved with respect to the previous analysis [12]. It uses the emission from the Galaxy, which enters the measured time traces of the antenna signals as ‘noise’. The galactic emission model LFMap [31] is used to obtain the contribution of each point on the sky at a given (sidereal) time. This is integrated over the visible sky, using the antenna response as known from [26]. Apart from this, the contributions of electronic noise in multiple stages of the signal chain have been fitted, by comparing the measured variations with sidereal time to the curve from LFMap.

Uncertainties in the calibration, and in the directional dependence in the antenna model, translate into systematic uncertainties on the energy estimates. The X_{\max} -estimate is, at least to lowest order, not affected, as all signals arrive from the same direction (to within a degree) for a given air shower. Systematic uncertainties on the calibration amount to 13% in total, where the main contributor (by 11%) is the uncertainty on the sky temperature in our frequency range. The other, minor contributions are uncertainties in the electronic noise levels and from the antenna model.

In [25], a cross-check is described between the energy scales determined from radio and from the particle detectors, respectively. For the particle-based reconstruction, one compares the particle footprint from the best-fitting Corsika shower to the signals at the LORA detectors. The conversion from particles reaching

the ground to LORA signals is simulated using the GEANT4 simulation package [32], a procedure described further in Sect. 2.5.1. Agreement within 10 % was found between the resulting energy scales from radio and from particles.

Additional contributions to the systematic uncertainty on primary energy have been tested and were found to be small. These arise from the choice of simulation code, and from the choice of hadronic interaction model within the simulation code. Switching from CoREAS to ZHAireS [23] yields a difference below 3 %. Thus, importantly, two independent simulation codes aimed at detailed simulations produce very close radio energy levels. A cross-analysis of the QGSJetII-04 interaction model versus Sibyll-2.3c gives another contribution of 3 %.

The resulting systematic uncertainty is 14 %, from adding the contributions in quadrature. This is a considerable improvement from the 27 % in the previous analysis based on the particle detectors.

The statistical uncertainty on the energy estimate follows from our Monte Carlo uncertainty analysis per shower (see Sect. 2.2). The average values for the uncertainties on energy and log-energy, i.e., σ_E and $\sigma_{\log E}$, corresponds to 9 %. Again, this is a notable improvement over the 32 % uncertainty in [8], arising from the large number of radio antennas compared to the 20 particle detectors used earlier.

2.4. Including local atmospheric parameters

To improve the accuracy of the simulations and the X_{\max} reconstructions, we have co-developed an updated version of CORSIKA and CoREAS, which allows to include local atmospheric altitude profiles of density and refractive index into the simulation runs (v7.7100 includes the update).

The atmospheric parameters at the time of each air shower are taken from the Global Data Assimilation System (GDAS) [33], which gives pressure, temperature, and humidity in 24 layers in the atmosphere. These are data used, e.g., in weather models.

The important quantities for us are the altitude profiles of density and refractive index. The density profile determines the amount of matter traversed by the particles along the shower evolution, and therefore the shower geometry depends on this. Due to natural variations in air pressure and temperature, the geometric distance to X_{\max} may be under- or overestimated, leading to a systematic error per shower on the order of 15 to 20 g/cm². In the earlier analysis of [7], the GDAS density profile was used to correct to first order the X_{\max} estimate from simulations using the US Standard Atmosphere.

The refractive index n and its variations are important for the radio emission processes. The refractive index is a function of both the density and the humidity. Natural variations in n make the Cherenkov angle wider or narrower, thus affecting the intensity footprint on the ground [11]. Typical variations of $(n - 1)$ are on the order of 4 %, and introduce a systematic error on the inferred X_{\max} . From simulations, this error was found to be about 4 to 11 g/cm², depending on the zenith angle.

Residual uncertainties in $(n - 1)$ as taken from GDAS temperature, pressure, and humidity are about 0.5 %. From this, uncertainties on X_{\max} are on the order of 1 to 2 g/cm², and will vary between positive and negative from one shower to another, adding to the statistical uncertainty per shower. We have thus removed a systematic uncertainty that is important for precision measurements.

In CORSIKA, five layers are used to parametrize the atmospheric density profile as a function of altitude. In each layer (except for the top layer), the density is set to fall off exponentially with altitude, with a scale height as a free parameter. We have used least-squares curve fitting to determine the optimal parameters to match the five-layer model atmosphere to the GDAS representation [34]. The error on X_{\max} induced by the five-layer approximation was found to be about 4 g/cm², and adds to the statistical uncertainty per shower. It introduces a systematic uncertainty of 1 to 2 g/cm², depending on altitude, hence taken as 2 g/cm².

2.5. Bias-free sample selection

In this section we show how to apply fiducial cuts, i.e., to reject showers that would introduce a composition bias to the sample. Cuts are made only based on the simulated ensemble of showers, not on the measured data (for instance, through fit quality). For the composition measurement, we aim to obtain a sample which is unbiased in X_{\max} . We do not expect, however, to obtain a sample reflecting the natural cosmic-ray energy spectrum, as the effective exposure area, both on the ground and on the sky, depends strongly on energy.

A bias may arise from the particle detector trigger, which is reached more easily for showers penetrating deeper into the atmosphere (high X_{\max}). Another, opposite source of bias arises from the radio detection threshold. We require at least 3 LOFAR stations to detect significant pulses for a given shower. Showers with low X_{\max} have a larger radio footprint, and hence are more likely to trigger three LOFAR stations.

We analyze each measured shower given its energy, reconstructed shower core position, and incoming direction. The central requirement is that this shower would have produced a trigger in both the particle detectors and in the radio data, if it had any other value of X_{\max} in the natural range. Moreover, it must meet the core reconstruction quality criterion explained below. As noted in Sect. 2.2, our simulated ensemble for each measured shower is based on a pre-selection from 600 random showers simulated with CONEX. This sufficiently represents the natural range of X_{\max} , as our (final) dataset is smaller than this.

A dataset comprising all measured showers that meet this requirement is then unbiased in X_{\max} , so this requirement is a sufficient condition. Due to the irregular array layout and moderate event count, a per-shower inclusion criterion is more efficient than attempting to construct a fiducial volume in parameter space (which would also be rather irregular).

2.5.1. Removing selection bias arising from the particle trigger

For each measured shower, we use the set of all simulated showers, including their particle content, to see if each simulated shower would have triggered LORA.

For this, we use the GEANT4 simulation tool [32], which simulates the particles traversing the detectors and their deposited energy. The simulation of the LORA detectors was also used in the measurement of the cosmic-ray energy spectrum presented in [35]. Only if all showers in the ensemble are able to trigger, the measured shower is included in the sample.

From CORSIKA we obtain a list of particles reaching the ground, with their respective positions and momenta. In the GEANT4 simulation, this is converted to an energy deposit at the detector locations. We divide the energy deposit by an average value of 6.2 MeV per particle. The value of 6.2 MeV arises from the most probable energy deposit of single, high-energy muons from an all-sky distribution [35]. Although the muons vary in energy, their deposit is nearly constant with energy.

At the time of each measured shower, we note the trigger threshold of each detector, which was derived during operation from the baseline and standard deviation of its signal time trace. This can be expressed in equivalent muons. When particles hit a detector and produce enough energy deposit, it will trigger. This is subject to Poisson statistics. We evaluate the probability of having $\geq n$ particles giving an energy deposit of 6.2 MeV each, where n is the first integer above the ratio trigger threshold / 1 equivalent muon.

In our trigger setup, a number k out of 20 LORA detectors must trigger in coincidence for the radio data of the air shower to be recorded. The threshold k has been variable over the years of measurements, where $k = 13$ was the most common value. Changes have been made mainly when one or more detectors were down. For each measurement, we use the trigger setting at that time. Hence, also from all simulated showers we require that with a probability of 99%, at least k detectors would trigger (due to statistical fluctuations, the probability cannot reach exactly 100%).

This test has a tendency to remove showers from the sample which have large reconstructed X_{\max} values, i.e., at relatively low altitude in the atmosphere, and/or high inclination. In this case, the given measured shower has produced a trigger, but had its X_{\max} been lower, the number of particles would have been too small. Similarly, showers with low energy and/or a core position far from the LORA detectors are more likely to be rejected.

2.5.2. Removing bias arising from the radio detection threshold

We perform a test against bias from the finite radio detection threshold. The criterion is, similar to the particle detection bias test, that the radio signal for each simulated shower in the ensemble would have been detected above the noise in at least three LOFAR stations.

To this end, we take the core position of the shower that fits best to the LOFAR-measured shower, and position also all other simulated showers here with respect to LOFAR. From the best-fitting shower, we have a fitted scale factor relating simulated to measured pulse energy. Using this scale factor, we obtain the pulse intensities for each simulated shower and for each antenna. The noise intensities from the LOFAR-measured

Figure 2: The uncertainty on X_{\max} versus the uncertainty on the core position, per measured shower, after cuts on energy and fiducial selection criteria. The dotted line indicates the chosen cutoff.

showers are taken as reference, and a threshold criterion is set as an energy signal-to-noise ratio of 6 in each antenna. In the data processing pipeline, we have a (somewhat arbitrary) threshold requiring half of the antennas per station to trigger to have a ‘good’ detection. Although that detection is amplitude-based, an energy signal-to-noise ratio of 6 was found to be slightly conservative, and otherwise in good agreement with the amplitude threshold detection.

This test typically rejects showers with a small reconstructed X_{\max} value, i.e., relatively high in the atmosphere, and/or zenith angle; a shower with the same parameters would then have a much smaller radio footprint at high X_{\max} , which may not be able to trigger three LOFAR stations.

2.6. Reconstruction quality cuts

The procedure described in Sect. 2.2 to infer the uncertainty on X_{\max} is also useful as a test of the reconstruction quality of the radio signal. Apart from the X_{\max} uncertainty, it also gives an uncertainty on the fitted shower core position and on the energy. These uncertainties are calculated from the entire simulated ensemble, and hence they are the same for each simulated shower being tested by the two above procedures.

From the three uncertainties, the precision of the core position reconstruction is arguably the most relevant indicator of overall shower reconstruction quality. When this precision is low, one cannot expect either X_{\max} or energy to be reconstructed accurately. Shown in Fig. 2 is the uncertainty on X_{\max} versus the core position uncertainty. They are clearly correlated, and a cut on the reconstruction uncertainty at 7.5 meters was found to be sufficient to reject the majority of poorly reconstructed showers, while retaining showers with low X_{\max} uncertainty.

The appearance of poorly reconstructed showers, despite meeting the other criteria, comes mainly from the position of some showers with respect to the LOFAR array geometry. Most notably, when the core

position is outside the array and/or only three stations have been triggered at low signal-to-noise ratio, the reconstruction precision becomes well below average. This criterion catches these cases automatically.

2.7. Systematic uncertainties

Our method to determine X_{\max} is affected by the following systematic uncertainties, which are summarized in Table 1. The choice of the hadronic interaction model used in CORSIKA, in this case QGSJetII-04, introduces a systematic uncertainty of 5 g/cm^2 [8] in the X_{\max} measurements, due to minor differences in radio footprints when changing the model, for example, to EPOS-LHC [17]. The choice of hadronic interaction model also causes another, larger uncertainty in the composition analysis, as the average X_{\max} for a given element varies by up to about 15 g/cm^2 between models. This is treated separately by repeating the composition analysis with different models.

Residual systematic uncertainties due to variations in the atmosphere, local weather etc. are about 2 g/cm^2 from the five-layer approximation of CORSIKA. This approximation also produces an additional statistical uncertainty of 4 g/cm^2 which is added in quadrature to the statistical uncertainty on X_{\max} per shower. A systematic uncertainty, or bias, in averages of X_{\max} may arise from possible residual bias after applying the above selection criteria. We test this in Sect. 4.2, obtaining a value of 3.3 g/cm^2 to be added as a systematic uncertainty on X_{\max} . Hence, a total systematic uncertainty on X_{\max} of 7 g/cm^2 follows. This is comparable to the systematic uncertainty on X_{\max} in the measurements of [36] who find a value between 7 and 10 g/cm^2 for primary energies above $10^{17.8} \text{ eV}$.

Table 1: Systematic uncertainties in the X_{\max} reconstruction

	Syst. uncertainty	Added stat. unc.
Choice of hadronic interaction model	5 g/cm^2	
Remaining atmospheric uncertainty	$\sim 1 \text{ g/cm}^2$	$\sim 2 \text{ g/cm}^2$
Five-layer atmosphere CORSIKA	2 g/cm^2	4 g/cm^2
Possible residual bias	3.3 g/cm^2	
Curve fit for χ^2 optimum	$\leq 1 \text{ g/cm}^2$	
Total, added in quadrature	7 g/cm^2	

When performing the parabolic fit to the χ^2 values per simulation, as in the middle panel of Fig. 1, a systematic error of up to 5 g/cm^2 may arise if the fit optimum is not contained in the dense region of simulations. This is removed by simulating extra showers around the optimum when needed. A Monte Carlo simulation shows no residual systematic error ($\leq 1 \text{ g/cm}^2$) if the dense region is positioned asymmetrically around the optimum but does contain it.

The systematic uncertainty in the energy estimate from the radio antennas was found to be 14%, or 0.057 in $\lg(E)$ [12]; by convention we write $\lg E \equiv \log_{10} E$.

3. Mass composition analysis

Having established the set of showers for the mass composition analysis, we perform statistical analysis on the measured data, being $(X_{\max}, \sigma_{X_{\max}}, \lg E, \sigma_{\lg E})$ for each shower. We make use of the probability density functions of X_{\max} as a function of energy and atomic mass number A , as parametrized by [37] and updated by [38]. The parametrizations follow a generalized Gumbel distribution, which is a function with 3 parameters, yielding a variable mean, spread, and tail-end asymmetry, respectively. The function has been fitted to a large sample of CONEX showers and has a precision within 2 g/cm^2 for both average and standard deviation of X_{\max} , as well as a close fit to the distribution itself; the high-end tail, which drops exponentially, was shown to be well represented. It should be noted that CONEX is a faster but less complete shower simulation method than CORSIKA. Average X_{\max} values were found to deviate by 4 to 5 g/cm^2 . This is therefore treated as an additional systematic uncertainty on X_{\max} , which for the composition analysis then amounts to 8 g/cm^2 .

Figure 3: The probability density functions for the depth of shower maximum X_{\max} , for the elements H, He, N, and Fe, at energy 10^{17} eV and hadronic interaction model QGSJetII-04.

Example curves are shown in Fig. 3 for $E = 10^{17}$ eV for protons, helium, nitrogen, and iron nuclei. The functions overlap substantially, limiting the extent to which the individual elements can be distinguished. This is the statistical challenge in performing a composition analysis on X_{\max} data. The mean X_{\max} shifts approximately proportionally to $\ln A$. Therefore, for a 4-component model of astrophysically relevant elements, a reasonable choice is to take p, He, C/N/O, and Fe. These are roughly equally spaced in $\ln A$; as C, N, and O cannot be readily distinguished, either of them can be chosen as a proxy for all three. We choose nitrogen, as this is in between carbon and oxygen, and the best choice in terms of equal spacing in $\ln A$.

3.1. Statistical analysis

We use an unbinned maximum likelihood method to determine the best-fitting parameters for the four-component composition model. This has the advantage of treating each shower separately, instead of relying on X_{\max} -histograms and/or binning in energy. This is especially suitable when the dataset is relatively small and a narrow binning in shower energies is inappropriate.

Given a measured shower with parameters $(X_{\max}, \sigma_{X_{\max}}, \lg E, \sigma_{\lg E})$, its likelihood function for a given element is described by the curves in Fig. 3, convolved with a Gaussian for the uncertainties $\sigma_{X_{\max}}$ and $\sigma_{\lg E}$. For a mixed composition, the likelihood function is a weighted average of these; the mix fractions maximizing the likelihood is taken as the best-fitting composition.

With this method, a complementary goodness-of-fit test is needed, for which we use a Kolmogorov-Smirnov test, enhanced with Monte Carlo simulation. This is a simple, well-known method, comparing the cumulative distribution function (cdf) of the best-fit model to the empirical cumulative distribution of the data. The Kolmogorov-Smirnov test statistic is defined as the maximum difference between the model's cdf $F(X)$ and the empirical distribution $E(X)$:

$$K = \sup_X |F(X) - E(X)|. \quad (2)$$

For our case, where the best-fitting distribution has been estimated from data, standard critical values of the test statistic K do not apply. Instead, to determine the p -value corresponding to K , we use parametric bootstrap sampling from $F(X)$, counting how often the K -value is larger than the one for the dataset. This tests the null hypothesis that the dataset is a random drawing from $F(X)$.

The best-fit model X_{\max} distribution $F(X)$ is taken as the cumulative integral of the linear combination of X_{\max} -distributions $f(X_{\max}, E)$ for the best-fitting composition:

$$f_{\text{sum}}(X_{\max}) = \frac{1}{N} \sum_{k=1}^N \sum_i \alpha_i f_i(X_{\max}, E_k) * \mathcal{N}_X(X_{\max}, \sigma_{X_{\max},k}^2) * \mathcal{N}_{\lg E}(\lg E_k, \sigma_{\lg E,k}^2), \quad (3)$$

summing over all showers (index k) and over the elements in the composition model (index i). Here, $*$ denotes convolution, in this case with Gaussians corresponding to uncertainties in X_{\max} and log-energy.

For the uncertainty analysis we use a likelihood ratio test. Denoting the likelihood of the best-fitting composition as $L(\{\hat{\alpha}\})$, we fix one of the element fractions, say the proton fraction, scanning over the range from 0 to 1. We then find the maximum likelihood composition given the fixed proton fraction, $L(\alpha_p, \{\hat{\alpha}_i\})$, again optimizing over the free parameters indexed by i . This gives the test statistic D :

$$D = 2 \ln \left(\frac{L(\{\hat{\alpha}\})}{L(\alpha_p, \{\hat{\alpha}_i\})} \right). \quad (4)$$

This is nonnegative by definition, and in the large- N limit it follows a chi-squared distribution with 1 degree of freedom, when fixing 1 parameter. The confidence intervals at significance level $1 - p$ then follow directly from the critical values of the chi-squared distribution. For confidence levels of 68, 95, and 99%, these are 1.00, 3.84, and 6.64, respectively.

Confidence intervals for two elements simultaneously, such as used in the contour plot Fig. 11 in Sect. 5 are computed analogously, fixing two parameters instead of one, and noting that the test statistic D then follows a $\chi^2(2)$ -distribution.

When splitting the sample into two equal-sized bins, such as done in Sect. 5.4, one can use another likelihood ratio test to assess the significance of the difference between results in the two bins. For instance, in a model with three independent parameters such as used in this analysis, splitting into two bins adds three parameters to the (model) description of the data. As a result, the combined (log)likelihood, and test statistic D , will be higher than in a single-bin analysis. The difference follows a $\chi^2(3)$ -distribution under the null hypothesis that the data in both bins is a drawing from the same model distributions. This yields a p -value for the difference between the bin results.

4. Results: the measured X_{\max} distribution

In the following sections, we present the results regarding statistics on X_{\max} , such as the estimate of the mean and standard deviation of the X_{\max} distribution. After this, the implications for the cosmic-ray composition in our energy range are given, based on the statistical analysis presented in Sect. 3.

The results are based on a dataset of $N = 334$ cosmic rays with energies between $10^{16.8}$ and $10^{18.3}$ eV, which pass all selection criteria for a bias-free sample with accurately reconstructable showers, as explained in Sect. 2.5. It is a subset of 720 showers measured in at least three LOFAR stations, of which 469 have a core reconstruction precision better than 7.5 m. Another 135 showers did not meet the sample selection criteria; their inclusion would lead to a dataset biased in X_{\max} . The uncertainty on the X_{\max} measurement per shower is on average 19 g/cm^2 . The average fit quality of the best-fitting simulation to the measured LOFAR data is $\chi^2/\text{dof} = 1.19$, indicating a good fit.

4.1. Mean and standard deviation of X_{\max} as a function of primary energy

We have divided the dataset into energy bins of width 0.25 in $\lg(E/\text{eV})$, and computed the mean and standard deviation in each bin.

The sample averages are shown in Fig. 4. The given uncertainty is the uncertainty on the mean of the X_{\max} distribution, i.e., $\sigma/\sqrt{N_{\text{bin}}}$, with sample standard deviation σ . For positioning the points we have used the average log-energy inside each bin. Two showers above $\lg(E/\text{eV}) = 18.25$ were discarded, as no meaningful average can be taken from them.

For comparison, results are included from the Pierre Auger Observatory [39], HiRes [40], Tunka [41], and Yakutsk [42]. We also include recent results from TALE [43], noting that their method to infer a bias-corrected $\langle X_{\max} \rangle$ is different and assumes the EPOS-LHC hadronic interaction model.

Figure 4: The average depth of shower maximum X_{\max} , as a function of primary particle energy. The annotated numbers indicate the number of showers in each bin, and the error margins indicate the uncertainty on the mean of the X_{\max} distribution. The upper lines indicate the mean values expected for protons, from simulations with QGSJetII-04 (solid), EPOS-LHC (dashed) and Sibyll-2.3d (dotted). The lower lines show the mean predicted values for iron nuclei. For comparison, results from Pierre Auger [39], Yakutsk [42], Tunka [41], HiRes/Mia [40], and TALE [43] are included.

The differences with respect to the earlier LOFAR results [8] can be explained through statistical fluctuations, and from the revised treatment of systematic effects including the atmosphere and the radio-derived energy scale. The lowest-energy data point stands out somewhat, with a difference of 17.6 g/cm^2 , at statistical uncertainties of 7.5 and 6.8 g/cm^2 for the older and newer result, respectively. Such a difference in one of three overlapping data points is not unreasonable just from statistics; it is also possible that improvements in fiducial selection criteria make some difference here, as differences are expected to appear especially at lower energies where signals are closer to trigger thresholds.

The average X_{\max} agrees reasonably well with the other experiments such as Tunka, Yakutsk, HiRes/Mia, and TALE, especially for $\lg E > 17.2$. However, the results from the Pierre Auger Observatory, which is the largest experiment, are somewhat higher starting at the bin around $\lg E = 17.325$. Their statistical uncertainty is smaller than the plotted symbols, arising from a high number of showers (1000 to 2600) per individual bin. Systematic uncertainties on X_{\max} in this energy range are about 11 g/cm^2 for Auger [44], and about 7 g/cm^2 for LOFAR. Additionally, there is a systematic uncertainty in energy, which for LOFAR as well as Auger [45] is about 0.057 in $\lg E$.

To better compare the results of LOFAR and Pierre Auger Observatory and their systematic uncertainties, we have plotted these separately in Fig. 5. The band plots are seen to have little to no overlap, although systematic uncertainties in energy could shift either result horizontally in this plot, according to the margins

Figure 5: Average X_{\max} versus primary energy, for LOFAR and Pierre Auger Observatory, with colored bands indicating their systematic uncertainty on X_{\max} . The uncertainty margins per data point are statistical uncertainties only. The systematic uncertainty on energy is the same for both experiments, and is indicated by the arrows to the lower right.

indicated by arrows.

Thus, there is tension between these results. There is a notable difference in methodology to measure X_{\max} , being direct fluorescence detection versus radio detection with Corsika/CoREAS simulations. In both cases, considerable attention was given to estimating systematic uncertainties from different contributions. In the range where LOFAR and Auger overlap, our results are in agreement with the other shown experiments on the Northern hemisphere, including the recent results from TALE. Also, our earlier results from 2016 are consistent with the present results, while for the latter, systematic uncertainties on energy and atmospheric effects have been lowered considerably. Hence, the apparent difference is not fully explained at present.

In Fig. 6, we show the standard deviation in each bin, along with its uncertainty. To calculate these, as an estimator $\hat{\sigma}$ of the underlying X_{\max} -distribution's standard deviation, we subtract the variance caused by the X_{\max} uncertainty per measured shower:

$$\hat{\sigma} = \sqrt{\sigma^2 - \frac{1}{N_j} \sum_{i=1}^{N_j} u_i^2}, \quad (5)$$

with σ the sample standard deviation, u_i the X_{\max} uncertainty on each shower, and N_j is the number of showers in energy bin j . The uncertainty on the standard deviation of the distribution is estimated using a parametric bootstrap, taking the best-fit mass composition from Sect. 5.1. In this method one needs to assume a particular model distribution, but it is suitable for estimating uncertainties in small samples. Switching the hadronic interaction model was found to make little difference here.

The results are consistent with those from the Pierre Auger Observatory, except for one bin around $\lg E = 17.625$. However, a caveat is the relatively low number of showers per bin, and the exponential tail of the X_{\max} -distributions. The showers at the high end of X_{\max} , roughly $X_{\max} > 800 \text{ g/cm}^2$, appear in our dataset only at low-number statistics level, while their presence shifts the standard deviation considerably upward. In the energy bin from $\lg E = 17.5$ to 17.75 , there happen to be none, thus lowering the sample standard deviation.

Figure 6: The standard deviation of X_{\max} as a function of primary particle energy. The margins indicate the uncertainty on the standard deviation of the X_{\max} distribution. Results from the Pierre Auger Observatory are shown, together with the values from simulations of protons and iron nuclei (high and low lines, respectively).

The results are summarized in Fig. 7, showing the histograms in each energy bin.

4.2. Tests for residual bias

In our energy range, the average X_{\max} of the measured showers is expected to be independent of shower parameters such as the zenith angle. This follows from the fact that the cosmic-ray composition in our energy range is independent of time and incoming direction, as far as is known from experiments. This allows to perform a test of our sample for a residual bias in X_{\max} due to variations in these parameters. Our sample of 334 showers has an average X_{\max} of $659 \pm 3.3 \text{ g/cm}^2$.

As discussed in Sect. 2.5, a biased sample would readily show a dependence of the average X_{\max} on zenith angle. However, the average X_{\max} also depends on the energy; its expected value is to good approximation linear in $\lg E$ over our energy range. From the parametrization using Gumbel distributions, as discussed in Sect. 3, and for the QGSJetII-04 hadronic interaction model, we find, for a factor 10 increase in energy, an average rise in X_{\max} (elongation rate) of 55.4, 57.8 and 60.3 g/cm^2 , for protons, nitrogen, and iron nuclei, respectively. This is in good agreement with the elongation rate of 58 g/cm^2 predicted, for example, by the Heitler-Matthews model [46].

The average (log-)energy of our measured showers tends to rise with zenith angle. This is no problem, as long as there is no bias in X_{\max} . A possible residual bias in X_{\max} , corrected for the influence of varying energy, is evaluated by introducing a parameter Y for each shower, as

$$Y = X_{\max} + 57 (\lg (E/\text{eV}) - 17.4) \text{ g/cm}^2, \quad (6)$$

where 17.4 is approximately the average value of log-energy in our sample.

The results are shown in the right panel of Fig. 8, together with a linear fit. The uncertainty margins are once again given by the standard error of the mean. A constant fit of $Y = 660$ as well as a linear fit are shown.

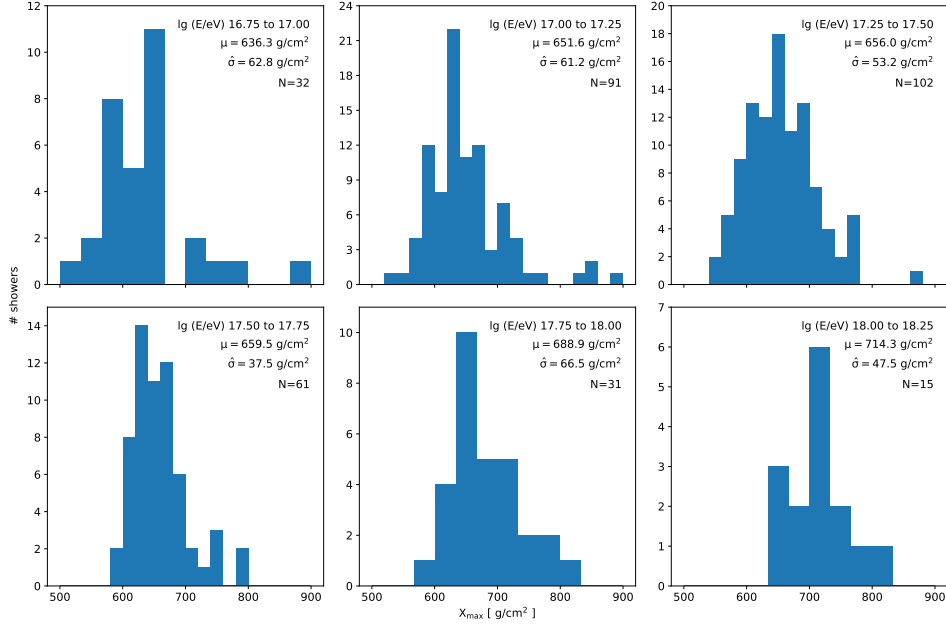

Figure 7: Histograms of X_{\max} for each energy bin. The average (μ) and standard deviation estimates ($\hat{\sigma}$) per bin are as shown in Figs. 4 and 6, respectively.

The linear fit has a slope parameter of -0.10 ± 0.30 . Hence, the slope is compatible with zero, and no residual bias is evident. The high value near 700 for the rightmost bin appears suggestive, but as it contains only eight showers and has a correspondingly large uncertainty, it is not significant. The constant fit has an uncertainty of 3.3 g/cm^2 . A bias at this level cannot be ruled out, hence this is added as a contribution to the systematic uncertainty on X_{\max} .

We also show a complete scatter plot of X_{\max} versus zenith angle, in Fig. 9. This plot shows the effect of the bias tests for the radio and particle detectors and the corresponding fiducial cuts (Sect. 2.5.1 and 2.5.2). As expected, the particle bias test flags most events at high inclination and high X_{\max} , especially above 45 degrees. The radio bias test flags mostly the opposite region, low X_{\max} and low inclination.

Consequently, we see only few showers passing the tests at $\theta < 10^\circ$, and there are only 8 in the highest zenith angle bin above 45° . The plot makes clear that the fiducial cuts from Sect. 2.5 are necessary, as there would have been a strong zenith angle dependence, and thus a biased X_{\max} -sample, had it been omitted.

Figure 8: Average Y (from Eq. 6) versus zenith angle, together with a constant and linear fit.

Figure 9: Scatter plot of X_{\max} versus zenith angle, for all 469 showers with core reconstruction precision better than 7.5 m. Colored circles represent the 334 showers passing all criteria, with the color denoting their energy. The showers flagged by the particle and radio bias tests are also shown.

5. Mass composition results

We have applied the statistical analysis in Sect. 3 to the set of 334 showers passing all selection criteria. Results are shown in detail for the QGSJetII-04 model, and summarized for the other two considered, which are EPOS-LHC [17] and Sibyll-2.3d [18]. We show the results for the full range, followed by a division in two equally-sized energy bins. Owing to the strong overlap in X_{\max} -distributions (see Fig. 3), an $N = 334$ dataset is modest-sized for mass composition analysis based on a multi-element model, hence further binning is not appropriate. The statistical method presented in Sect. 3.1 is well suited for analysis of a wide energy range without loss of measurement information.

5.1. Statistics for the QGSJetII-04 hadronic interaction model

The maximum likelihood estimate was found to be 28% protons, 11% helium, 60% nitrogen and 1% iron. A histogram of X_{\max} is shown in Fig. 10 (top), for the full energy range. The coverage of this energy range can be summarized by a mean log-energy of $\lg(E/\text{eV}) = 17.39$ and a standard deviation of 0.32. Hence, the ‘center of mass’ of the dataset lies between 17.07 and 17.71.

The red (solid) curve is the best-fitting distribution, found using the maximum likelihood method and Eq. 3. The distributions for the elements that make up the best-fitting distribution are also shown, scaled by their respective mix fractions.

We have tested the goodness-of-fit of the best-fitting model to our dataset, using the Kolmogorov-Smirnov distance between the cumulative and empirical distributions (Sect. 3.1) as compared to random drawings from the best-fit distribution. As shown in Fig. 10 (bottom), the model is a good fit to the data ($p = 0.96$). Switching the hadronic interaction model to EPOS-LHC or Sibyll-2.3d produces about equally good fits to the data, at $p = 0.93$ and $p = 0.90$ respectively. Hence, all three models fit the data well, at their respective best-fitting composition. It is of course possible that this would change with a larger dataset and/or smaller energy bins.

We observe that protons and helium are to a significant degree interchangeable in the statistical analysis of our model, given our dataset. This is readily seen in the contour plot in Fig. 11, showing the D -statistic for the likelihood ratio test, versus proton and helium fractions. The contours show the allowed regions with confidence levels one-sigma (68%), 95%, and 99%, respectively. Within the one-sigma region, one can exchange helium for protons in a ratio of about 3 to 1. The contour plot underlines, for example, that the dataset only allows a very low proton fraction if the helium fraction is rather large instead.

5.2. Accounting for systematic uncertainties

The systematic uncertainty in X_{\max} amounts to $\pm 8.1 \text{ g/cm}^2$ (before roundoff), including the contribution from the CONEX-based parametrizations. The energy uncertainty of 14%, or 0.057 in $\lg E$ has, to first order, the effect of an overall shift of X_{\max} in the X_{\max} -distributions (see Eq. 6), of 3.1 g/cm^2 . By adding both uncertainties in quadrature, we obtain a systematic uncertainty of 9 g/cm^2 .

Evaluating the composition results for $X_{\max} \pm 9 \text{ g/cm}^2$ for all showers, we obtain limits for the best fit, as well as the (expanded) confidence intervals that arise for a systematic shift in this range. Noteworthy is for example that when the average X_{\max} is shifted downward, the helium fraction is fitted much higher at the expense of the nitrogen fraction. Helium is then favored over nitrogen in the fit, due to the lower expected X_{\max} at lower energies, and the longer ‘tail’ of the X_{\max} distribution for helium.

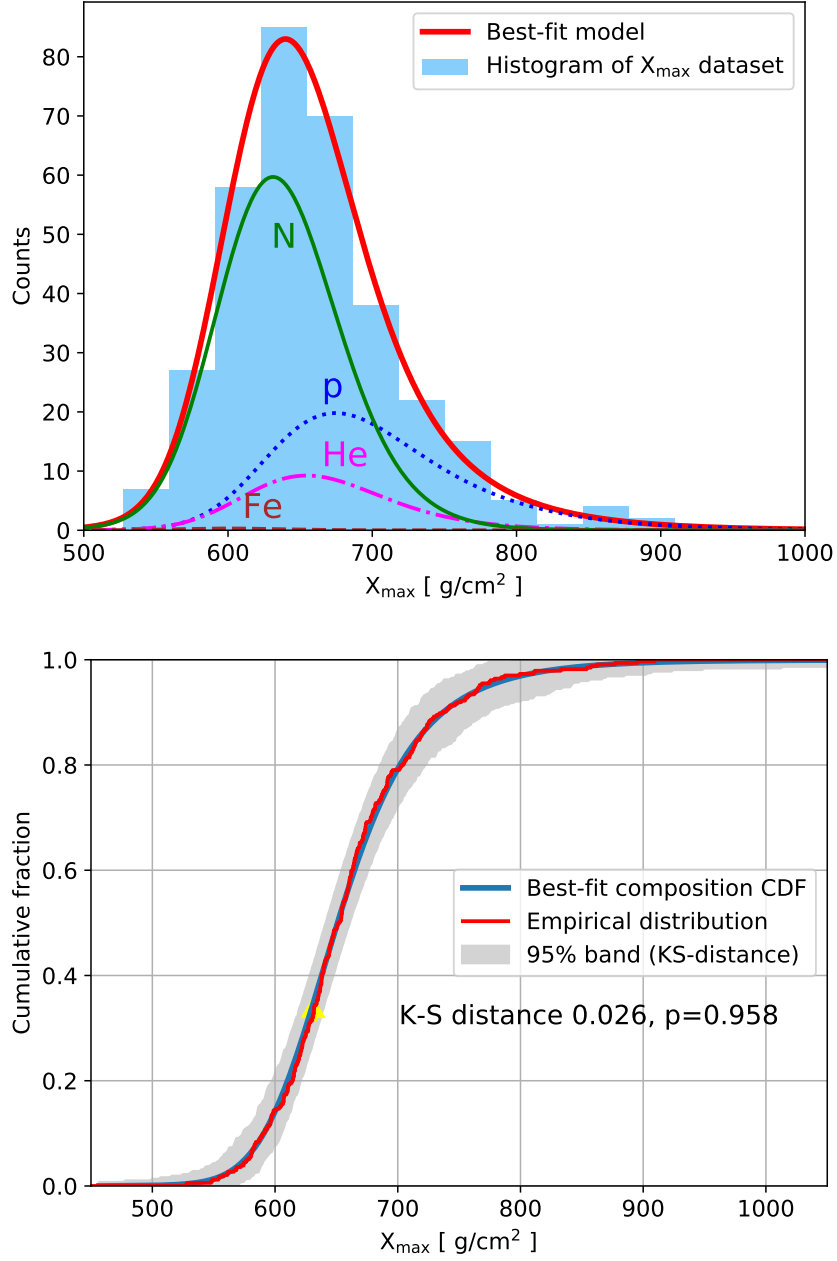

Figure 10: Top: A histogram of X_{\max} , together with the best-fitting distribution from Eq. 3. Bottom: The cumulative distribution corresponding to the best-fit composition model, together with the empirical distribution from our dataset. The yellow arrow indicates where the distance between CDF and empirical distribution is maximal. The grey band is the envelope of all simulated empirical distributions that have a K-S distance to the CDF below its 95-percentile level. Both graphs indicate a good fit.

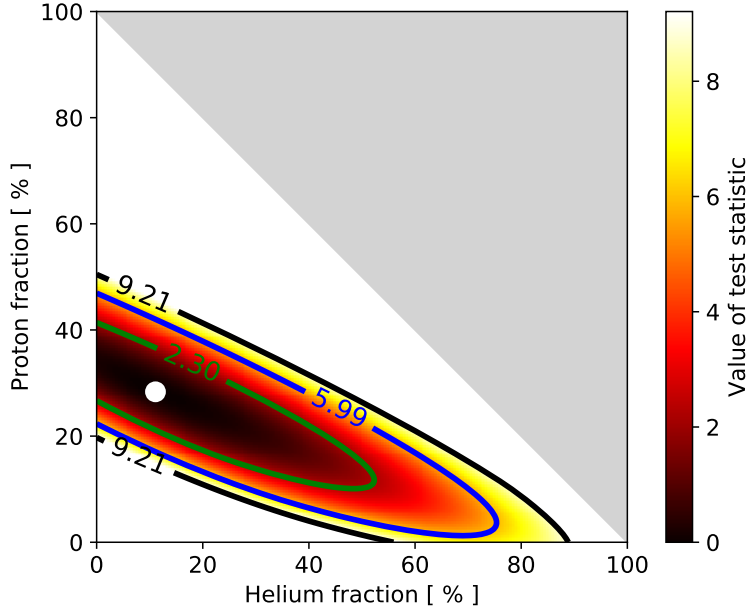

Figure 11: Contour plot of the proton and helium fraction, giving the regions consistent with a one-sigma, 95% and 99% confidence level, respectively.

5.3. Results for three hadronic interaction models

The results for the hadronic interaction models QGSJetII-04, EPOS-LHC, and Sibyll-2.3d are plotted in Fig. 12.

For EPOS-LHC, it is seen that the fit favors a more heavy composition, with more iron instead of nitrogen, and with a significant upper bound on the helium fraction. Sibyll-2.3d shows a still somewhat heavier composition, with a lower proton fraction and a higher nitrogen fraction at best fit. Otherwise, the results are very similar across these three hadronic interaction models, especially considering the uncertainty margins. The intermediate-mass elements in the C/N/O range (possibly stretching to somewhat higher mass numbers as well) are dominant, and there is a significant fraction of light elements, i.e., protons and helium, at best fit ranging from 23 to 39%, depending on the interaction model. Apart from a crossover from C/N/O to iron, the choice of hadronic interaction model has only a limited effect on the best-fit results. From the large intermediate-mass contribution it is clear that the composition cannot be described as a two-component mixture of protons and iron. This is confirmed by a likelihood ratio test with respect to the 4-component model, yielding a p-value $p < 10^{-10}$. However, a two-component mixture of protons and nitrogen would work for QGSJetII-04 ($p = 0.9$).

For this dataset, helium and nitrogen are not fully resolved in the composition model. The fitted values for the helium and nitrogen fraction are highly anti-correlated, which follows from the requirement that all mix fractions sum up to 1. Helium and nitrogen are a factor 3.5 apart in atomic mass number, whereas the other consecutive elements are a factor 4 apart; constant factors here correspond to a constant shift in $\ln A$, and the mean of the X_{\max} -distributions varies by an amount proportional to $\ln A$. Moreover, helium and nitrogen have two 'neighboring' elements in the composition model, unlike hydrogen and iron. This increases sensitivity to a systematic shift (up or down) in X_{\max} .

Importantly, when comparing the current results to the earlier LOFAR results published in [8], the results are found to be consistent, after various improvements to the analysis setup, the systematic uncertainties, and having a larger dataset.

The previous, smaller dataset allowed for a near-100% helium fraction and essentially no protons; this

Figure 12: Composition results from our dataset, assuming each of the three hadronic interaction models shown at the bottom. The best fit is shown along with statistical and systematic uncertainties.

scenario is now very unlikely. As shown in Fig. 11, a similar but somewhat more constrained interchange between protons and helium is still possible. There are astrophysical scenarios where one would see very few protons but a large helium and carbon fraction. For example, a transition from a Galactic component dominated by Wolf-Rayet supernovae to a particularly strong extragalactic component at these energies could produce a helium fraction near 60% plus a small proton fraction of about 5% at our central energy around $2 \cdot 10^{17}$ eV [4]. This is still allowed within 95% confidence limits.

Comparing the results to those from Pierre Auger Observatory [47], starting at $\lg(E/\text{eV}) = 17.25$, agreement is found within statistical and systematic margins. At best fit, their proton fractions are higher, in line with the higher average X_{max} . The difficulty in resolving helium and nitrogen remains, at their higher level of statistics.

Generally, the statistical margins indicate that the analysis would improve with more data. This is no surprise, at a modest number of showers. However, systematic uncertainties are also important at any level of statistics, as they enlarge the margins of statistical plus systematic uncertainties together. This is especially evident in the fitted iron fraction, which is well bounded by statistics, but has substantially expanded margins when systematic uncertainties are included. Also, looking once more at the substantially overlapping X_{max} -distributions in Fig. 3, it is clear that achieving lower systematic offsets in X_{max} is still important, to improve the resolution of the composition analysis as well as the separability of the element fractions.

5.4. Analysis in two energy bins

We have divided the dataset into two bins with equal number of showers, being those below versus above the median of $\lg(E/\text{eV}) = 17.34$. This is a conservative choice with respect to statistical significance. The results for the three interaction models are shown in Fig. 13. The coverage of the energy bins, summarized as an average and standard deviation, is mainly at $\lg(E/\text{eV}) = 17.14 \pm 0.13$, and 17.65 ± 0.23 , respectively.

Notable is the best-fit proton fraction, which is lower in the high-energy bin for all three interaction models. However, from a likelihood ratio test (see Sect. 3.1, bottom) the difference between the two bins

Figure 13: Mass composition results in two energy bins. The energy ranges per bin are shown; their main coverage is at 17.14 ± 0.13 , and 17.65 ± 0.23 , respectively.

was found not to be statistically significant. That is, a null hypothesis that the observed difference between the two bins would arise from a mass composition constant with energy, as in Fig. 12, is not rejected ($p = 0.58$).

A similar, simpler test is to use Eq. 6 to take out the first-order energy-dependence of X_{\max} , and split the dataset in two equal-sized bins, for lower and higher energy, respectively. This is a non-parametric test which does not depend on element-based composition models using X_{\max} -distributions. Also, the elongation rate does not have a strong dependence on the interaction model.

The difference in average Y_{\max} between the low and the high-energy bin is not significant ($p = 0.25$). Thus, it is clear that a larger dataset is needed to draw conclusions on possible variations of the element fractions with energy. Would such a trend towards lower proton fractions be confirmed, it would challenge the hypothesis of a transition from a helium and C/N/O-dominated Galactic to a proton-dominated extragalactic component at energies below 10^{18} eV.

6. Summary

We have presented an updated cosmic-ray mass composition analysis from LOFAR radio data, built on an improved method for measuring the depth of shower maximum X_{\max} of air showers. For the reconstruction of shower parameters, CORSIKA / CoREAS simulations have been used.

We have incorporated several refinements to our analysis, such as including local atmospheric parameters, the Galaxy-based radio calibration and energy measurement, and improved detector characterisation in the fiducial sampling procedure. This leads to an energy resolution of 9% and an X_{\max} -resolution of 19 g/cm² on average, and a systematic uncertainty of 14% on energy and 7 g/cm² on X_{\max} , or 9 g/cm² in the mass composition analysis.

To obtain an unbiased dataset suitable for composition studies, three selection criteria were applied to a set of 720 reconstructed showers, based on the ensemble of simulations per measured shower. Requiring a shower core precision better than 7.5 m gives a sufficient general cut on reconstruction quality. We further require that each simulated shower in the CORSIKA / CoREAS ensemble must be able to trigger the LORA particle detector array, and also pass the detection and quality criteria of the LOFAR radio analysis pipeline. This procedure leaves a sample of 334 showers for analysis of X_{\max} -statistics and (mixed) element composition.

The inferred average and standard deviation of X_{\max} have been presented in a (log-)energy range of $16.75 < \lg(E/\text{eV}) < 18.25$. The average X_{\max} was found to be in line with results from Northern hemisphere-based observatories such as Tunka, Yakutsk, HiRes/Mia, and TALE. However, the values are somewhat lower than those from the Pierre Auger Observatory, where their energy range overlaps. The origin of this tension remains unclear and requires additional research.

Apart from the first two moments, we have also analysed the X_{\max} -data at (complete) distribution level, using a four-component model of elements, about equally spaced in $\ln A$. An unbinned maximum likelihood method was found suitable to obtain the best-fitting mass composition in our energy range, together with a separate goodness-of-fit test. This relies on high-precision parametrizations of the X_{\max} -distributions of the elements, as produced by [37] and updated by [38].

From this analysis, the best-fitting mass composition for our dataset is 28% protons, 11% helium, 60% nitrogen and 1% iron, assuming the QGSJetII-04 hadronic interaction model. This is averaged over our energy range, with coverage mainly at a log-energy of $\lg(E/\text{eV}) = 17.39 \pm 0.32$. The EPOS-LHC and Sibyll-2.3d models tend towards a heavier composition, with an iron fraction just above 20% as a best fit. The light-mass elements together, protons plus helium, form a fraction of 23 to 39% at best fit. Overall, the differences in composition results between these three important hadronic interaction models are minor, apart from a shift between nitrogen and iron. For these differences to become significant, a larger dataset would be needed. A division of the dataset into two equal-sized bins, for lower and higher energy respectively, yielded no significant difference, both in the model-based composition analysis and in the difference in elongation-rate-corrected X_{\max} (Eq. 6).

The present results are consistent with the earlier LOFAR results [8], thus confirming an appreciable light-mass component in this energy range, at a lower level of systematic uncertainties and from an extended dataset. The element-based mass composition results are in agreement with those from the Pierre Auger Observatory, within systematic and statistical uncertainties. Hence, the tension in the average X_{\max} results does not translate to element-based results outside their uncertainty margins. To conclude, we have shown that our X_{\max} -analysis per air shower achieves an accuracy in line with the current state of the art, and demonstrates the value of the radio detection method for measuring air showers.

ABSTRACT: This article presents the design of the Radio Neutrino Observatory Greenland (RNO-G) and discusses its scientific prospects. Using an array of radio sensors, RNO-G seeks to measure neutrinos above 10 PeV by exploiting the Askaryan effect in neutrino-induced cascades in ice. We discuss the experimental considerations that drive the design of RNO-G, present first measurements of the hardware that is to be deployed and discuss the projected sensitivity of the instrument. RNO-G will be the first production-scale radio detector for in-ice neutrino signals.

1 Introduction

This paper describes the Radio Neutrino Observatory Greenland (RNO-G) as it will be constructed at Summit Station in Greenland starting in 2021. RNO-G science targets astrophysical neutrinos of several PeV in energy up to the EeV range.

In this paper, we first motivate the science case for RNO-G, elaborate on experimental design considerations and then outline the instrument design. Awaiting in-field performance data, this article does not serve as a technical document, but describes the concept, the current hardware developments and boundary conditions behind the RNO-G approach. We conclude with a description of initial estimates of the design sensitivity of the instrument, as well as the expected resolution for such quantities as neutrino arrival direction and energy.

1.1 Scope of RNO-G

RNO-G will be constructed over three installation seasons. RNO-G will reach unprecedented yearly sensitivity to neutrino signals above 10 PeV, and will demonstrate a large-scale implementation (35 stations) of the in-ice radio neutrino detection technique. Even further scaling up of the in-ice radio technique, beyond the scale of RNO-G, is being developed as part of IceCube-Gen2 [1].

Considering both logistical constraints and also science opportunities (detailed below), RNO-G will be constructed at Summit Station in Greenland. The RNO-G collaboration consists of members of all previous radio in-ice neutrino experiments from both Europe and the United States.

1.2 Relation to previous and current radio experiments

Due to the extremely low neutrino flux at energies above 10 PeV, no neutrino has yet been detected using the radio technique. However, several experiments have shown the feasibility of this detection method and its potential. RNO-G builds heavily on the experience of previous radio neutrinos detectors, like the pioneering RICE [2, 3], the ARA [4–6] and ARIANNA [7, 8] experiments, as well as the balloon-borne ANITA [9, 10] experiment. These efforts tested different aspects of the radio technique and helped illuminate technologically important aspects of operating in remote locations in harsh polar conditions.

The first experience with in-ice radio detectors was gained with the Radio Ice Cherenkov Experiment (RICE) [2] at the South Pole. After a number of prototypes and initial measurements of the ice characteristics, the main experiment operated from 1999 until 2010. RICE provided the first neutrino limits [3] from radio detectors and valuable experience in operating radio detectors at depths of down to 200 m.

The Askaryan Radio Array (ARA) [5] has operated at South Pole since 2010 [11] and is a direct successor to RICE. While the RICE antennas were co-located with the AMANDA and IceCube experiments at South Pole, all five ARA stations operate in dedicated dry holes of depths 50 m–200 m. While different hardware has been deployed in different ARA stations, the station layout is mostly uniform. Every station consists of four receiver strings down to 200 m. Each string is equipped with two vertically-polarized birdcage dipole antennas (VPol) and two ferrite-loaded slot antennas (Hpol) to reconstruct the radio signals. In addition, one or two calibration strings as well as surface antennas (on the earlier stations) are deployed. As the narrow cylindrical borehole

geometry limits the intrinsic antenna gain, ARA pioneered the phased-array technique for radio detection of neutrinos at the most recently completed station [12].

To date, the ARA collaboration has published constraints on the diffuse ultra-high energy (UHE) neutrino flux [6], neutrinos from gamma-ray bursts (GRBs) [13], and radio emission from solar flares [14]. The performance of the instrument has been verified using transmitters lowered into the SPICE borehole [15], which also allowed for the measurement of glaciological properties of the ice — some of which can be used for improved neutrino event reconstruction [16, 17].

The Antarctic Ross Ice-Shelf ANtenna Neutrino Array (ARIANNA) began construction at the Ross Ice-Shelf in 2010, with a first hexagonal radio array being completed in 2015 [7, 8]. The ARIANNA concept is based around surface stations, i.e. the antennas are deployed just underneath the snow-surface. High-gain log-periodic dipole antennas (LPDAs) are deployed in shallow slots in the snow, where they are not restricted by the borehole geometry and exhibit broadband characteristics and dedicated polarization sensitivity, particularly to horizontally polarized signals. By placing the antennas at Moore’s Bay on the Ross Ice-Shelf, the neutrino-detection strategy utilizes the reflective surface at the bottom of the ice at the water interface, which reflects downward going neutrino signals back to the stations. Without external infrastructure, ARIANNA pioneered autonomous low-power stations, based on renewable energy sources, operated via wireless communications. Most recently wind turbines were added to the solar power-provision system [18].

ARIANNA has successfully detected the radio signal of air showers as calibration and verification signals [19] and published limits on the UHE neutrino flux [20]. The collaboration also published the effectiveness of recording signals reflected from the surface by monitoring snow accumulation [21]. Two ARIANNA stations have also been deployed at South Pole to test the robustness of the hardware under environmental circumstances differing from the Ross Ice Shelf. The same calibration source as used for ARA from the SPICE borehole was then also used to verify the reconstruction capabilities of the ARIANNA experiment with respect to arrival direction and polarization [22].

The Antarctic Impulsive Transient Antenna (ANITA) experiment has flown four separate missions over Antarctica. ANITA is a balloon-borne radio receiver array that scans the surface from afar for upcoming neutrino signals generated below the ice surface. Several components of the ANITA hardware have been incorporated into the ARA and ARIANNA designs [9, 10, 23]. While equipped with much different power and lifetime requirements, the technological challenges remain similar. A data acquisition system with high timing accuracy and thorough calibration is needed to reliably reconstruct neutrino or cosmic-ray signals. ANITA was the first radio-neutrino experiment to report the detection of air shower signals [24], which helped to verify the simulation chain and the understanding of the energy calibration [25]. The ANITA collaboration observed several events which, if neutrinos, would seem to be in tension with Standard-Model cross-sections [26–28]. Those events may also stem from unexplained systematics or ice effects [29, 30].

Operation of existing ARA stations continue in close cooperation with IceCube. In addition, proposals for an ANITA-successor ballooning effort are being discussed, as well as an extension of the ARIANNA array at Moore’s Bay.

In addition to building on experiences with dedicated radio neutrino experiments, RNO-G also profits from knowledge gained at accelerator experiments about the nature of the in-medium emission from particle showers [31–34], as well as those from mid-scale air shower arrays measuring the radio emission of cosmic ray induced showers e.g. [35–39]. First efforts at exploring the feasibility

Figure 1. A multi-messenger view of the high-energy universe, inspired by [43], showing the science reach for radio detection of neutrinos. Shown are models predicting neutrinos from sources (in red lines) [44–49] and those from the interaction of the ultra-high energy cosmic rays with various photon backgrounds (in dark yellow lines). Overlaid are [50, 51] the γ -ray measurements from Fermi [52], the IceCube neutrino measurements and the fit to the muon neutrino spectrum [53–55], as well as the spectrum of ultra-high energy cosmic rays as reported by the Pierre Auger Observatory [56].

of a detector in Greenland have been conducted previously by members of the collaboration [40–42] and have encouraged the development of RNO-G.

2 Science case and design requirements

Neutrinos are ideal messengers to identify the UHE sources in the universe. Unlike cosmic rays, which are deflected by magnetic fields and interact with intervening matter and radiation, neutrinos point back to their sources and can reach Earth from the most distant corners of the universe. Furthermore, due to their low interaction cross section, neutrinos are unique messengers to convey information about the inner engine of cosmic accelerator sites. Unlike γ -rays, which can also be created by inverse Compton scattering, the observation of high-energy neutrinos from astronomical objects provides incontrovertible evidence for hadronic cosmic-ray acceleration. Identifying the sources of cosmic rays and the acceleration mechanisms requires a comprehensive multi-messenger observation program comprising cosmic rays, γ -rays, and neutrinos across many decades of energy.

In the last years, neutrinos have delivered on their promise to provide a key piece of this astronomical puzzle with the discovery of a diffuse flux of astrophysical neutrinos [57–60]. IceCube has measured the neutrino energy spectrum to above 1 PeV — the highest-energy neutrinos ever observed. Beyond the PeV scale, the limited size of IceCube prohibits observation of the steeply falling neutrino flux. Figure 1 compares the neutrino flux measured by IceCube with the diffuse flux of γ -rays measured by Fermi [52] and the cosmic-ray spectrum measured by Auger [56]. The

three spectra display tantalizingly similar energy densities, suggesting a common origin. In such a scenario, cosmic-ray collisions produce pions, where gamma-rays then stem from decays of neutral pions and neutrinos from those of charged pions. The figure also shows the gap in observations of UHE neutrinos beyond the energies reachable by IceCube.

Multi-messenger observations are even more intriguing in light of the announcement in July 2018 of the first coincident observation of a neutrino from the direction of a source (the blazar TXS 0506+056) that was flaring simultaneously in γ -rays [61, 62]. This was also the first multi-messenger observation triggered by a high-energy neutrino, demonstrating the capability to send real time alerts and establishing the field as a vital pillar of multi-messenger astronomy. To fully understand the neutrino sky, however, a larger detector must be built and observations extended to the PeV–EeV energy range.

The radio detection technique naturally targets neutrino energies beyond the reach of IceCube. Due to the kilometer scale attenuation length of radio waves in ice, very sparse radio detectors cover large volumes of material, providing huge effective volumes at 10 PeV to 100 EeV. In this energy range, several transient and diffuse sources of neutrinos are expected and an experimental measurement would strongly impact identification of the sources of ultra-high energy cosmic rays.

The general science case of neutrino astronomy has been reviewed in the context of the 2020 US decadal survey [63, 64]. This section will thus focus specifically on the science program that can be conducted by radio detectors for high-energy neutrinos.

2.1 Diffuse neutrino flux

The radio detection of neutrinos targets the energy range from 10 PeV to beyond 100 EeV. In this range, diffuse neutrino fluxes both directly from sources (*astrophysical neutrinos*), as well as from the interaction of ultra-high energy cosmic rays (UHECRs) with photon backgrounds (*cosmogenic neutrinos*) are predicted. Detecting either will enable studies of high-energy neutrino production mechanisms locally, at the still unknown sources.

Figure 1 shows different models for astrophysical (red) and cosmogenic (yellow) neutrinos that fall in the energy range of radio detectors. Cosmogenic neutrinos result from interactions of UHECRs with photon fields like the extra-galactic background light, the infra-red background, or the cosmic microwave background [65]. The flux and spectrum of these neutrinos are grounded in the UHECR mass composition, but are subject to model assumptions about the cosmological luminosity and chemical evolution of the sources, which can differ outside of the local universe probed by UHECRs [66]. For the cosmogenic neutrino predictions shown in figure 1, we compare predictions based on compositions measured by the Telescope Array (TA) [67, 68] and the Pierre Auger Observatory (Auger) [50, 69]. These are in fact only examples of the full range of possible models admitted by current constraints [51].

While the cosmogenic fluxes predicted assuming the Auger and TA compositions vary significantly, composition measurements from the two experiments are compatible within systematic uncertainties [70]. With a measurement of UHE neutrinos, radio detectors can resolve the question of a pure-proton composition, which is disfavored by Auger, but still allowed by TA data. More generally, measuring UHE neutrinos will constrain a combination of proton fraction, source evolution and highest-energy cutoffs of UHECRs well beyond local sources.

We consider ‘astrophysical’ neutrinos as those created directly in (or very close to) the sources of UHECRs. These neutrinos tend to have lower energies than cosmogenic neutrinos, but also reach the energy range of radio detectors. They will definitely trace their sources, allowing for stacking analyses to reveal them. These neutrinos are not necessarily time-coincident with explosive events (see section 2.3), but contribute to a constant diffuse flux. Potential candidates range from Active Galactic Nuclei (AGN) [47] to various types of gamma-ray bursts (GRBs) [46, 49], pulsars [45], galaxy clusters [44], Flat Spectrum Radio Quasars (FSRQs) [71], and blazars [48].

The diversity of models of astrophysical neutrinos is already large and promising, but we expect more models to become available as detectors with the necessary sensitivities are commissioned.

It remains to be explored whether astrophysical neutrinos are the source of the diffuse flux as measured by IceCube or whether the observed flux is the low energy tail of the cosmogenic neutrinos. So far, despite the multi-messenger successes, studies demonstrate that neutrinos from blazars cannot comprise the bulk of the diffuse neutrino spectrum at energies accessible by IceCube [72–77]. A radio detector will be able to measure the continuation of the IceCube flux to higher energies and thereby provide additional information on the spectral shape of the flux, which may be useful to disentangle the source contributions.

A successful search for the diffuse neutrino flux at energies beyond 10 PeV requires, above all, an adequate flux sensitivity to ensure a first observation. To subsequently discriminate putative production mechanisms, a detector must provide an adequate energy estimate for every neutrino and an angular reconstruction that allows for the correlation of arrival directions with known sources.

2.2 Sky coverage

Figure 2 demonstrates the field of view of a radio neutrino telescope sited in Greenland. When targeting point-like sources, either steady or transient (see section 2.3), the field of view of the detector becomes relevant. The Earth is opaque to neutrinos at PeV to EeV energies, such that UHE neutrino observatories are most sensitive to down-going or Earth-skimming neutrinos. As will be discussed in more detail section 2.5, a radio neutrino detector in glacial ice on bedrock will be most sensitive to an annulus above the horizon.

Combining the opacity of the Earth to neutrinos above PeV energies with the inherent radio detector sensitivity means that, for example, a follow-up of TeV-scale IceCube events at higher energies requires a Northern detector such as RNO-G. A *single event* observed by a radio detector in the Northern hemisphere will define the flux in a new energy regime, and even a non-detection will constrain the allowed flux through *multi-wavelength* neutrino observations.

The continuous sky coverage and large field-of-view will enable studies of point sources of high-energy neutrinos. The hotspot of UHECRs observed by TA [79] (red ellipse in figure 2) lies in the Northern Hemisphere. While the cosmogenic neutrino flux is expected to be diffuse, studies attributing the TA hotspot to a single source of cosmic rays like M82 predict point sources of EeV neutrinos [80]. There are additionally four intriguing point sources nearing the threshold for a high-confidence long-term detection in IceCube (shown as navy blue diamonds in figure 2), all of which lie in the Northern Hemisphere due to the sensitivity of IceCube. These include not only TXS 0506+056, but also NGC 1068, an AGN which lies near the strongest hotspot in IceCube’s all-sky scan [78].

Figure 2. The field of view, in equatorial coordinates, of an in-ice radio detector for neutrinos in Greenland. The colored background represents the diurnally-averaged total field of view of the detector. Also shown are targets with interesting multi-messenger implications. The blue sources are those seen by IceCube as the most significant sources in a point-source search [78]. In orange, we show other interesting candidates, with strong γ -ray emission and/or radio emission. Furthermore, we indicate what is known as the *TA hotspot* as indicated by the anisotropy measurement in cosmic ray measured with the Telescope Array [79].

2.3 Transient sources

Detecting neutrino emission in temporal and spatial coincidence with an explosive event has shaped and will continue to shape multi-messenger astronomy [61, 62]. By uniquely identifying sources, neutrinos will help to characterize and discover the most energetic non-thermal sources on the sky. Many models of astrophysical transient phenomena predict neutrinos in the detectable energy range of radio neutrino detectors.

The overlap in sky coverage with IceCube, where IceCube has its best efficiency for directional reconstruction of astrophysical neutrinos, will enable studies of several interesting flaring, transient sources over a broad energy band. Should the first tentative extra-galactic neutrino source, the blazar TXS 0506+056, flare [61, 62] again, observations made by IceCube and RNO-G may be able to define the neutrino spectrum. Similarly, the first blazars known to flare with TeV γ -rays emission, Markarian 501 [81] and Markarian 421 [82], also lie in the Northern sky. Models of transient bursts of neutrinos due to tidally disrupted stars [83–89] and binary neutron star mergers [90, 91] also predict neutrinos in the PeV to EeV energy scale. The latter are targets for multi-messenger observations of gravitational waves and neutrinos. Figure 3 shows a fraction of the parameter space over which neutrinos are expected as transient phenomena from various source classes. In the figure, model-dependent fluence is compared to duration for varying neutrino energies around EeV. Furthermore, different populations of blazars, including low-luminosity BL Lacs, high-luminosity BL Lacs and FSRQs [48], the most powerful blazars in the γ -ray band [71], could provide intriguing candidates for multi-wavelength follow up. The energy threshold of RNO-G will allow sensitive

Figure 3. Expected neutrino flux at Earth integrated over transient duration from different classes of astrophysical objects placed at probable and previously studied distances. These include short GRBs (possibly associated with a Neutron Star-Neutron Star merger) [130] and GRB afterglows [49] at a distance of 40 Mpc, the high state SED of Tidal Disruption Events (TDEs) at 50 Mpc [89], and stable fast-spinning young magnetars [131] at 10 Mpc roughly 4 days post merger. Blazar flares [132] are shown based on a proton synchrotron model applied to multi-wavelength observations of PKS 1502+106, which has a redshift of $z=1.8$. The expected transient fluence for each object is plotted against duration, or flare time, for three neutrino energies: 10^{17} eV (hollow shapes), 10^{18} eV (half shapes), and 10^{19} eV (filled shapes).

searches for GRBs [46, 49, 92–113, 113–128] with lower neutrino luminosity than previously conducted with radio neutrino experiments [13, 129].

A successful radio detector for transient signals needs reliable absolute timing and good angular reconstruction. Ideally, the angular reconstruction is both sufficiently rapid and accurate to allow meaningful alerts to be quickly sent to the multi-messenger community. Absolute timing is critical to the multi-messenger mission.

2.4 Fundamental physics

High-energy cosmic neutrinos uniquely probe fundamental particles and interactions in an uncharted and otherwise unreachable energy and redshift regime, as summarized in [64].

The energy regime of neutrino radio detectors encompasses a relatively unmapped parameter space, helping to answer questions about the fundamental neutrino properties such as the behavior of neutrino cross-sections [133–140] and flavor mixing at high energies [141–147], or even whether neutrinos are stable in general [144, 148–154]. There is the chance to contribute to broader phenomenology such as the nature of dark matter [155–171], the quest for the fundamental symmetries of nature, [172–184] and/or potential hidden interactions with cosmic backgrounds [144, 185–190].

Overall, for a radio detector to provide experimental data for fundamental physics experiments, the highest priority is to detect neutrinos with adequate statistics. After this is given, the accuracy of statements regarding fundamental physics will strongly depend on the accuracy of the reconstruction.

Figure 4. Electric-field waveforms (left) and spectra (right) of the radio signal emitted at different viewing angles relative to the Cherenkov angle, for a hadronic shower with energy deposition of 1 EeV. For enhanced readability, the waveforms have been offset in time. No propagation or detector effects have been included.

The obtainable energy resolution directly impacts spectral measurements and the accuracy of energy dependent quantities in fundamental physics. For studies relying on for example the amount of matter traversed, angular resolution has a direct impact. Potential flavor sensitivity of radio experiments would be interesting to answer yet another set of fundamental physics questions.

2.5 Radio emission from neutrino interactions in ice and consequences for site selection

The radio emission following a neutrino interaction stems from the *Askaryan* effect [191]. Postulated more than 50 years ago, the effect has been demonstrated in accelerator experiments in several dielectrics including ice [31–34], as well as identified as secondary emission mechanisms in air showers [192, 193].

Askaryan emission is caused by showers developing in a (dense) medium. Thus, a radio signal follows the interaction of neutrino of all flavors, as long as a particle shower is generated, both for hadronic and electromagnetic showers [194]. It is also possible to detect showers induced by catastrophic energy-losses of secondaries such as muons or taus [195]. The emission is a coherent effect, originating in the charge imbalance resulting from medium electrons either Compton scattering into the advancing shower or annihilating with shower positrons. With respect to the surrounding medium a net-negative charge is present in the shower front.

The radio signal itself is a broad-band bipolar pulse with \sim ns-duration. Coherence is given over all frequencies (typically tens of MHz to tens of GHz) close to the Cherenkov angle, where the signal is strongest as the emission at all frequencies arrives in phase. Coherence is lost off the Cherenkov angle first at high frequencies, so that the Cherenkov ring is rather narrow at high frequencies and broader at low frequencies. A discussion of a variety of models for the radio emission of neutrinos can be found in [196], they range from simplified parameterized models in the frequency domain to

more advanced semi-analytical time-domain models. In figure 4 we show typical pulses and their frequency spectra derived from [197], for an illustration of the variety and the behavior.

The energy threshold for a neutrino detection is significantly higher in radio than for optical instruments [2]. Depending on the exact instrumental parameters, the pulse amplitude at a distance of 100 m reaches the level of the typical thermal noise in low-noise radio receivers at approximately 1 PeV. Although the energy per radio photon is significantly smaller than for optical photons, signal coherence compensates as the charge imbalance grows. As a coherent effect, the amplitude scales linearly with the number of excess electrons, which itself is linear in shower energy [31, 198]. However, it should be noted that the detected signal amplitude scales with $\frac{1}{r}$, with r being the distance to the neutrino interaction vertex.

At the same observer distance r , the detected signal amplitudes linearly as function of energy. This has been confirmed in air showers since the attenuation in air is negligible [37]. The situation is different for instrumentation deployed in-ice. The kilometer-scale attenuation length in ice [5, 41, 199–201], determines the range to an observable neutrino interaction, and, therefore, the detector effective volume. The attenuation length decreases with increasing temperature, which favors cold and thick ice for deployment.

Naturally occurring ice follows a depth-dependent density profile with a gradient, from fresh snow to solid ice, resulting in a varying light velocity with depth, and therefore non-rectilinear ray trajectories. In a medium with a refractive index gradient, radio signals are bent towards the denser medium, producing bent trajectories and a limited field of view for detectors in or close to the near-surface firn layer. These bent trajectories complicate the reconstruction, particularly when there are uncertainties in the ice properties. The simplest ansatz assumes a smooth ice density gradient. Calculations demonstrate that anisotropies in the firn (or below) may support unexpected horizontal propagation, as borne out by experimental data [42, 202]. A radio detector should therefore preferably be built at a site with a small firn layer and otherwise smooth and homogeneous ice.

Starting from PeV energies, the Earth is opaque to neutrinos, such that radio detectors will be sensitive to an annulus of neutrino directions above and slightly below the horizon. The deeper the detector, the more vertically incoming neutrino directions can be detected. For a detector at a few hundred meters depth, the sensitivity does not reach far beyond 30° elevation, unless the reflective property of the bottom of a shelf-ice is used, as for the ARIANNA experiment [203].

In summary, an in-ice radio neutrino detector in glacial ice on bedrock will have the largest acceptance if installed in thick, smooth and cold ice. It will never be able to provide full sky coverage, but only be sensitive to a ring of elevations above and slightly below the local horizon.

Figure 5 provides an overview of the geometry for the detection radio signals with a detector buried in the ice. Every station monitors a large volume of ice, which means that by shear geometry a detection is most likely to show small signals as this corresponds to an interaction in the largest visible volume.

2.6 Air showers as both a potential background and calibration signal

The radio emission of air showers from the electron charge excess is similar to that for neutrino induced showers in ice. However, in air the geomagnetic emission [204, 205] dominates over the Askaryan effect. The geomagnetic emission stems from the charge separation induced by the Lorentz force in the Earth’s magnetic field. The different signatures of the two contributions

Figure 5. Schematic of the detection of the radio emission following a neutrino interaction (not to scale). The emission is strongest at the Cherenkov angle (blue cone) and can follow straight and bent trajectories to the receiving station depending on the profile of the index of refraction of the ice. The signal is usually detected at large distances and is strongly polarized as illustrated in the insets.

can be disentangled by their polarization. While still mostly linearly polarized, the main axis of the polarization from geomagnetic emission is aligned with the cross-product of shower axis and magnetic field [192, 193].

Due to their larger extent and the resulting consequences for coherence, air shower signals typically contain more low frequencies than those from showers in dense media [206]. Nevertheless, signals from air showers and denser in-ice showers are remarkably similar, which makes the much more abundant air shower signals a suitable calibration signal. Since the cosmic ray energy spectrum is well-known (e. g. [70]) and the radio energy scale understood [37, 207], measuring air showers will allow any detector to be calibrated *in-situ*, which includes checking the sensitivity simulations on an absolute scale. This will lend confidence to the signal identification and reconstruction [19].

The remarkable similarity can of course also be a reason for concern. The in-air signal will be (partly) refracted into the ice, where it may be picked-up by antennas and incorrectly identified as neutrino induced signal. While the signal will clearly be down-going, so may be signals from neutrino interactions, due to the ray bending properties of the ice [196]. It has also been argued that an incompletely developed air shower may cause transition radiation and other phenomena observable in deep detector stations [208]. In addition, stochastic energy losses by high energy muons in an air shower penetrating the ice may mimic the interaction of a neutrino [195]. Without additional detectors, the muons themselves are invisible to radio detectors, while the energy losses are detectable. Depending on the exact detector configuration and trigger, these background events may limit the analysis efficiency, albeit dropping sharply in number with energy.

Overall, this argues to equip all radio neutrino detectors with their own dedicated air shower array, for both calibration and veto purposes. Conveniently, due to the signal similarity, no additional

Figure 6. Simulated radio air shower footprints at 4 different incoming zenith angles. Simulations were performed using CORSIKA and the RNO-G site (magnetic field and height above sea level) in Greenland, and include the response of upward facing logarithmic periodic dipole antennas, as planned for RNO-G (see figure 7). The global maximum of the amplitudes in three antennas is shown. The air shower energy is 3.2×10^{18} eV for all showers, and the zenith angles are indicated in the figure.

technology is needed for such a detector, but does require additional surface antennas connected to the same data-acquisition system (DAQ). A dedicated air shower trigger, optimized to the lower frequency content of the air shower signals, would significantly enhance efficiency and detection rate. Due to the height of the interaction in the atmosphere and the fact that $n_{air} \approx 1.0$ co-aligns the emission with the shower axis, the detectable footprint of the radio signal from air showers is centered on the shower axis, with lateral extent distributed ellipsoidally on the ground, as shown in figure 6. The exact size is governed by the distance to shower maximum and the projection effect of the zenith angle [209]. The figure qualitatively illustrates that vetoing horizontal air showers will be relatively straightforward, while retaining high efficiency for vertical showers presents more of a challenge. The typical threshold for air shower detection is around 10 PeV, which is again similar to the threshold of in-ice detection.

3 Experimental design considerations

RNO-G is designed to demonstrate the scalability of the radio detection technology, while enabling the world's-best UHE neutrino sensitivity through low thresholds and also high efficiency. The system is designed to provide high fidelity identification of neutrino signals and reconstruction of neutrino properties. Building on these requirements, a station and array design as schematically depicted in figure 7 was developed.

Figure 7. Left: map of the planned RNO-G array at Summit Station; grid spacing is approximately 1 km. Right: a single RNO-G station consists of three strings of antennas (Hpol and Vpol) plus surface antennas (LPDAs), as well as three calibration pulsers located both deep in the ice and also at the surface. The string containing the phased array trigger is designated as the *power string*, while the two additional strings are designated as *support strings*.

The design of RNO-G combines the experience gained with all prior in-ice radio neutrino experiments, especially ARA [5] and ARIANNA [210], and also builds on lessons learned with radio air shower arrays that have first demonstrated the experimental power of the radio detection technique, e.g. [37, 38].

As outlined above, a location is needed with thick, homogeneous and cold ice to yield the best experimental results. An additional requirement is the availability of a sufficiently developed infrastructure to allow for installation, running and maintenance of the detector. While the instrumented stations can be fully autonomous, the amount of cargo and personnel needed for installation requires accessibility by plane or large vehicle. The number of accessible research stations fitting these requirements in either Antarctica or Greenland is limited. The host institutions of the RNO-G collaboration members and their access to national infrastructure additionally excludes some obvious candidate sites (Dome A, Dome C and Vostok in Antarctica, e.g.), leaving essentially South Pole Station and Summit Station in Greenland. South Pole station already houses a premier CMB instrument (the South Pole Telescope [211]), as well as the world’s largest neutrino telescope (IceCube), which is in the process of installing the IceCube-Upgrade [212]. The logistical burden is, thus, already high at South Pole.

If RNO-G is also to be used to develop and test hardware for the radio component of IceCube-Gen2 [1], a site similar to South Pole has advantages, if South Pole station is unavailable. Interesting coastal sites, like the Ross-Ice-Shelf close to McMurdo Station, which hosts the ARIANNA experiment [213], can assist in developing other technologies, but would be unable to replicate some of the particular challenges of South Pole.

To achieve a high trigger efficiency, a cosmic-ray veto, and the ability to reconstruct events with high accuracy, the RNO-G design combines a surface with a deep array capable of operating at low threshold (see figure 7). The collaboration will develop the necessary expertise for rapid installation with a minimum of logistical impact, enabled by newer, fast drilling technology and lightweight, low-power, autonomous stations that still achieve excellent single-station effective volume.

3.1 Summit station, Greenland

Going to Greenland also has some fundamental consequences for the design decisions. The Antarctic has been host to several pioneering arrays that aim to detect in-ice radio emission from UHE neutrinos. Through previous efforts, the Arctic has been established as a parallel site for a future radio neutrino observatory [41, 42, 214]. Summit Station offers several advantages as a testbed site. It is located at $72^{\circ}35'46''$ N, $38^{\circ}25'19''$ W at the peak of the Greenland ice cap, atop more than 3 km of glacial ice that we have measured to be remarkably radio transparent [41] at ~ 100 MHz, and with a ~ 100 m deep firn layer that we have preliminarily characterized [42]. It is a year-round scientific research station sponsored by the National Science Foundation. It has a snow runway that accommodates LC-130 Hercules flights to deliver cargo and personnel, and facilities on site to support science. Compared to sites in Antarctica, Summit Station (72° N Latitude) is easier to access from the Northern hemisphere, in particular through commercial flights from Europe, and has a larger fraction of the year with daily periods of light, providing a higher livetime for autonomous solar-powered stations. This final aspect is particularly important, given the reduced electrical generator infrastructure at Summit compared to South Pole. The restriction to renewable energies, combined with battery buffering limitations and the desire for high livetime, cap the amount of power the detector can draw and ultimately drive the station design.

Logistical considerations at Summit also favor a compact geometry with fewer, more sensitive stations rather than more, less sensitive stations. Similarly, the drilling technique must be lightweight and mobile and, therefore, mechanical.

The ASIG drill, which is able to drill 5.75'' diameter boreholes to 100 m at a rate of 1 hole per day, was initially considered as the main option [215]; subsequent antenna design was adapted to that form factor. Alternatively, the British Antarctic Survey (BAS) has been developing a mechanical drill that provides larger boreholes of 11.2'', which will allow for greater flexibility in antenna design. Both drills satisfy the drilling rate, hole diameter and logistical impact specifications. See section 5.1 for an in-depth discussion of drilling and installation.

To compensate for the warmer, more attenuating ice in Greenland compared to South Pole, triggering is performed with the deeper antennas, below the firn. Since no detector has detected the radio emission following a neutrino interaction yet, the exact experimental signature is predicted by simulations only, arguing for a detector design that detects the neutrino signal in a multitude of channels to increase confidence. It can be considered to adapt and simplify the detection strategy once the first neutrino has been conclusively identified.

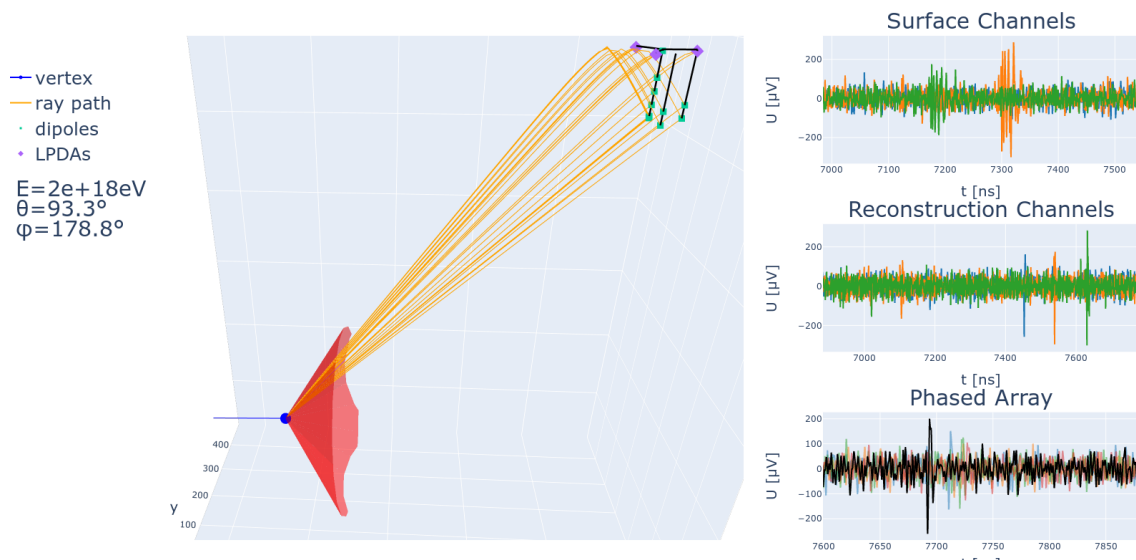

Figure 8. A simulated RNO-G neutrino event. The left side shows the event geometry illustrating both the direct and reflected ray-paths to the antennas, as well as the incoming neutrino and interaction vertex (blue) and its Cherenkov cone (red), where the strongest signals are expected. The right side shows the waveforms in selected antennas, and the improvement in signal-to-noise-ratio obtained by phasing the signals as done in the phased array trigger (shown in black, bottom row). This simulation and online event display utilize tools developed by the greater radio community [196, 216]. For better visibility, only selected channels are shown.

3.2 A low-power, low-threshold trigger and data acquisition system

The RNO-G stations are built around an interferometric phased array, similar to what has been demonstrated *in situ* at the South Pole on the ARA experiment [12, 214], achieving the lowest sustainable signal trigger threshold demonstrated in the field. Since the astrophysical neutrino flux shows a falling spectrum, improved sensitivity to lower-energy events dramatically increases the detected neutrino event rate. The phased-array technology has been adapted for RNO-G to provide similar sensitivity, albeit with a reduced power consumption.

The phased array trigger coherently sums single channel waveforms with time delays corresponding to a range of angles of incident plane waves, improving the trigger-level signal-to-noise ratio roughly linearly with the number of antennas in the array [12], as illustrated in figure 8. Projecting the performance of the existing ARA system, we expect to achieve an elevation-averaged 50% trigger efficiency point at a $2\sigma_{\text{noise}}$ threshold in voltage. This low threshold is needed to observe the largest volume of ice possible as discussed in section 2.5.

It should be noted that for the simulations, the following definition for signal-to-noise ratio (SNR) and noise is handled. SNR is defined as the amplitude of the noiseless signal over the standard deviation σ_{noise} of a pure noise waveform. A threshold of $2\sigma_{\text{noise}}$ thus means a threshold of twice the standard deviation of a trace without signal.

3.3 Detector geometry: an integrated approach with deep and surface components

After extensive trade studies, we have coalesced on a station design that integrates a deep component with a surface component, as shown in figure 7. This integrated design achieves the highest effective

Figure 9. Scaling of the effective volume as a function of the depth of antennas used for the phased-array trigger for a single station deployed at Summit Station. 100 m was used during the design process as the technological limit due to drilling restrictions. As the trigger antennas are placed deeper into the ice, the effective volume increases, due to the number of allowed ray trajectories in the ice. The curves have been obtained using a $2\sigma_{\text{noise}}$ dipole proxy for the phased array. Shown are statistical uncertainties only. Below 10 PeV the uncertainties on the effective volume become too large to draw firm conclusions.

volume per station given the phased-array trigger and mechanical drilling technology to 100 m. As shown in figure 9, the effective volume per station increases with increasing depth, so our design places the deep component of the station as deep as is logistically feasible, given the current constraints of drilling.

In addition to maximizing effective volume, the station design has been optimized for neutrino reconstruction efficiency. The string containing the phased array trigger will feature additional Vpol antennas almost equally spaced vertically along the string allowing us to pin-point the neutrino vertex and zenith angle of the signal arrival direction, and achieving high accuracy by exploiting azimuthal symmetry. Since the down-hole Vpol antennas are typically more sensitive than the Hpol antennas and the trigger selects signals having a measurable component in the vertical polarization, the Vpol antennas dominate vertex and signal arrival direction reconstruction. Adding two Hpol antennas above the phased array will allow us to improve the reconstruction of the full electric field. Combining the four Vpol antennas of the phased array with the two Hpols in proximity, should provide sufficient information to reconstruct the polarization of the signal, as well as its frequency slope, and thereby the off-Cherenkov signal angle and neutrino arrival direction.

The radio signal from a neutrino interaction often travels along direct, refracted or reflected paths (designated DnR) to the deep array, as shown in figure 8. The characteristic double pulse would be a smoking-gun signature of an in-ice source. The difference in direct and refracted arrival times significantly improves the reconstruction of the neutrino vertex position, and thereby the shower energy, as well as arrival direction [21]. The probability to observe both a direct and a reflected signal is depth dependent. The spacing of the Vpol antennas on the main string is the result of an optimization between double pulse detection and long lever arm for good angular reconstruction.

The two additional deep boreholes are needed for a full direction reconstruction. Three independent measurements are needed for azimuthal information, which is provided by the Vpol antennas. By placing the Hpol antennas at different depths on every string, both zenith and azimuth information will be provided for those signals with a strong horizontal polarization component, as well as increasing the probability to reconstruct a signal for those events with little signal strength in the horizontal component.

The additional strings also host the calibration pulsers, which will ensure regular monitoring of the performance of the station and provide information useful for precise calibration of the antenna geometry. In addition, a surface pulser is foreseen, which will be deployed in a hand-drilled hole below the surface.

The surface component will deliver precision polarization measurements and timing information for all events detected at the surface. Also, the broad-band sensitivity of the log-periodic dipole antennas (LPDAs) will broaden the frequency coverage of the detector, which helps determine the radio detection angle with respect to the Cherenkov cone, improving energy reconstruction and pointing resolution. Events detected only in the surface components, however, only add minimally to the total neutrino effective volume.

With the planned layout, any events observed in coincidence between the surface component and the deep component are particularly valuable for event reconstruction; the fraction of these events is discussed in section 3.4. In addition, the surface channels serve as an efficient air shower veto, reducing the background for neutrino searches as will be discussed in the following section.

The stations will be deployed on a square grid with 1 km baseline. This means that at energies beyond 1×10^{18} eV the effective volumes of the stations start to overlap and coincident measurements of the same neutrino become likely. This can be seen from figure 10, where the fraction of events triggered in coincidence is shown for different neutrino energies and grid spacings. While limiting the total effective volume of the system, 1 km was chosen to restrict the logistical impact in installation and preserve the opportunity of coincident events, which will simplify event identification and provide excellent reconstructed properties. As the project advanced, one may consider spacing stations further apart.

3.4 High analysis efficiency and low background to enhance discovery potential

In addition to triggering on and extracting event parameters from neutrino events, we must be able to separate any neutrino events in our recorded data set with high efficiency from all backgrounds. The three major sources of background are incoherent thermal noise, impulsive anthropogenic noise, and radio impulses resulting from cosmic-ray air showers. A discovery experiment of this scale requires low backgrounds at the level of 0.01 per station per year (or less). RNO-G is designed to achieve this ambitious background level by building on two key measures that have been developed to ensure event purity.

- (1) Triggering from deep in the ice (at a depth of 100 m), where the backgrounds are smaller than at the surface: ARA has shown that the anthropogenic and thermal backgrounds decrease for receivers deployed deeper in the ice [217] and further from human activity at research stations, achieving a background on the most recent analysis of 0.01 events in two stations over

Figure 10. Fraction of coincident triggers on nearby stations as a function of the grid distance between stations for different neutrino energies. In addition to the 100 m deep power string, the coincidence fraction expected for a trigger near the surface is given for comparison.

1100 days of livetime [4]. This shows that successful background rejection can be achieved also during the summer at South Pole when anthropogenic backgrounds are more significant.

- (2) Vetoing backgrounds using a surface detector component: non-thermal backgrounds are introduced from the surface or from close to the surface by man-made sources or air shower remnants. Surface antennas will help to separate neutrino induced signals originating within the ice from those of air showers [208] and those from showers caused by catastrophic energy losses from atmospheric muons [195].

Neutrino events triggered near threshold in the phased array system carry the risk to have low SNR in antennas needed for reconstruction. The information content in different numbers of antennas is illustrated in figure 11. Three channels detecting a signal $>3\sigma_{\text{noise}}$ is taken as a simple proxy for events that can be identified and reconstructed with currently available analysis techniques such as interferometry [218], template matching [7] and signal de-dispersion [23]. With a signal in the antennas of the phased array as well as in an antenna on the support string, it is possible to reconstruct the neutrino arrival direction (see section 6.3). To reconstruct the shower energy, at least 3 of the reconstruction antennas on the *power string* need to detect a pulse so that the distance to the interaction vertex can be reconstructed (see section 6.2). In some cases, the radio signal is reflected off the ice-air interface or diffracted downwards, so that two signals from the same shower can be detected. These so-called *DnR pulses* become more likely with higher neutrino energies and can be used to greatly improve the reconstruction accuracy. More details on reconstruction and resolution is given in section 6.2 and 6.3. Foreseeable advances in analysis techniques will further improve the efficiency near threshold, both in firmware and also in off-line analysis.

An accurate knowledge of the existing background is needed in order to project what fraction of triggers are due to non-neutrino backgrounds, and also to assess whether a veto mechanism is

Figure 11. Estimate of anticipated analysis efficiency, defined here as the fraction of events recorded in a pre-defined number of antennas (channels) above a given threshold. The left figure illustrates detections in the deep part of the array only. A detection in the support string (see figure 7) will allow for a reconstruction of the arrival direction of the signal and three antennas on the power string are needed for a vertex reconstruction. The right figure shows the fraction of DnR signals, which are particularly valuable for the vertex reconstruction and the fraction of very valuable events measured in both the deep array and the surface antennas. For these simulations we assume a trigger at $2.0\sigma_{\text{noise}}$ trigger in the phased array.

advisable (or mandatory). An important type of background which is difficult to distinguish from actual neutrino events is the background created by the energy losses from atmospheric muons from cosmic ray showers. These muons are produced in the atmosphere, continue their propagation into the ice; their subsequent interactions (mainly bremsstrahlung, photonuclear interaction, and pair production) create hadronic and electromagnetic showers that emit radiation and are therefore detectable by an in-ice radio array [219]. These muons share shower characteristics, arrival directions and vertex positions with the sought-after neutrinos (see [195]). We have calculated the number of expected muon-initiated showers for a 35-station array at Summit Station, using a 100 m-deep dipole with an amplitude threshold between $1.5\sigma_{\text{noise}}$ and $2.5\sigma_{\text{noise}}$ as a proxy for the phased array. The effective areas have been calculated using NuRadioMC [196] and its interface to PROPOSAL [220]. Then, these effective areas are convolved with the expected muon flux at the detector, calculated by MCEq [221]. The chosen cosmic ray flux model is the Global Spline Fit from [222]. This procedure is explained more in detail in [195]. The results are presented in figure 12, where each band represents the results for a hadronic interaction model. Shown are the expected number of detected muons for the phased array proxies (from 1.5 to $2.5\sigma_{\text{noise}}$) and also the 68% CL interval for the uncertainty due to cosmic ray flux, hadronic modeling and effective area. Figure 12, left, contains the expected detected number of muons per year for 35 stations as a function of shower energy, while figure 12, right, presents the same results as a function of cosmic ray energy.

The lower and upper bounds on the number of detected atmospheric muons per year for a 35-station layout, as well as the average number for a $2.0\sigma_{\text{noise}}$ trigger, can be found in table 1. While these values are relatively benign, we remind that the neutrino event rate may be equally low,

Figure 12. Number of atmospheric muons detected by a 35-station array at Summit Station. The phased array is modeled with dipoles having amplitude thresholds varying from 1.5 to $2.5\sigma_{\text{noise}}$, at 100 m of depth. Each color represents a different hadronic model, as specified in the legend. The bands include the range of expected events for the different simulated thresholds as well as the 68% CL contour corresponding to the effective area uncertainty. Left: number of detected atmospheric muons per year as a function of shower energy. Right: same results, presented as a function of cosmic ray energy. The drop off at low energies is an artifact of only simulating muons down to 1×10^6 GeV.

	$2.5\sigma_{\text{noise}}$ 68% CL LB	$2.0\sigma_{\text{noise}}$ average	$1.5\sigma_{\text{noise}}$ 68% CL UB
SIBYLL 2.3C	0.212	0.296	0.684
EPOS-LHC	0.129	0.173	0.444
QGSJet-II-04	0.031	0.044	0.180

Table 1. Number of detected atmospheric muons per year for a 35-station layout. Three hadronic models are shown. The numbers shown are the lower 68% CL lower bound for a $2.5\sigma_{\text{noise}}$ trigger (first column), the average values for a $2.0\sigma_{\text{noise}}$ trigger, and the 68% upper bound for a $1.5\sigma_{\text{noise}}$ trigger. See text for details.

at least at the threshold energy of the detector. Hence, the air shower self-vetoing on the detector deserves special attention, as well as the development of algorithms using event parameters such as arrival direction and vertex location to disentangle neutrino signals from those potential background events. Also, since the flux and composition of cosmic rays at the relevant energies is subject to large uncertainties, those same uncertainties propagate into the background prediction for radio arrays.

4 The RNO-G instrument design

RNO-G will provide high-quality science data and a robust, low trigger threshold with minimal power consumption using a station design schematically depicted in figure 13. In nominal operating mode, a station will use 25 W, including DC-DC converter losses. All equipment is rated to operate at -40° C and 3200 m altitude.

4.1 Antennas

The initial downhole antenna designs are driven by the 5.75'' diameter of the boreholes (ASIG drill [215]), with some modifications possible, if bigger boreholes are available (see section 3.1.

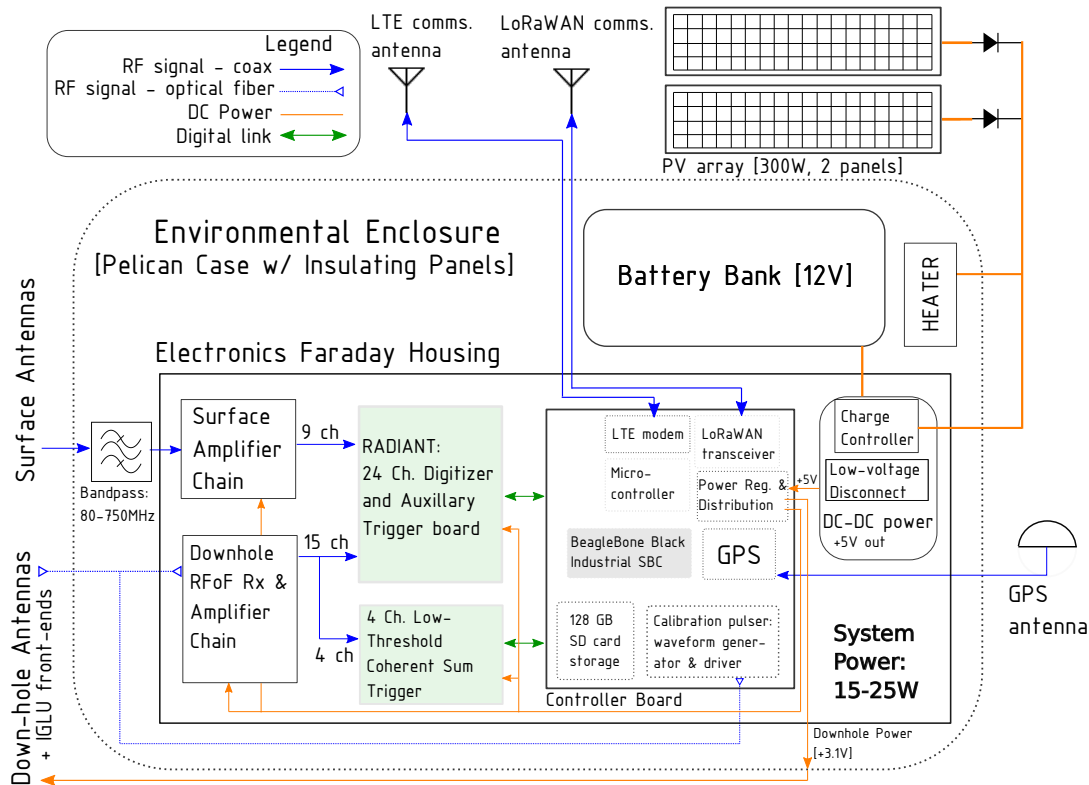

Figure 13. System diagram for an RNO-G station. See text for details.

The vertically-polarized (Vpol) antennas will be a *fat dipole* design (see figure 14) previously used in neutrino detection experiments, which have an azimuthally symmetric beam pattern and usable bandwidth ranging from 150-600 MHz [2, 214]. For horizontal polarization (Hpol), cylindrical *tri-slot antennas* are considered. They are nearly azimuthally-symmetric in gain, with differences of less than 1 dB up to 800 MHz, which corresponds to differences of less than 12% in effective length. Only Vpol antennas are used for the trigger because the Hpol antennas inherently have narrower usable bandwidth than the fat dipoles, as shown in figure 15. With the current Hpol designs, there is enough overlap with the Vpol band to combine the signals for polarization reconstruction in analysis. Larger boreholes (RAID drill) will especially help improve the broadband characteristics of the Hpol antennas. It is under consideration to exchange the tri-slot design for 8" quad-slot antennas, which will have a lower frequency turn-on and improved gain characteristics taking advantage of the larger allowed diameter.

The surface component employs commercially available log-periodic dipole antennas (LPDAs, Create CLP-5130-2N), successfully used by the ARIANNA experiment. ARIANNA's extensive in-field experience with these antennas will significantly simplify calibration. Owing to the high gain allowed without the borehole constraints, the nine LPDAs arranged in various orientations (see figure 7, right) will measure all polarization components with high-precision, and provide a clear separation of upgoing versus downgoing signals. Due to their size the LPDAs have the largest gain of all employed antennas and will provide the greatest frequency coverage for the detected signals.

Figure 14. Photo of a Vpol prototype (top) and technical drawings of options for the Hpol antennas (trislots, middle, quadslots, bottom). The Vpol and trislots are the first iterations of the deep antennas for RNO-G, while the quadslot is being considered for use in conjunction with larger diameter boreholes.

Figure 15. Antenna effective length magnitude for the LPDA, Vpol and Hpol (tri-slot) in the direction of maximum gain H_θ (V-pol and LPDA) or H_ϕ (H-pol). Results of detailed antenna simulations of the v1 iterations as shown in figure 14.

Particular care will be taken to placement and alignment of the LPDAs in the trenches at the surface, as well as surveying the position of boreholes and antenna locations to ensure good starting values for the system calibration using the *in situ* pulsers.

4.2 Radio-frequency front-end design

To minimize system noise temperature, the feed of each antenna deployed in the borehole is connected with a short coaxial cable to a downhole front-end (figure 13), where a Low-Noise Amplifier (LNA, type IGLU, see figure 16) boosts the signal strength. To prevent a significant gain slope from long lengths of copper coaxial cable, each front-end contains a Radio Frequency over Fiber (RFoF) transmitter. The RFoF link and LNA are both powered by a DC connection from the surface, which is the only through-going coaxial cable in the boreholes. The LNA and RFoF are custom designs optimized for minimal noise temperature (≤ 150 K) and low power. Each downhole channel consumes 140 mW, compared to 2.5 W in the previous installation of the phased-array in ARA. A total of 15 downhole antennas are distributed across three boreholes.

After being transmitted over fiber, the signals are received by another set of amplifiers in the DAQ box (type DRAB, see figure 16) and converted back to analog signals. At the DAQ box, the signals from the surface channels are also received and amplified. Given the relatively short run of coaxial cable from the LPDAs to the DAQ box of less than 20 m, the signals require only one amplification stage after being fed into the DAQ box (type SURFACE, see figure 16).

All amplifiers are placed in custom-designed RF-tight housings using iridized aluminium (chromate conversion coating). This significantly reduces the influence of noise on the amplifiers and protects the IGLU amplifiers in the boreholes from the environment. The amplifiers exhibit excellent uniformity in laboratory tests (see figure 17). Nevertheless, all amplifiers will be calibrated individually to reduce systematic uncertainties on the reconstructed signals.

4.3 Triggering, digitization, and data acquisition

The main trigger of RNO-G will come from a phased-array at depth of 100 m. The design of the field-proven phased-array installed at ARA [12] had to be changed to accommodate the lower power requirements of autonomous stations and was optimized with respect to the neutrino signals typically expected in Greenland and with respect to per-item cost for the scalability of the array.

The primary trigger will thus be a coherent-sum and beam-forming trigger from a compact array of four vertically-polarized antennas installed at the bottom of the main borehole string at a depth of 100 m. A commercially available 8-bit 500 MSa/s ADC is used to digitize and continuously stream data to an FPGA. This reduces the effective band to operate at the low-end of the signal bandwidth, 80 MHz–250 MHz. The lower cut-off is determined by the amplifier design that takes advantage of the full-range of low-frequency power that the antenna delivers.

Eight beams will be formed that cover the full range of expected signal arrival directions. Compared to the previous phased-array implementation in ARA there will be fewer beams, but each of them wider, thus no angular coverage loss is incurred. Overall, the power-savings total to about a factor of 10 for the trigger board, using 4 W in full operation mode.

A single-antenna voltage threshold of $2\sigma_{\text{noise}}$ can be achieved with this trigger, based on simulation studies as shown in figure 18. The smaller bandwidth reduces the SNR of on-cone

Figure 16. Amplifiers as designed for RNO-G. Left: SURFACE amplifiers for the signals coming from the LPDAs via coaxial cable. Middle: an IGLU board (In-ice Gain with Low-power Unit) used to convert signals from antennas deep in the ice to analog RF signals and then feed them into the indicated fiber. Right: DRAB board (Down-hole Receiver and Amplifier Board) located within the station housing. All amplifiers are shown without their environmental enclosures.

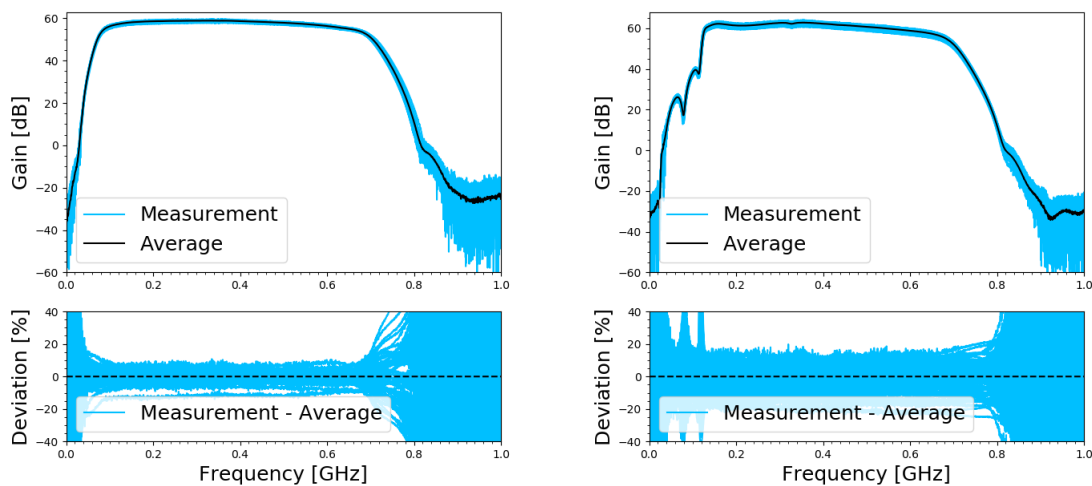

Figure 17. Gain of the RNO-G amplifiers. Left: 12 SURFACE amplifiers. Right: combination of 23 IGLU and DRAB amplifiers, including a 50 m optical fiber cable. All amplifiers are revision v1 hardware.

Figure 18. End-to-end simulation of the 4-antenna phased array trigger design for RNO-G. The simulated trigger efficiency for a number of neutrino signals at different off-cone viewing angles in the trigger bandwidth of 80 MHz–250 MHz.

signals (i.e. 0.5 deg in figure 18) by 10%, however, increases the SNR for off-cone events by up to 80%, thereby incurring very little loss on the absolute neutrino effective volume. This is due to the limited high-frequency content of off-cone neutrino signals (see also figure 4).

The full-band waveforms for all 24 antennas within a station will be digitized using the Radio DIgitizer and Auxiliary Neutrino Trigger (RADIANT) board (figure 19). The single-channel LAB4D switched-capacitor array sampling ASIC is used for waveform recording at a rate up to 3.0 GSa/s with an adjustable record length up to ~ 700 ns and the capability for multi-event buffering on-chip [223]. For RNO-G it is planned to operate the LAB4D in 2x 2048-sample buffers for essentially deadtime-less performance.

A trigger decision can be made using input from the primary neutrino trigger board (phased-array) or an auxiliary on-board trigger using similar Schottky diode detector circuits. The auxiliary on-board trigger is formed using a comparison between a DC voltage level and the enveloped waveform, which is fed to the on-board FPGA to build a combinatoric trigger decision. As the auxiliary trigger will have a higher overall threshold than is possible with the primary neutrino trigger board, it will predominately be used as additional trigger for the surface antennas as an air shower trigger. In periods in which the power available to the stations is low (see section 4.4) it can serve as main trigger, however, with a much weaker sensitivity to neutrino signals.

Once an event is digitized, the waveforms and metadata are transferred to a BeagleBoneBlack Industrial, an ARMv71 Linux system, over a Serial Peripheral Interface (SPI) link, which allows data transfer at up to 20 Mbps. The operating system and acquisition software are stored on robust eMMC storage, while a 128 GB industrial SD card stage data before it is transmitted wirelessly to Summit Station. The acquisition software is an evolution of field-proven ARA phased array acquisition software.

Figure 19. First iteration of the Radiant Board that will be the main DAQ of RNO-G. All 24 channels are accommodated on one board and read out by LAB-4D chips.

4.4 Autonomous power and wireless communications

Autonomous power and wireless communications simplify logistics for an experiment of this scale and become even more efficient for even larger arrays, such as IceCube-Gen2. Each station will be powered by two solar panels, with a total maximum power output of 300 W, and a 5 kWh sealed lead-acid battery bank that provides three days of full-system (24 W) running capacity during cloudy or inclement conditions, with a 60% de-rating margin. Lead-acid batteries, when lightly discharged relative to total capacity, have a proven track record in Arctic environments as demonstrated by the UNAVCO remote stations [224]. The daily solar energy delivered to a RNO-G station using a 300 W solar panel array is shown in figure 20, using realistic estimates of 70% total sun fraction (including diffuse and snow-reflected contributions) and a 90% charge-controller efficiency. A low-power microcontroller (μC) will manage the power system and turn parts of the detector on and off as necessary. The μC communicates with the Beaglebone SBC via a serial connection so that the SBC may be shut down cleanly if necessary. Enough power granularity is available to run the detector in a low-power, lower-sensitivity mode if needed.

The RNO-G station can be operated in several different modes depending on the available solar power capacity, in order to maintain constant science data during long stretches of inclement weather and during the shoulder seasons, when the sun only rises above the horizon for short periods per day. These operating modes include:

1. **Full-station mode:** power, trigger, and data acquisition on the full 24-channel station including the low-threshold trigger and full LTE data telemetry. Power: ~ 24 W.

Figure 20. Predicted daily energy delivered by a 300 W photo-voltaic (PV) array to an RNO-G station at Summit Station. The PV array comprises two Ameresco 150J rugged panels mounted vertically and facing south. The total PV area is 2 m².

2. **High-threshold mode:** power, trigger, and data acquisition on the full 24-channel station without the low-threshold trigger and minimal LTE data telemetry. Power:~17 W.
3. **Surface-only mode:** power, trigger, and data acquisition only on the 9 surface LPDAs and minimal LTE data telemetry. Power:~6 W.
4. **Winter-over mode:** operating mode during the polar night. All power is turned off except to the charge-controller, LoRaWAN network, and station-control microcontroller. Only minimal housekeeping data is telemetered over LoRa. The estimated power draw is ~70 mW.

The expected uptime for an RNO-G station at Summit Camp with the 300 W PV panel array is 216 days in operating mode 1 (59%), 25 days in mode 2 (7%), and another 20 days in mode 3 (5%) for a total science livetime of ~70% averaged over the year. For the remaining 30% of the year, the station will be put in winter-over mode. These different operating modes can be engaged by the RNO-G station controller autonomously or commanded remotely over one of the wireless networks.

Options to operate further into the winter are being explored. This R&D is particularly relevant for a potential larger array at the South Pole such as IceCube-Gen2, where the polar night is longer. Although not part of the baseline RNO-G design, wind-turbines may allow to extend the full-station mode operations of RNO-G throughout the winter. Development of radio-quiet wind turbines that can survive in the polar environment is ongoing [18]. Modeling using historical wind data [225, 226] suggests that a feasible 25%-efficient turbine at a height of 10 m would produce a daily average of 1200 Wh per square meter of collection area. Due to extended periods of low wind speeds a larger battery buffer will be needed for operation on wind power.

The main data transfer link from each detector to Summit Station will use modern cellular technology. A private LTE network provides high bandwidth (up to 75 Mbps total uplink) and long range while consuming minimal power (<1 W average) at each station. A commercially-sourced

Figure 21. The station solar charge controller and high-efficiency DC-DC board for RNO-G.

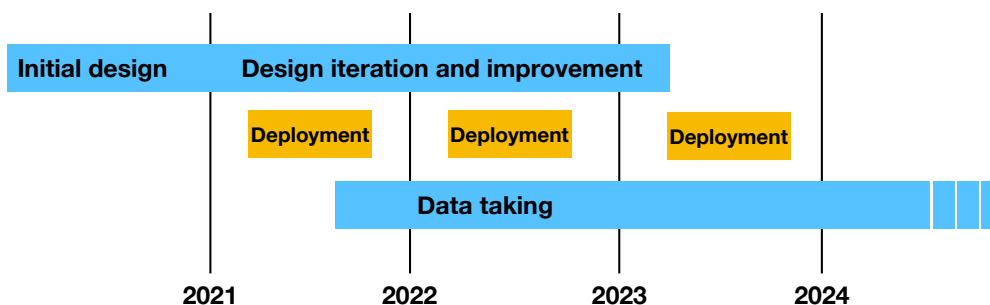

Figure 22. The anticipated timeline of RNO-G. The initial design work is ongoing. Installation will take place in the summer of 2021, 2022, and 2023, tentatively scheduling the installation of 10, 10 and 15 stations, respectively. Data taking will commence with the first deployed station.

LTE base station will be deployed with an antenna on the roof of the Science and Operations Building at Summit Station. As a compromise between range and minimizing interference with our detectors, LTE Band 8 (880-915 MHz uplink, 925-960 MHz downlink) was chosen and a permit has been acquired from the Greenlandic Radio Administration. Link modeling, including terrain shielding and a 10 dB fading margin, predicts a usable range up to 10 km.

A 34-dBi roof-top sectorial antenna at Summit can cover the azimuthal extent of the array and each station will be equipped with a 9 dBi antenna on a 3 m mast. A secondary LoRaWAN [227] network will also be deployed, providing a backup low-power but low-bandwidth connection for control and monitoring.

5 Installation, calibration, and operations

The anticipated timeline of the construction of RNO-G is shown in figure 22. The initial design work is already on-going and a first installation of stations is anticipated for 2021, provided that there are no continued restrictions due to the COVID-19 virus.

5.1 Drilling and installation plan

The main tasks for installation of each RNO-G station are:

1. drill boreholes for deep instrumentation,
2. deploy the solar panels and communications,
3. deploy detector instrumentation in boreholes and trenches,
4. confirm station operation and take calibration data.

The baseline RNO-G scenario assumed use of the ASIG mechanical drilling technology. The ASIG drill, owned and operated by the US Ice Drilling Program (IDP) is an auger with add-in drill sections. One 100 m deep hole requires a single working shift of 10 hours for three people. Therefore, the three holes required for each RNO-G station can be drilled in three days assuming one work shift per day, or one and a half days assuming two work shifts per day.

The preferred drill under consideration is the Rapid Access Isotope Drill (RAID) from the British Antarctic Survey (BAS). Holes of the diameter of 3 '' were successfully drilled to 461 m at Little Dome C. For RNO-G larger diameter holes are needed, which is why an existing proto-type development BigRAID is being considered [228]. It will provide 285 mm or 11.2 '' holes, taking about 0.85 days to reach 200 m or 0.38 days to reach 100 m, making it both faster and more versatile than the ASIG drill.

Using a mechanical drilling approach is much more scalable than previous drilling efforts for the ARA experiment at the South Pole, which used a hot water drill to reach 200 m depths. Mechanical drills are significantly lighter weight and less complex. Future development in drilling technology may enable exploring a wider range of more aggressive designs with RNO-G, which may lead to further improved sensitivity or event reconstruction capability. Drilling below the firn layer may provide significant increases in field-of-view due to fewer limitations in ray bending. However, care needs to be taken that any drill remains fast enough so as not to be the rate limiting step in installation and that personnel to operate the drill remains limited. Partly autonomous drilling operation is also under consideration.

Although subject to considerations such as firn thickness (which impacts drill depth) and ice temperature, local snow accumulation rate, average daily temperatures and the availability of solar and wind power, the station design is purposely general. This allows easy adaptation of the design for future larger in-ice arrays at other sites, such as IceCube-Gen2 at the South Pole.

The installation of both infrastructure (solar panels and communication antennas) and instrumentation is anticipated to be faster than hole-drilling. A drilling and installation team of seven people is foreseen for the first installation season, with installation beginning a week after commencing drilling. We project that an installation of up to 20 stations a year at Summit Station seems feasible. After installation, additional time will be required in the field to commission and validate station operation.

5.2 Calibration requirements and strategies

In order to optimally reconstruct events, the relative antenna positions must be known to a small fraction of the wavelength. Calibration using a local radio transmitter is necessary to achieve the

Figure 23. RNO-G installation plans are based on prior deployments of (a) surface stations at ARIANNA and (b) strings of antennas deployed in boreholes for ARA, both in compact phased arrays and reconstruction strings. A deployment shed for the drill and installation will be built on skis based on prior work done for ARA (c). Site studies conducted at Summit Station in Greenland also informed the installation plans (d).

required few-cm precision. Two deep transmitting antennas will be included with each station, as well as one at the surface. The calibration signal is generated in the surface controller board and sent downhole over RFoF. By measuring the relative time delays of the signal at each receiving antenna, the positions may be determined. After initial calibration, occasional runs of the pulser serve as a check of system stability.

An existing 740 m deep nearby borehole (DISC) [229], will also be used to send pulses to the array from various depths. This serves as a check of the antenna position and, by varying the depth of transmission, allows inversion of the radio properties of the ice. Understanding the refractive index profile of the firm is key to reconstruction and sensitivity modeling. Additional pulsing from the surface will be performed to further understand the ice.

Every station is equipped with a GPS, which will be used to synchronize event timing between stations at the 10 ns level. This is especially important for analyzing extensive air shower events, multi-station neutrino events and for absolute time difference measurements useful for ice studies. The GPS will also track the movement of station locations with the ice flow, which will provide valuable input for ice-modeling. A higher timing precision between stations can be obtained if suitable transmitters are identified at site [230] or through the usage of airplane signals [231]. This may also allow the combined reconstruction of neutrino signals detected in multiple stations [195], which would then yield improved precision.

All S-parameters of amplifiers, cables, and components will be calibrated before installation. Experience from radio air shower arrays has shown that a measurement of all individual components, including a temperature-dependent gain correction will be crucial to reduce systematic uncertainties. A continually-updated MongoDB database fully integrated with the simulation and reconstruction software [196, 216] will be used to track the parameters of all components.

5.3 Operations and data systems

The acquisition software on the Single-board computer (SBC) adjusts the trigger thresholds to maintain as fast a trigger rate as possible ($\mathcal{O}(10\text{ Hz})$) without incurring significant downtime. This high sustained rate drives system performance downstream, so second-stage filtering is applied

on the SBC to reduce the rate of saved triggers to a time-averaged 1 Hz. Additionally, 0.1 Hz of forced-trigger data will be recorded at regular intervals to help characterize the noise environment.

The on-disk compressed size of each event is an estimated 30 kB, implying an average data rate of around 260 kbps per station at 1.1 Hz. The LTE network can easily accommodate this rate with a relatively low duty-cycle at each modem, thereby saving power. This rate allows storage for six weeks on the local SD cards in the event of an unexpected network outage. If more time is needed, the station can be instructed via LoraWAN to reduce the rate. In the unlikely case of simultaneous LTE and LoraWAN failure, the software on the station will automatically throttle the rate. Once data is transmitted to Summit Station, it will be stored on a redundant disk array for collection each summer. At the estimated 1 TB/station/per year of data, full build-out requires a redundant storage capacity (with margin) of 35 TB, which can easily be achieved with a single commodity rack server (e.g. Dell PowerEdge R7515).

All instrument status data and event metadata as well as a subset of the waveform data (5 GB/day total) will be transmitted with low latency via Summit Station’s satellite link to the University of Wisconsin for monitoring and quality assurance. A small portion of available bandwidth will be reserved for remote login for any configuration changes or remote maintenance required. The JADE software [232] successfully developed and deployed for IceCube data management will be used for RNO-G. For data acquisition performance, all data is initially stored in a compressed packed-binary format resembling the in-memory format used by the data acquisition system. Converters will be maintained from the raw data format to more convenient archival formats (e.g. HDF5).

All low-latency data will be readily available to the collaboration via an interactive monitoring web site.¹ A comprehensive set of checks on the metadata and system health will be performed by the computer systems at Summit Station. Any anomalies will result in an email alert.

Monitoring duty will be apportioned to institutes on a rotating basis. While monitoring, an institution is responsible for timely investigation of all alerts and daily checks of the low-latency data for potential issues. Weekly monitoring reports will be issued to provide historical context for any issues that may arise.

Several mock stations, taking pure thermal noise data from terminated amplifiers, will be operated at collaborating institutions. These provide a testing ground for any configuration changes, assist with training, and help debug any issues that may arise. The pure thermal noise data also serves as a useful tool in developing analyses.

6 Projected sensitivity of RNO-G

In order to calculate the sensitivity of RNO-G, we have simulated the full 35-station array with a detailed modelling of the baseline hardware. Simulations for radio detectors are constantly evolving, incorporating experience from air shower simulations [38, 233–235] and previous codes for neutrino radio detectors [217, 236–238].

All simulation results presented herein have been performed with the NuRadioMC code [196]. For the same emission model, ice model and detector quantities, the results of this code have been shown to agree to the percent level with previous and independent codes, both for single event

¹Based on <https://github.com/vPhase/monutor>.

signatures as well as for the calculations of effective volumes. It has been found that the trigger-level sensitivities are in particular affected by the precise implementation of the trigger, the exact frequency band of the detector, the noise temperature of the system, the chosen emission model describing the Askaryan effect, whether a complete array is simulated or the array is scaled up from one station (impacting the number of events detected by multiple stations), and whether the interactions of secondary particles (taus and muons) are included in the sensitivity calculation. The latter three factors are most significant, with variations up to 50% in effective area depending on the energy. Since, in the design process, many of the instrument parameters are not completely fixed, we carefully quote in the following the assumptions made for the array and the hardware, bearing in mind that these design sensitivities are subject to change as the instrument design matures.

For the simulations, we use as a simplified proxy for the trigger in section 4.3, a single vertical dipole per station with an amplitude threshold. A range of thresholds was used from $1.5\sigma_{\text{noise}}$ to $2.5\sigma_{\text{noise}}$ to account for possible variations in the exact design of the phased-array. Currently, $2.0\sigma_{\text{noise}}$ is the expected to be the best proxy for the phased-array trigger using 4 dipole antennas that is in production (see figure 18). Dipoles are simulated at 100 m of depth, roughly at the same depth as the planned phased array.

We have simulated the response of a dipole of 50 cm length similar to the one in figure 14 and used it for the sensitivity calculation. The simulations performed with XFDTD [239] provide full gain and phase information as a function of incoming signal direction.

We have used NuRadioMC [196] with the *ARZ2020* parameterization given in [197, 240] as our model for signal emission. We have included triggers induced by secondary particles produced by the outgoing lepton after a charged current (CC) interaction, following the procedure outlined in [195]. The simulated station layout is that shown in figure 7, with 35 stations having 1 km spacing between them on a rectangular grid.

We first discuss the sensitivity of RNO-G to a diffuse neutrino flux and how the neutrino energy will be determined, then its angular sensitivity and lastly the sensitivity to a transient event. We will also briefly report on the expected sensitivity to air shower signals.

6.1 Sensitivity to diffuse flux

Figure 24 shows the expected 90% CL upper limit to an all-flavor flux for 5 years of operation of the full 35 station array, assuming a 67% duty cycle, as expected under only solar power. This is using effective volumes for an isotropic all-sky flux and full-decade energy bins. See [196] for more details on the V_{eff} calculation, and the inclusion of the interaction length to convert from A_{eff} to V_{eff} .

We have applied the Feldman-Cousins method [243] for no detected events and zero background. The zero background assumption is justified as a first approximation, as according to table 1, we expect ~ 0.58 detected muons over the full energy range for five years of operation time (using SIBYLL 2.3C for signal generation and a $2\sigma_{\text{noise}}$ proxy).

The expected upper limit is shown in figure 24 along with other experimental bounds and model predictions. The red band shows the expected range of 90% CL upper limits for noise levels varying from $1.5\sigma_{\text{noise}}$ -equivalent trigger (lower part of the band) to $2.5\sigma_{\text{noise}}$ -equivalent trigger (higher part), and includes 95% CL contours due to the effective volume uncertainty. The black band shows the obtained 90% CL sensitivity for a $2.0\sigma_{\text{noise}}$ -equivalent trigger, which is the most realistic assumption for the RNO-G experiment. We also show in figure 24 the sensitivity for a

Figure 24. The five-year sensitivity (90% CL upper limits) of RNO-G to the all-flavor diffuse flux for 35 stations (assuming the stations are active two thirds of the total time), compared with existing experiments and several predicted fluxes [4, 23, 241, 242]. The red band represents the differential sensitivity band for a range of phased array proxies, spanning the interval from $1.5\sigma_{\text{noise}}$ to $2.5\sigma_{\text{noise}}$ using decade energy bins. 95% CL contours are represented by the orange band. The black band is the sensitivity expected for a $2.0\sigma_{\text{noise}}$ trigger, including 95% CL contours. The purple band depicts the expected integrated sensitivity (90% CL upper limits) for an IceCube-like flux, over the $[1.5\sigma_{\text{noise}}, 2.5\sigma_{\text{noise}}]$ trigger range.

single power law spectrum with exponents in the range indicated by the flux observed in IceCube. The purple band represents the upper limit for the IceCube flux spanned by the $[1.5\sigma_{\text{noise}}, 2.5\sigma_{\text{noise}}]$ range. The dashed line in the middle of the band is the result for the $2.0\sigma_{\text{noise}}$ trigger. These upper limits have been calculated using the expected number of events above 20 PeV for a range IceCube flux spectral indices and finding that value that yields the number of events equal to the Feldman-Cousins 90% CL upper limit under the assumption of no background. The median upper limit exponents for the plausible trigger range cover the interval $[-2.24, -2.19]$, with -2.21 being the median upper limit spectral index for a $2.0\sigma_{\text{noise}}$ trigger. If no neutrino events are detected, RNO-G will be able to exclude IceCube-like fluxes above these levels.

6.2 Energy measurement

The ability of RNO-G to measure the neutrino spectrum will depend on the accuracy at which the energy of each event can be determined. The relation between the neutrino energy E_ν and the amplitude $|\vec{E}|$ of the electric field of the radio signal at the station is given by:

$$|\vec{E}| \sim E_\nu \cdot y \cdot f(\varphi) \cdot \frac{\exp(-d/l_{\text{atten}})}{d} \quad (6.1)$$

where y is the fraction of the neutrino energy deposited into the shower, and $f(\varphi)$ a dependence on the angle under which the particle shower is observed. The last term accounts for the attenuation of the radio signal as it travels to the antenna, with d being the distance of the interaction vertex from the station and l_{atten} the attenuation length of the ice.

Figure 25. Neutrino interaction vertex reconstruction for one event using correlations between different channels (top left), correlations between different rays reaching the same antenna (top right) and a combination of both (bottom). Colors specify the normalized sum of correlations between channels, shifted by the difference in signal travel time expected for a given vertex position.

In general, the (*inelasticity*) fraction y of the neutrino energy that contributes to a particle shower undergoes event-by-event fluctuations and cannot be reconstructed on a single-event basis. It therefore must be estimated from theory, resulting in a statistical uncertainty of, on average, a factor of ~ 2 [21]. This restriction imposes a hard bound on the energy resolution obtainable with any neutrino detector that only observes the cascade. The goal is therefore to reconstruct the other parameters in eq. (6.1) precisely enough for the uncertainty in y to be dominant. It should be noted that in case of an electron neutrino interaction, the full amount of energy is transferred to two particle showers very close to each other, which argues against having the unknown fraction y as bound. However, these two cascades can interfere constructively or destructively and pure-electromagnetic cascades are subject to the LPM-effect [244, 245] at high energies, which changes their radio emission [246]. This makes it reasonable to treat the inelasticity for all cases as bound in a first general consideration.

The resolution on the RNO-G measurement of the full electric field $|\vec{E}|$ depends on a number of factors. Ideally, the amplitude should be obtained for all polarization components, with separate levels of noise. In general, the larger the detected amplitude of the signals (larger measured signal-to-noise ratio (SNR_m), see below), the smaller the influence of noise on the uncertainty. Similarly, noise effects are mitigated as antenna hit-multiplicities increase. As the Hpol antennas have lower gain than the Vpol antennas, the Hpol signals will typically have smaller SNR_m . Several methods such as *forward folding* [196], template matching [19], or information field theory [247] can be

used to mitigate noise effects; nevertheless, the obtainable resolution of the amplitude will vary significantly from event to event.

It should be pointed out that using SNR_m differs from the situation of simulations (as defined in section 3.2), as the true amplitude of the signal S without noise is unknown, so the measured $\text{SNR}_m = (\text{signal} + \text{noise}) / \text{noise}$. Using a definition of $\text{SNR}_m = 0.5(\max(S) - \min(S)) / \sigma_{\text{noise}}$, a typical waveform of the length of RNO-G has a roughly 50% chance of reaching $\text{SNR}_m = 3$ simply by fluctuations of noise. At $\text{SNR}_m = 3.5$ this probability is reduced to about 1%.

Due to constructive interference, the radio signal emitted by the particle shower is strongest if viewed directly at the Cherenkov angle, and diminishes (in a frequency-dependent manner) the further the observer viewing angle departs from the Cherenkov angle. As shown in figure 4, the higher frequencies lose signal coherence earliest. Therefore, the shape of the frequency spectrum of the signal can be used to reconstruct the viewing angle relative to the Cherenkov angle and, ultimately, make a correction. This method has been demonstrated for particle showers in air [206], and our first simulations indicate the same to be true for neutrino showers. Quantitatively, we anticipate that $f(\varphi)$ will be obtainable for RNO-G for signals detected with at least a measured $\text{SNR}_m = 3.5$.

The signal pathlength d (eq. (6.1)) will depend on the reconstruction of the interaction vertex, so the resolution of the vertex position is another important ingredient for energy reconstruction.

Figure 25 shows one example of vertex reconstruction for a simulated neutrino interaction detected with RNO-G. This method to obtain the vertex position is based on cross-correlating the signals detected in all antennas with each other and deriving a probability map of the vertex location. Especially for those events in which RNO-G records both the direct emission, as well as the one reflected at/refracted-below the surface, the resolution on the vertex position will be excellent, making the unknown factor y (eq. (6.1)) the dominating uncertainty. Further work will be carried out to determine the fraction of events for which a good vertex resolution will be obtainable and the SNR_m for which this will be possible. Preliminary results indicate that, conservatively, an analysis efficiency at least corresponding to the green curve in figure 11 is reachable for the vertex and thereby energy reconstruction.

The profile of the attenuation length of the ice in Greenland, which defines l_{atten} in eq. (6.1) has been measured [41] and is used for the simulations. The remaining systematic uncertainty and variations across the array will be addressed by additional calibration campaigns as discussed in section 5.2.

6.3 Angular sensitivity

The sky coverage of RNO-G is mostly determined by the geometry of its location in Greenland. In figure 26 we show the effective areas for different zenith angle bands for RNO-G, as well as their projection onto equatorial coordinates. Outside of these bands, the effective area decreases rapidly (see also [195]), making RNO-G mostly sensitive to an annulus of roughly 45° just above the horizon.

The ability of RNO-G to provide an accurate arrival direction for detected neutrinos depends on its ability to detect the signal arrival direction and the angle with respect to the Cherenkov cone, as well as the signal polarization, and is again a strong function of the number of antennas with detected signal and their SNR_m .

The signal arrival direction can be directly determined from the time difference in the captured channel-by-channel waveforms, using (for example) cross-correlation. The obtained resolution is a

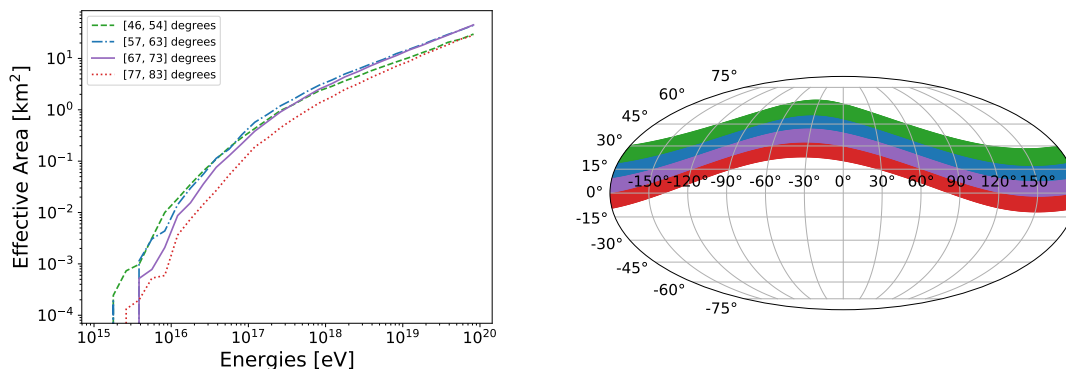

Figure 26. RNO-G instantaneous sky coverage. Left: simulated effective area as a function of neutrino energy is shown for the four most sensitive zenith bands, centered at 50° , 60° , 70° , and 80° . Simulations were performed for the full RNO-G array of 35 stations with a distance of 1 km. Right: these bands are projected in Right Ascension (RA) and Declination (Dec) for one particular time of day to illustrate the instantaneous sky coverage. Bands outside this range still show some, albeit a strongly reduced (< 0.1 fraction of maximum effective area), sensitivity for neutrino interactions.

function of the number of antennas with signal; sub-degree values have typically been obtained by previous experiments [4, 16, 21, 22]. Knowing only the arrival direction for the signal at a specific station, the neutrino arrival direction can be determined to lie on a cone, projecting to a ring on-sky as shown in figure 27. Only a fraction of the ring corresponds to a probable physical solution, as many arrival directions can be excluded by the known Earth absorption.

The radio signal is the strongest on the Cherenkov cone and then weakens once the angle to the shower axis deviates from the Cherenkov angle. Depending on the type of event, viewing angles of more than 10 degrees with respect to the Cherenkov angle may still be observable. As discussed in section 6.2, the electric-field is a function of the viewing angle, as the higher frequencies fall off further away from the Cherenkov cone, so the viewing angle is reconstructable via the frequency slope. Combining signal arrival direction and viewing angle narrows the ring of possible arrival directions.

As the radio signal is due to the Askaryan effect, the polarization of the induced electric-field points radially inwards towards the shower axis. Therefore, a measure of the polarization is needed for a unique neutrino arrival direction. As shown in figure 27, adding polarization allows reducing the entire ring to a small patch on the sky. The absolute angular resolution as function of energy, elevation and SNR_m per antenna is still under study. Thus, figure 27 has been constructed to highlight the influence of different signal parameters on the angular resolution, while using a simulated event, as detectable in RNO-G, including noise but no detector uncertainties. The event shown has an $\text{SNR}_m \approx 6$ in both Vpol and Hpol antennas, meaning that all pulses can be clearly identified.

6.4 Sensitivity to transient events

Using the same simulations as performed for section 6.1, the sensitivity of RNO-G to transient events has been obtained, as shown in figure 28. Most models predict small neutrinos fluxes in the energy range of RNO-G, as compiled in figure 3. However, given, e.g., large uncertainties in the modelling of mergers of neutron stars and that this area of multi-messenger astronomy is still in its infancy, RNO-G may make serendipitous discoveries. Its location in the Northern hemisphere

Figure 27. Radio neutrino detector arrival direction reconstruction. Given the limited field of view, the reconstructed signal arrival direction restricts the neutrino arrival direction to the red circular band shown. Adding information from the frequency content constrains the viewing angle, and reduces the width of the band. Finally, including data from both Hpol and Vpol antennas, polarization reconstruction reduces the allowed arrival direction to a small area on sky. The reconstruction and uncertainties are shown for one event simulated for RNO-G with NuRadioMC. The coordinates are local azimuth and zenith angle.

makes it uniquely sensitive, and complementary to other planned radio neutrino observatories in the Southern Hemisphere.

GRBs and other cataclysmic events are promising candidates for transient flares of UHE neutrinos. GRB afterglows are expected to produce the highest energy neutrinos over months-long time scales [49]. Short GRBs resulting from binary neutron star mergers may be detectable with RNO-G if they are nearby or connected with the production of giant flares from magnetars [248]. Similarly, magnetars resulting from binary neutron star mergers can drive UHE neutrino production [131]. As shown in figure 28, RNO-G can constrain the neutrino fluence from GRB afterglows, short GRBs, and long-lived magnetars within tens of Megaparsecs. Furthermore, Tidal Disruption Events (TDEs) are another cataclysmic source class still in the infancy of their discovery, with frequent new observations and population increases thanks to transient observatories such as the Zwicky Transient Facility (ZTF) [249]. As more is uncovered about their nature, they may also become a viable multi-messenger target for RNO-G.

Flaring blazars are particularly interesting targets for RNO-G. As an example, a model of the neutrino fluence expected from the flare of the bright gamma-ray blazar PKS 1502+106 [132] is compared to the RNO-G sensitivities in figure 28. This particular blazar is an FSRQ, which are notable for their expected high UHE neutrino fluxes [71], and spatially coincident with a “golden” event (IC190730A) seen in IceCube [250, 251]. In the model, neutrinos are produced in the two different scenarios that are consistent with multi-wavelength photon observations, but the neutrino spectrum is strongly impacted by the radiation mechanism. Stacking searches in RNO-G for flares of blazars or multi-messenger driven searches may reveal UHE neutrinos or constrain the neutrino spectrum at the highest energies. Note that while PKS 1506+106 is at a distant redshift, closer blazars will have a stronger neutrino fluence.

Figure 28. 95% CL fluence sensitivities between triggers at $1.5\sigma_{\text{noise}}$ and $2.5\sigma_{\text{noise}}$ are shown for four zenith bands centered at (top to bottom) 50° (green), 60° (blue), 70° (purple), and 80° (red). Sensitivities are calculated for a full decade in energy. Model-predicted fluences from several transient classes (bright gamma-ray blazars [132], short GRBs [130], magnetars [131], and GRB afterglows [49]) are also shown for direct comparison. We scale the short GRB and GRB afterglows by several luminosity distances to demonstrate the distance over which RNO-G will be sensitive to transients; a similar scaling can be applied to other source classes. For the calculation of sensitivities here we have used an integrated background expectation of no events. Note that for longer duration transients, integrated background may become non-negligible.

RNO-G has unique capabilities to process alerts in nearly real time. Summit Station’s continuous satellite link and the LTE communications strategy can permit alerts from other multi-messenger observatories to be sent to and from the RNO-G stations.

6.5 Sensitivity to air shower signals

RNO-G will be equipped with upward-facing LPDAs, sensitive to air shower signals. These will be triggered through the auxiliary trigger as described in section 4.3. First simulations indicate a turn-on of the trigger efficiency to air showers between 1×10^{16} eV and 1×10^{17} eV, with details depending on the exact system noise temperature and environmental noise conditions that will need to be confirmed during the first deployment season in-situ. The DAQ is designed to store 0.1 Hz of triggers from the surface antennas, dedicated to the detection of air showers. The passband of the envelope trigger has been optimized for the highest surface antenna trigger efficiency and will be between 80 MHz and 180 MHz. We expect the detection in the order of one air shower per day per station.

The air shower trigger at RNO-G will serve two purposes. As discussed in section 3.4, the muonic component of air showers may constitute a background for neutrino detection with RNO-G. While the flux of these background events depends strongly on the composition of the cosmic ray flux, as well as hadronic interaction models, the safest way to contain the impact of this background is to unambiguously tag air showers. RNO-G will therefore continue to be optimized to provide

its own air shower veto. In addition, air shower reconstruction will help calibrate the system and ensure an independent cross-check of up-time and efficiency.

7 Conclusions

We have presented the concept of the Radio Neutrino Observatory in Greenland (RNO-G), currently scheduled to commence installation at Summit Station in 2021. The location in Greenland both drives design considerations, such as autonomous low-power stations, and, given the unique field of view from the Northern Hemisphere, also defines the strong science case.

The RNO-G hardware builds on previous radio array experience and strives for a very low-noise system that can sustain a low trigger-threshold, but high duty-cycle operation of autonomous stations. Each of the 35 RNO-G stations will consist of log-periodic dipole antennas deployed at the surface and custom-made dipole and tri- or quad-slot antennas deployed in three mechanically drilled holes to a depth of 100 m. The stations will mainly be triggered by a phased array of four deep dipoles at the 100 m maximum depth, which will ensure the best neutrino aperture. Auxiliary envelope triggers are available for low-power operations in the seasons with less abundant solar-power and for reading out the surface antennas to detect and veto air showers.

RNO-G will be the first uniform deployment of a neutrino radio array that will demonstrate the feasibility of scaling to arbitrarily large arrays. The delivered per-year sensitivity will be the largest achieved to-date with a radio array. RNO-G with its unique view of the Northern hemisphere may provide insights into transient sources of UHE neutrinos and will bring the detection of a continuation of the astrophysical neutrinos flux to high energies as detected by IceCube within reach. Additionally, models for cosmogenic neutrinos assuming a significant proton fraction in UHE cosmic-rays will be either be conclusively ruled out or will lead, if confirmed, to a detection of neutrinos with RNO-G.

Acknowledgments

We would like to acknowledge our home institutions and funding agencies for supporting the RNO-G work; in particular the Belgian Funds for Scientific Research (FRS-FNRS and FWO) and the FWO programme for International Research Infrastructure (IRI), the German research foundation (DFG, Grant NE 2031/2-1), and the Helmholtz Association (Initiative and Networking Fund, W2/W3 Program).

 (Received 18 October 2019; revised manuscript received 13 December 2019; accepted 6 January 2020; published 6 February 2020)

This Letter presents the results from pointlike neutrino source searches using ten years of IceCube data collected between April 6, 2008 and July 10, 2018. We evaluate the significance of an astrophysical signal from a pointlike source looking for an excess of clustered neutrino events with energies typically above ~ 1 TeV among the background of atmospheric muons and neutrinos. We perform a full-sky scan, a search within a selected source catalog, a catalog population study, and three stacked Galactic catalog searches.

The most significant point in the northern hemisphere from scanning the sky is coincident with the Seyfert II galaxy NGC 1068, which was included in the source catalog search. The excess at the coordinates of NGC 1068 is inconsistent with background expectations at the level of 2.9σ after accounting for statistical trials from the entire catalog. The combination of this result along with excesses observed at the coordinates of three other sources, including TXS 0506 + 056, suggests that, collectively, correlations with sources in the northern catalog are inconsistent with background at 3.3σ significance. The southern catalog is consistent with background. These results, all based on searches for a cumulative neutrino signal integrated over the 10 years of available data, motivate further study of these and similar sources, including time-dependent analyses, multimessenger correlations, and the possibility of stronger evidence with coming upgrades to the detector.

DOI: [10.1103/PhysRevLett.124.051103](https://doi.org/10.1103/PhysRevLett.124.051103)

Cosmic rays (CRs) have been observed for over a hundred years [1] penetrating the entire surface of the Earth's atmosphere in the form of leptonic and hadronic charged particles with energies up to $\sim 10^{20}$ eV [2]. These particles are heavily deflected on their journey to the Earth by magnetic fields and, although at energies $\gtrsim 10^{19}$ eV this deflection could become much smaller, their origin is still largely unknown. Very-high-energy (VHE) γ rays ($E_\gamma > 100$ GeV) travel without deflection and so provide evidence for astrophysical acceleration sites. However, these photons can be produced by both leptonic and hadronic processes and are attenuated by extragalactic background light, meaning they cannot probe redshifts larger than $z \sim 1$ at energies above ~ 1 TeV. In comparison, only hadronic processes can produce an astrophysical neutrino flux which would travel unattenuated and undeflected from the source to the Earth. Thus, astrophysical neutrino observations are critical to identify CR sources, or to discover distant very-high-energy accelerators.

IceCube has discovered a flux of astrophysical neutrinos in multiple diffuse searches [3–6], which integrate observed emission over most of the sky. Notably, a potential neutrino source, TXS 0506 + 056, has been identified through a multimessenger campaign around a high-energy IceCube event in September 2017 [7]. IceCube also found evidence for neutrino emission over ~ 110 days from 2014–2015 at the location of TXS 0506 + 056 when examining over nine years of archival data [8]. Nonetheless, the estimated flux from this source alone is less than 1% of the total astrophysical neutrino flux [3] and the contribution of a catalog of blazars as a population to the best fit total astrophysical neutrino flux between 10 TeV and 2 PeV is limited to 27% [9]. In this Letter we search for various pointlike neutrino sources using 10 years of IceCube observations.

The IceCube neutrino telescope is a cubic kilometer array of digital optical modules (DOMs) each containing a 10" PMT [10] and on-board read-out electronics [11]. These DOMs are arranged in 86 strings between 1.45 and 2.45 km below the surface of the ice at the South Pole [12]. The DOMs are sensitive to Cherenkov light from energy

losses of ultrarelativistic charged particles traversing the ice. This analysis targets astrophysical muon neutrinos and antineutrinos (ν_μ), which undergo charged-current interactions in the ice to produce a muon traversing the detector. The majority of the background for this analysis originates from CRs interacting with the atmosphere to produce showers of particles including atmospheric muons and neutrinos. The atmospheric muons from the southern hemisphere are able to penetrate the ice and are detected as tracklike events in IceCube at a rate orders of magnitude higher than the corresponding atmospheric neutrinos [12]. Almost all of the atmospheric muons from the northern hemisphere are filtered out by the Earth. However, poorly reconstructed atmospheric muons from the southern sky create a significant background in the northern hemisphere. Atmospheric neutrinos also produce muons from charged-current ν_μ interactions, acting as an irreducible background in both hemispheres. Neutral-current interactions or ν_e and ν_τ charged-current interactions produce particle showers with spherical topology known as cascade events. Tracks at \sim TeV energies are reconstructed with a typical angular resolution of $\lesssim 1^\circ$, while cascades have an angular resolution of $\sim 10^\circ$ – 15° [13]. This analysis selects tracklike events because of their better angular resolution. Tracks have the additional advantage that they can be used even if the neutrino interaction vertex is located outside of the detector. This greatly increases the detection efficiency.

During the first three years of data included here, IceCube was incomplete and functioned with 40, 59, and 79 strings. For these years and also during the first year of data taking of the full detector (IC86), the event selection and reconstruction was updated until it stabilized in 2012, as detailed in Table I. Seven years of tracks were previously analyzed to search for point sources [14]. Subsequently, an eight-year sample of tracks from the northern sky used for diffuse muon neutrino searches was also analyzed looking for point sources [15]. The aim of this Letter is to introduce a selection which unifies the event filtering adopted in these two past searches. Additionally, the direction reconstruction [16,17] has been updated to use the deposited event energy in the detector. This improves

the angular resolution by more than 10% for events above 10 TeV compared to the seven-year study [14], and achieves a similar angular resolution as the eight-year northern diffuse track selection [15], which also uses deposited event energy in the direction reconstruction (see Fig. 1). The absolute pointing accuracy of IceCube by combining many events has been demonstrated to be $\lesssim 0.2^\circ$ [18] via measurements of the effect of the Moon shadow on the background CR flux.

Different criteria are applied to select track-like events from the northern and southern hemisphere (with a boundary between them at declination $\delta = -5^\circ$), because the background differs in these two regions. Almost all the atmospheric muons in the northern hemisphere can be removed by selecting high-quality tracklike events. In the southern hemisphere, the atmospheric background is reduced by strict cuts on the reconstruction quality and minimum energy deposited in the detector, since the astrophysical neutrino fluxes are expected to have a harder energy spectrum than the background of atmospheric muons and neutrinos. This effectively removes almost all

southern hemisphere events with an estimated energy below ~ 10 TeV [23].

In both hemispheres, atmospheric muons and cascade events are further filtered using multivariate boosted decision trees (BDTs). In this analysis, a single BDT is trained to recognize three classes of events in the northern hemisphere: single muon tracks from atmospheric and astrophysical neutrinos, atmospheric muons, and cascades, where neutrino-induced tracks are treated as signal. This BDT uses 11 variables related to event topology and reconstruction quality. When applied to simulated events, the northern BDT preserves $\sim 90\%$ of the atmospheric neutrinos and $\sim 0.1\%$ of the atmospheric muons from the initial selection of tracklike events, also applied in previous muon neutrino searches [14,15]. In the southern hemisphere, the BDT and selection filters are taken from Ref. [14]. The final all-sky event rate of ~ 2 mHz is dominated by muons from atmospheric neutrinos in the northern hemisphere and by high-energy, well-reconstructed muons in the southern hemisphere. This updated selection applied to the final six years of data shown in Table I. The preceding four years of data are handled exactly as in the past.

The point-source searches conducted in this paper use the existing maximum-likelihood ratio method which compares the hypothesis of pointlike signal plus diffuse background versus a background-only null hypothesis. All of the searches and source catalogs were predefined before any of the following results were obtained. This technique, described in Refs. [19,30], was also applied in the seven- and eight-year point source searches [14,15]. The all-sky scan and the selected source catalog searches look for directions which maximize the likelihood-ratio in the northern and southern hemisphere separately. Since this analysis assumes pointlike sources, it is suboptimal to those with extended neutrino emission regions. The sensitivity of this analysis to a neutrino flux with an E^{-2} spectrum, calculated according to [19], shows a $\sim 35\%$ improvement compared to the seven-year all-sky search [14] due to the longer livetime, updated event selection, and updated reconstructions. While the sensitivity in the northern hemisphere is comparable to the eight-year study for an E^{-2} spectrum [15], the analysis presented in this work achieves

FIG. 1. The median angle between simulated neutrino and reconstructed muon directions as a function of energy for the data selection used in the latest six years compared to that in Ref. [14] (solid and dashed lines are for northern and southern hemispheres, respectively) and in Ref. [15] for the northern hemisphere. The differences between hemispheres come from the differences in the background composition and the respective selection criteria.

a $\sim 30\%$ improvement in sensitivity to sources with a softer spectrum, such as E^{-3} . This difference is due to the more general nature of this work which assumes an $E^{-\gamma}$ power-law energy spectrum, where $1 \leq \gamma \leq 4$, whereas the eight-year study targets the sources responsible for the diffuse astrophysical neutrino flux seen in [31] by applying a strict Gaussian prior on the spectral index, γ , centered at 2.19 ± 0.1 .

All-sky scan.—The brightest sources of astrophysical neutrinos may differ from the brightest sources observed in the electromagnetic (EM) spectrum. For example, cosmic accelerators can be surrounded by a dense medium which attenuates photon emission while neutrinos could be further generated by cosmic-ray interactions in the medium. For this reason, a general all-sky search for the brightest single pointlike neutrino source in each hemisphere is conducted, and is unbiased by EM observations. This involves maximizing the signal-over-background likelihood-ratio at a grid of points across the entire sky with a finer spacing ($\sim 0.1^\circ \times \sim 0.1^\circ$) than the typical event angular uncertainty. The points within 8° of the celestial poles are excluded due to poor statistics and limitations in the background estimation technique.

At each position on the grid, the likelihood-ratio function is maximized resulting in a maximum test-statistic (TS), a best fit number of astrophysical neutrino events (\hat{n}_s), and the spectral index ($\hat{\gamma}$) for an assumed power-law energy spectrum. The local pre-trial probability (p -value) of obtaining the given or larger TS value at a certain location from only background is estimated at every grid point by fitting the TS distribution from many background trials with a χ^2 function. Each background trial is obtained from the data themselves by scrambling the right ascension of each event, thereby removing any clustering of the signal. The location of the most significant p -value in each hemisphere is defined to be the hottest spot. The post-trial probability is estimated by comparing the p -value of the hottest spot in the data with a distribution of hottest spots in the corresponding hemisphere from a large number of background trials.

The most significant point in the northern hemisphere is found at equatorial coordinates (J2000) right ascension 40.9° , declination -0.3° with a local p -value of 3.5×10^{-7} . The best fit parameters at this spot are $\hat{n}_s = 61.5$ and $\hat{\gamma} = 3.4$. Considering the trials from examining the entire hemisphere increases the p -value to 9.9×10^{-2} post-trial. The probability sky map in a 3° by 3° window around the most significant point in the northern hemisphere is plotted in Fig. 2. This point is found 0.35° from the active galaxy NGC 1068, which is independently included as a source in the northern source catalog. To study whether the 0.35° offset between the all-sky hotspot and NGC 1068 is typical of the reconstruction uncertainty of a neutrino source, we inject a soft-spectrum source according to the best-fit $E^{-3.2}$ flux at the *Fermi*-LAT coordinates for NGC 1068 into our

FIG. 2. Local pre-trial p -value map around the most significant point in the Northern hemisphere. The black cross marks the coordinates of the galaxy NGC 1068 taken from *Fermi*-4FGL.

background samples. Scanning in a 5° window around the injection point, we find that the median separation between the most significant hotspot and the injection point is 0.35° . Thus, if the excess is due to an astrophysical signal from NGC 1068, the offset between the all-sky hotspot and *Fermi*-LAT's coordinates is consistent with the IceCube angular resolution for such a source.

The most significant hotspot in the southern hemisphere, at right ascension 350.2° and declination -56.5° , is less significant with a pre-trial p -value of 4.3×10^{-6} and fit parameters $\hat{n}_s = 17.8$, and $\hat{\gamma} = 3.3$. The p -value of this hotspot becomes 0.75 post-trial. Both hotspots alone are consistent with a background-only hypothesis.

Source catalog searches.—The motivation of this search is to improve sensitivity to detect possible neutrino sources already observed in γ rays. A new catalog composed of 110 sources has been constructed which updates the catalog used in previous sources searches [14]. The new catalog uses the latest γ ray observations and is based on rigorous application of a few simple criteria, described below. The size of the catalog was chosen to limit the trials factor applied to the most significant source in the catalog such that a 5σ significance before trials would remain above 4σ after trials. These 110 sources are composed of Galactic and extragalactic sources, which are selected separately.

The extragalactic sources are selected from the *Fermi*-LAT 4FGL catalog [32] since it provides the highest-energy unbiased measurements of γ -ray sources over the full sky. Sources from 4FGL are weighted according to the integral *Fermi*-LAT flux above 1 GeV divided by the sensitivity flux for this analysis at the respective source declination. The 5% highest-weighted BL Lacs and flat spectrum radio quasars (FSRQs) are each selected. The minimum weighted integral flux from the combined selection of BL Lac and FSRQs is used as a flux threshold to include sources marked as unidentified blazars and AGN. Eight 4FGL sources are identified as starburst galaxies. Since these types of objects are thought to host hadronic emission

[33,34], they are all included in the final source list. The blazar TXS 0506 + 056 is selected in the top 5% of BL Lacs due to its high luminosity in γ rays and its location in the most sensitive region of the sky for IceCube.

To select Galactic sources, we consider measurements of VHE γ -ray sources from TeVCat [35,36] and gammaCat [37]. Spectra of the γ rays were converted to equivalent neutrino fluxes, assuming a purely hadronic origin of the observed γ -ray emission where $E_\gamma \simeq 2E_\nu$, and compared to the sensitivity of this analysis at the declination of the source (Fig. 3). Those Galactic objects with predicted energy fluxes $> 50\%$ of IceCube's sensitivity limit for an E^{-2} spectrum, were included in the source catalog. A total of 12 Galactic γ -ray sources survived the selection.

The final list of neutrino source candidates is a northern-sky catalog containing 97 objects (87 extragalactic and 10 Galactic) and a southern-sky catalog containing 13 sources (11 extragalactic and 2 Galactic). The large north-south difference is due to the difference in the sensitivity of IceCube in the northern and southern hemispheres. The post-trial p -value for each catalog describes the significance of the single most significant source in the catalog and is calculated as the fraction of background trials where the pre-trial p -value of the most significant fluctuation is smaller than the pre-trial p -value found in data.

The obtained pre-trial p -values are provided in the supplementary material and their associated 90% C.L. flux upper limits are shown in Fig. 3, together with the expected sensitivity and discovery potential fluxes. The most significant excess in the northern catalog of 97 sources is found in the direction of the galaxy NGC 1068, analyzed for the first time by IceCube in this analysis, with a local pre-trial p -value of 1.8×10^{-5} (4.1σ). The best

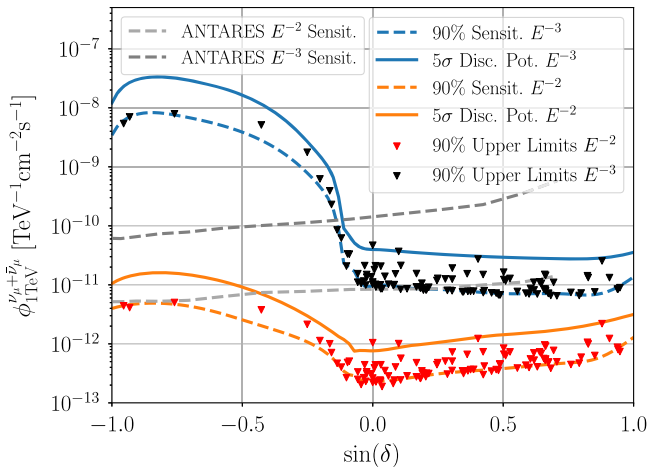

FIG. 3. 90% C.L. median sensitivity and 5σ discovery potential as a function of source declination for a neutrino source with an E^{-2} and E^{-3} spectrum. The 90% upper limits are shown excluding an E^{-2} and E^{-3} source spectrum for the sources in the source list. The grey curves show the 90% C.L. median sensitivity from 11 yrs of ANTARES data [38].

fit parameters are $\gamma = 3.2$ and $\hat{n}_s = 50.4$, consistent with the results for the all-sky northern hottest spot, 0.35° away. From Fig. 2 it can be inferred that the significance of the all-sky hotspot and the excess at NGC 1068 are dominated by the same cluster of events. The parameters of the best fit spectrum at the coordinates of NGC 1068 are shown in Fig. 4. When the significance of NGC 1068 is compared to the most significant excesses in the northern catalog from many background trials, the post-trial significance is 2.9σ .

Out of the 13 different source locations examined in the Southern catalog, the most significant excess has a pretrial p -value of 0.06 in the direction of PKS 2233-148. The associated post-trial p -value is 0.55, which is consistent with background.

Four sources in the northern catalog found a pretrial p -value < 0.01 : NGC 1068, TXS 0506 + 056, PKS 1424 + 240, and GB6 J1542 + 6129. Evidence has been presented for TXS 0506 + 056 to be a neutrino source [8] using an overlapping event selection in a time-dependent analysis. However, TXS 0506 + 056 was included in the northern catalog independently of this result due to its relatively high γ -ray flux observed by *Fermi*-LAT. In this Letter, in which we only consider the cumulative signal integrated over 10 years, we find a pretrial significance of 3.6σ at the coordinates of TXS 0506 + 056 for a best fit spectrum of $E^{-2.1}$, consistent with previous results.

In addition to the single source search, a source population study is conducted to understand if excesses from several sources, each not yet at evidence level, can cumulatively indicate a population of neutrino sources in the catalog.

The population study uses the pretrial p -values of each source in the catalog and searches for an excess in the

FIG. 4. Likelihood map at the position of NGC 1068 as a function of the astrophysical flux spectral index and normalization at 1 TeV. Contours show 1, 2, 3, and 4σ confidence intervals assuming Wilks' theorem with 2 degrees of freedom [39]. The best fit spectrum is point marked with "x".

number of small p -values compared to the uniform background expectation. If the number of objects in the search catalog is N , and the number of sources below a given threshold p_k is k , then the probability of background producing k or more sources with p -values smaller than p_k is given by the cumulative binomial probability:

$$p_{\text{bkg}} = \sum_{i=k}^N P_{\text{binom}}(i|p_k, N) = \sum_{i=k}^N \binom{N}{i} p_k^i (1-p_k)^{N-i}. \quad (1)$$

In order to maximize sensitivity to any possible population size of neutrino sources within the catalog, the probability threshold (p_k) is increased iteratively to vary k between 1 and N . The result of this search is the most significant p_{bkg} from N different tested values of k , then the post-trial p -value from this search must take into account a trial factor for the different tested values of k .

The most significant p_{bkg} from the northern catalog population analysis is 3.3×10^{-5} (4.0σ), which is found when $k = 4$. The four most significant sources which contribute to this excess are those with p -value < 0.01 as described above. When accounting for the fact that different signal population sizes are tested, the post-trial p -value is 4.8×10^{-4} (3.3σ). Since evidence has already been presented for TXS 0506 + 056 to be a neutrino source [8], an *a posteriori* search is conducted removing this source from the catalog. The resulting most significant excess is 2.3σ post-trial due to the remaining three most significant sources. For the southern catalog, the pretrial p -value of the most significant excess is 0.12, provided by 5 of the 13 sources. The resulting post-trial p -value is 0.36.

Stacked source searches.—In the case of catalogs of sources that produce similar fluxes, stacking searches require a lower flux per source for a discovery than considering each source individually. Three catalogs of Galactic γ -ray sources are stacked in this paper. Sources are selected from VHE γ -ray measurements and categorized into pulsar wind nebulae (PWN), supernova remnants (SNR), and unidentified objects (UNID), with the aim of grouping objects likely to have similar properties as Galactic neutrino emitters. The final groups consist of 33 PWN, 23 SNR, and 58 UNID described in the Supplemental Material. A weighting scheme is adopted to describe the relative contribution expected from each source in a single catalog based on the integral of the extrapolated γ -ray flux above 10 TeV. All three catalogs find p -values > 0.1 .

Conclusion.—This Letter presents an updated event selection optimized for pointlike neutrino source signals applied to 10 years of IceCube data taken from April 2008 to July 2018. Multiple neutrino source searches are performed: an all-sky scan, a source catalog and corresponding catalog population study for each hemisphere, and three stacked Galactic-source searches.

TABLE II. Summary of final p -values (pretrial and post-trial) for each pointlike source search implemented in this Letter.

Analysis	Category	Pretrial significance (p_{local})	Post-trial significance
All-Sky Scan	North	3.5×10^{-7}	9.9×10^{-2}
	South	4.3×10^{-6}	0.75

The results of these analyses, all searching for cumulative neutrino signals integrated over the 10 years of data-taking, are summarized in Table II. The most significant source in the northern catalog, NGC 1068, is inconsistent with a background-only hypothesis at 2.9σ due to being located 0.35° from the most significant excess in the northern hemisphere and the northern source catalog provides a 3.3σ inconsistency with a background-only hypothesis for the entire catalog. This result comes from an excess of significant p -values in the directions of the Seyfert II galaxy NGC 1068, the blazar TXS 0506 + 056, and the BL Lacs PKS 1424 + 240 and GB6 J1542 + 6129. NGC 1068, at a 14.4 Mpc distance, is the most luminous Seyfert II galaxy detected by *Fermi*-LAT [24]. NGC 1068 is an observed particle accelerator, charged particles are accelerated in the jet of the AGN or in the AGN-driven molecular wind [40], producing γ rays and potentially neutrinos. Other work has previously indicated NGC 1068 as a potential CR accelerator [33,41,42]. Assuming that the observed excess is indeed of astrophysical origin and connected with NGC 1068, the best-fit neutrino spectrum inferred from this work is significantly higher than that predicted from models developed to explain the *Fermi*-LAT gamma-ray measurements [25]. However, the large uncertainty from our spectral measurement and the high x-ray and γ -ray absorption along the line of sight [26,43] prevent a straight forward connection. Time-dependent analyses and the possibility of correlating with multimessenger observations for this and other sources may provide additional evidence of neutrino emission and insights into its origin. Continued data-taking, more refined event reconstruction, and the planned upgrade of IceCube promise further improvements in sensitivity [44].

INTRODUCTION: Neutrinos are tracers of cosmic-ray acceleration: electrically neutral and traveling at nearly the speed of light, they can escape the densest environments and may be traced back to their source of origin. High-energy neutrinos are expected to be produced in blazars: intense extragalactic radio, optical, x-ray, and, in some cases, γ -ray sources characterized by relativistic jets of plasma pointing close to our line of sight. Blazars are among the most powerful objects in the Universe and are widely speculated to be sources of high-energy cosmic rays. These cosmic rays generate high-energy neutrinos and γ -rays, which are produced when the cosmic rays accelerated in the jet interact with nearby gas or photons. On 22 September 2017, the cubic-kilometer IceCube Neutrino Observatory detected a ~ 290 -TeV neutrino from a direction consistent with the flaring γ -ray blazar TXS 0506+056. We report the details of this observation and the results of a multiwavelength follow-up campaign.

RATIONALE: Multimessenger astronomy aims for globally coordinated observations of cosmic rays, neutrinos, gravitational waves, and electromagnetic radiation across a broad range of wavelengths. The combination is expected to yield crucial information on the mechanisms energizing the most powerful astrophysical sources. That the production of neutrinos is accompanied by electromagnetic radiation from the source favors the chances of a multiwavelength identification. In particular, a measured association of high-energy neutrinos with a flaring source of γ -rays would elucidate the mechanisms and conditions for acceleration of the highest-energy cos-

mic rays. The discovery of an extraterrestrial diffuse flux of high-energy neutrinos, announced by IceCube in 2013, has characteristic properties that hint at contributions from extragalactic sources, although the individual sources remain as yet unidentified. Continuously monitoring the entire sky for astrophysical neu-

Multimessenger observations of blazar TXS 0506+056. The 50% and 90% containment regions for the neutrino IceCube-170922A (dashed red and solid gray contours, respectively), overlain on a V-band optical image of the sky. Gamma-ray sources in this region previously detected with the *Fermi* spacecraft are shown as blue circles, with sizes representing their 95% positional uncertainty and labeled with the source names. The IceCube neutrino is coincident with the blazar TXS 0506+056, whose optical position is shown by the pink square. The yellow circle shows the 95% positional uncertainty of very-high-energy γ -rays detected by the MAGIC telescopes during the follow-up campaign. The inset shows a magnified view of the region around TXS 0506+056 on an R-band optical image of the sky.

trinos, IceCube provides real-time triggers for observatories around the world measuring γ -rays, x-rays, optical, radio, and gravitational waves, allowing for the potential identification of even rapidly fading sources.

RESULTS: A high-energy neutrino-induced muon track was detected on 22 September 2017, automatically generating an alert that was

distributed worldwide within 1 min of detection and prompted follow-up searches by telescopes over a broad range of wavelengths. On 28 September 2017, the *Fermi* Large Area Telescope Collaboration reported that the direction of the neutrino was coincident with a cataloged γ -ray source, 0.1° from the neutrino direction. The source, a blazar known as TXS 0506+056 at a measured redshift of 0.34, was in a flaring state at the time with enhanced γ -ray activity in the GeV range. Follow-up observations by imaging atmospheric Cherenkov telescopes, notably the Major Atmospheric

Gamma Imaging Cherenkov (MAGIC) telescopes, revealed periods where the detected γ -ray flux from the blazar reached energies up to 400 GeV. Measurements of the source have also been completed at x-ray, optical, and radio wavelengths. We have investigated models associating neutrino and γ -ray production and find that correlation of the neutrino with the flare of TXS 0506+056 is statistically significant at the level of 3 standard deviations (σ). On the basis of the redshift of TXS 0506+056, we derive constraints for the muon-neutrino luminosity for this source and find them to be similar to the luminosity observed in γ -rays.

CONCLUSION: The energies of the γ -rays and the neutrino indicate that blazar jets may accelerate cosmic rays to at least several PeV. The observed association of a high-energy neutrino with a blazar during a period of enhanced γ -ray emission suggests that blazars may indeed be one of the long-sought sources of very-high-energy cosmic rays, and hence responsible for a sizable fraction of the cosmic neutrino flux observed by IceCube. ■

RESEARCH ARTICLE

NEUTRINO ASTROPHYSICS

Multimessenger observations of a flaring blazar coincident with high-energy neutrino IceCube-170922A

The IceCube Collaboration, *Fermi*-LAT, MAGIC, AGILE, ASAS-SN, HAWC, H.E.S.S., INTEGRAL, Kanata, Kiso, Kapteyn, Liverpool Telescope, Subaru, *Swift*/NuSTAR, VERITAS, and VLA/17B-403 teams*†

Previous detections of individual astrophysical sources of neutrinos are limited to the Sun and the supernova 1987A, whereas the origins of the diffuse flux of high-energy cosmic neutrinos remain unidentified. On 22 September 2017, we detected a high-energy neutrino, IceCube-170922A, with an energy of ~ 290 tera-electron volts. Its arrival direction was consistent with the location of a known γ -ray blazar, TXS 0506+056, observed to be in a flaring state. An extensive multiwavelength campaign followed, ranging from radio frequencies to γ -rays. These observations characterize the variability and energetics of the blazar and include the detection of TXS 0506+056 in very-high-energy γ -rays. This observation of a neutrino in spatial coincidence with a γ -ray-emitting blazar during an active phase suggests that blazars may be a source of high-energy neutrinos.

Since the discovery of a diffuse flux of high-energy astrophysical neutrinos (1, 2), IceCube has searched for its sources. The only nonterrestrial neutrino sources identified previously are the Sun and the supernova 1987A, producing neutrinos with energies millions of times lower than the high-energy diffuse flux, such that the mechanisms and the environments responsible for the high-energy cosmic neutrinos are still to be ascertained (3, 4). Many candidate source types exist, with active galactic nuclei (AGN) among the most prominent (5), in particular the small fraction of them designated as radio-loud (6). In these AGNs, the central supermassive black hole converts gravitational energy of accreting matter and/or the rotational energy of the black hole into powerful relativistic jets, within which particles can be accelerated to high energies. If a number of these particles are protons or nuclei, their interactions with the radiation fields and matter close to the source would give rise to a flux of high-energy pions that eventually decay into photons and neutrinos (7). In blazars (8)—AGNs that have one of the jets pointing close to our line of sight—the observable flux of neutrinos and radiation is expected to be greatly enhanced owing to relativistic Doppler boosting. Blazar electromagnetic (EM) emission is known to be highly variable on time scales from minutes to years (9).

Neutrinos travel largely unhindered by matter and radiation. Even if high-energy photons (TeV

and above) are unable to escape the source owing to intrinsic absorption, or are absorbed by interactions with the extragalactic background light (EBL) (10, 11), high-energy neutrinos may escape and travel unimpeded to Earth. An association of observed astrophysical neutrinos with blazars would therefore imply that high-energy protons or nuclei up to energies of at least tens of PeV are produced in blazar jets, suggesting that they may be the birthplaces of the most energetic particles observed in the Universe, the ultrahigh-energy cosmic rays (12). If neutrinos are produced in correlation with photons, the coincident observation of neutrinos with electromagnetic flares would greatly increase the chances of identifying the source(s). Neutrino detections must therefore be combined with the information from broadband observations across the electromagnetic spectrum (multimessenger observations).

To take advantage of multimessenger opportunities, the IceCube neutrino observatory (13) has established a system of real-time alerts that rapidly notify the astronomical community of the direction of astrophysical neutrino candidates (14). From the start of the program in April 2016 through October 2017, 10 public alerts have been issued for high-energy neutrino candidate events with well-reconstructed directions (15).

We report the detection of a high-energy neutrino by IceCube and the multiwavelength/multi-instrument observations of a flaring γ -ray blazar, TXS 0506+056, which was found to be positionally coincident with the neutrino direction (16). Chance coincidence of the IceCube-170922A event with the flare of TXS 0506+056 is statistically disfavored at the level of 3σ in models

evaluated below, associating neutrino and γ -ray production.

The neutrino alert

IceCube is a neutrino observatory with more than 5000 optical sensors embedded in 1 km^3 of the Antarctic ice-sheet close to the Amundsen-Scott South Pole Station. The detector consists of 86 vertical strings frozen into the ice 125 m apart, each equipped with 60 digital optical modules (DOMs) at depths between 1450 and 2450 m. When a high-energy muon-neutrino interacts with an atomic nucleus in or close to the detector array, a muon is produced moving through the ice at superluminal speed and creating Cherenkov radiation detected by the DOMs. On 22 September 2017 at 20:54:30.43 Coordinated Universal Time (UTC), a high-energy neutrino-induced muon track event was detected in an automated analysis that is part of IceCube's real-time alert system. An automated alert was distributed (17) to observers 43 s later, providing an initial estimate of the direction and energy of the event. A sequence of refined reconstruction algorithms was automatically started at the same time, using the full event information. A representation of this neutrino event with the best-fitting reconstructed direction is shown in Fig. 1. Monitoring data from IceCube indicate that the observatory was functioning normally at the time of the event.

A Gamma-ray Coordinates Network (GCN) Circular (18) was issued ~ 4 hours after the initial notice, including the refined directional information (offset 0.14° from the initial direction; see Fig. 2). Subsequently, further studies were performed to determine the uncertainty of the directional reconstruction arising from statistical and systematic effects, leading to a best-fitting right ascension (RA) $77.43^{+0.95}_{-0.65}$ and declination (Dec) $+5.72^{+0.50}_{-0.30}$ (degrees, J2000 equinox, 90% containment region). The alert was later reported to be in positional coincidence with the known γ -ray blazar TXS 0506+056 (16), which is located at RA 77.36° and Dec $+5.69^\circ$ (J2000) (19), 0.1° from the arrival direction of the high-energy neutrino.

The IceCube alert prompted a follow-up search by the Mediterranean neutrino telescope ANTARES (Astronomy with a Neutrino Telescope and Abyss environmental REsearch) (20). The sensitivity of ANTARES at the declination of IceCube-170922A is about one-tenth that of IceCube's (21), and no neutrino candidates were found in a ± 1 day period around the event time (22).

An energy of 23.7 ± 2.8 TeV was deposited in IceCube by the traversing muon. To estimate the parent neutrino energy, we performed simulations of the response of the detector array, considering that the muon-neutrino might have interacted outside the detector at an unknown distance. We assumed the best-fitting power-law energy spectrum for astrophysical high-energy muon neutrinos, $dN/dE \propto E^{-2.13}$ (2), where N is the number of neutrinos as a function of energy E . The simulations yielded a most probable neutrino energy of 290 TeV, with a 90% confidence level (CL)

*The full lists of participating members for each team and their affiliations are provided in the supplementary materials.
†Email: analysis@icecube.wisc.edu

lower limit of 183 TeV, depending only weakly on the assumed astrophysical energy spectrum (25).

The vast majority of neutrinos detected by IceCube arise from cosmic-ray interactions within Earth's atmosphere. Although atmospheric neutrinos are dominant at energies below 100 TeV, their spectrum falls steeply with energy, allowing astrophysical neutrinos to be more easily identified at higher energies. The muon-neutrino as-

trophysical spectrum, together with simulated data, was used to calculate the probability that a neutrino at the observed track energy and zenith angle in IceCube is of astrophysical origin. This probability, the so-called signalness of the event (14), was reported to be 56.5% (17). Although IceCube can robustly identify astrophysical neutrinos at PeV energies, for individual neutrinos at several hundred TeV, an atmospheric origin

cannot be excluded. Electromagnetic observations are valuable to assess the possible association of a single neutrino to an astrophysical source.

Following the alert, IceCube performed a complete analysis of relevant data prior to 31 October 2017. Although no additional excess of neutrinos was found from the direction of TXS 0506+056 near the time of the alert, there are indications at the 3σ level of high-energy neutrino

Fig. 1. Event display for neutrino event IceCube-170922A.

The time at which a DOM observed a signal is reflected in the color of the hit, with dark blues for earliest hits and yellow for latest. Times shown are relative to the first DOM hit according to the track reconstruction, and earlier and later times are shown with the same colors as the first and last times, respectively. The total time the event took to cross the detector is ~ 3000 ns. The size of a colored sphere is proportional to the logarithm of the amount of light observed at the DOM, with larger spheres corresponding to larger signals. The total charge recorded is ~ 5800 photoelectrons. Inset is an overhead perspective view of the event. The best-fitting track direction is shown as an arrow, consistent with a zenith angle $5.7_{-0.30}^{+0.50}$ degrees below the horizon.

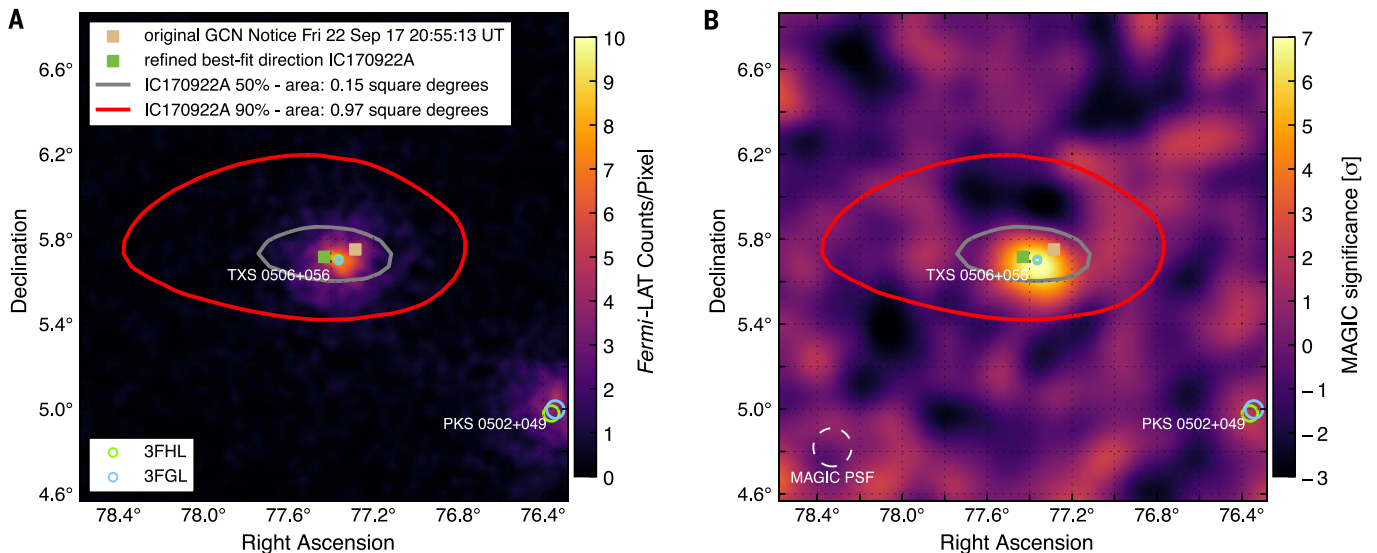

Fig. 2. Fermi-LAT and MAGIC observations of IceCube-170922A's location. Sky position of IceCube-170922A in J2000 equatorial coordinates overlaying the γ -ray counts from Fermi-LAT above 1 GeV (A) and the signal significance as observed by MAGIC (B) in this region. The tan square indicates the position reported in the initial alert, and the green square indicates the final best-fitting position from follow-up reconstructions (18). Gray and red curves show the 50% and 90% neutrino containment regions, respectively, including statistical and systematic errors. Fermi-LAT data are shown as a photon counts map in 9.5 years of data in units of counts per

pixel, using detected photons with energy of 1 to 300 GeV in a 2° by 2° region around TXS0506+056. The map has a pixel size of 0.02° and was smoothed with a 0.02° -wide Gaussian kernel. MAGIC data are shown as signal significance for γ -rays above 90 GeV. Also shown are the locations of a γ -ray source observed by Fermi-LAT as given in the Fermi-LAT Third Source Catalog (3FGL) (23) and the Third Catalog of Hard Fermi-LAT Sources (3FHL) (24) source catalogs, including the identified positionally coincident 3FGL object TXS 0506+056. For Fermi-LAT catalog objects, marker sizes indicate the 95% CL positional uncertainty of the source.

emission from that direction in data prior to 2017, as discussed in a companion paper (26).

High-energy γ -ray observations of TXS 0506+056

On 28 September 2017, the *Fermi* Large Area Telescope (LAT) Collaboration reported that the direction of origin of IceCube-170922A was consistent with a known γ -ray source in a state of enhanced emission (16). *Fermi*-LAT is a pair-conversion telescope aboard the *Fermi Gamma-ray Space Telescope* sensitive to γ -rays with energies from 20 MeV to greater than 300 GeV (27). Since August 2008, it has operated continuously, primarily in an all-sky survey mode. Its wide field of view of ~ 2.4 steradian provides coverage of the entire γ -ray sky every 3 hours. The search for possible counterparts to IceCube-170922A was part of the *Fermi*-LAT collaboration's routine multiwavelength, multimessenger program.

Inside the error region of the neutrino event, a positional coincidence was found with a previously cataloged γ -ray source, 0.1° from the best-fitting neutrino direction. TXS 0506+056 is a blazar of BL Lacertae (BL Lac) type. Its redshift of $z = 0.3365 \pm 0.0010$ was measured only recently based on the optical emission spectrum in a study triggered by the observation of IceCube-170922A (28).

TXS 0506+056 is a known *Fermi*-LAT γ -ray source, appearing in three catalogs of *Fermi* sources (23, 24, 29) at energies above 0.1, 50, and 10 GeV, respectively. An examination of the *Fermi* All-Sky Variability Analysis (FAVA) (30) photometric light curve for this object showed that TXS 0506+056 had brightened considerably in the GeV band starting in April 2017 (16). Independently, a γ -ray flare was also found by *Fermi*'s Automated Science Processing [ASP (25)]. Such flaring is not unusual for a BL Lac object and would not have been followed up as extensively if the neutrino were not detected.

Figure 3 shows the *Fermi*-LAT light curve and the detection time of the neutrino alert. The light curve of TXS 0506+056 from August 2008 to October 2017 was calculated in bins of 28 days for the energy range above 0.1 GeV. An additional light curve with 7-day bins was calculated for the period around the time of the neutrino alert. The γ -ray flux of TXS 0506+056 in each time bin was determined through a simultaneous fit of this source and the other *Fermi*-LAT sources in a 10° by 10° region of interest along with the Galactic and isotropic diffuse backgrounds, using a maximum-likelihood technique (25). The integrated γ -ray flux of TXS 0506+056 for $E > 0.1$ GeV, averaged over all *Fermi*-LAT observations spanning 9.5 years, is $(7.6 \pm 0.2) \times 10^{-8} \text{ cm}^{-2} \text{ s}^{-1}$. The

highest flux observed in a single 7-day light curve bin was $(5.3 \pm 0.6) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$, measured in the week 4 to 11 July 2017. Strong flux variations were observed during the γ -ray flare, the most prominent being a flux increase from $(7.9 \pm 2.9) \times 10^{-8} \text{ cm}^{-2} \text{ s}^{-1}$ in the week 8 to 15 August 2017 to $(4.0 \pm 0.5) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$ in the week 15 to 22 August 2017.

The Astro-Rivelatore Gamma a Immagini Leggero (*AGILE*) γ -ray telescope (31) confirmed the elevated level of γ -ray emission at energies above 0.1 GeV from TXS 0506+056 in a 13-day window (10 to 23 September 2017). The *AGILE* measured flux of $(5.3 \pm 2.1) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$ is consistent with the *Fermi*-LAT observations in this time period.

High-energy γ -ray observations are shown in Figs. 3 and 4. Details on the *Fermi*-LAT and *AGILE* analyses can be found in (25).

Very-high-energy γ -ray observations of TXS 0506+056

Following the announcement of IceCube-170922A, TXS 0506+056 was observed by several ground-based Imaging Atmospheric Cherenkov Telescopes (IACTs). A total of 1.3 hours of observations in the direction of the blazar TXS 0506+056 were taken using the High-Energy Stereoscopic System (H.E.S.S.) (32), located in Namibia, on 23 September 2017 [Modified Julian Date (MJD)

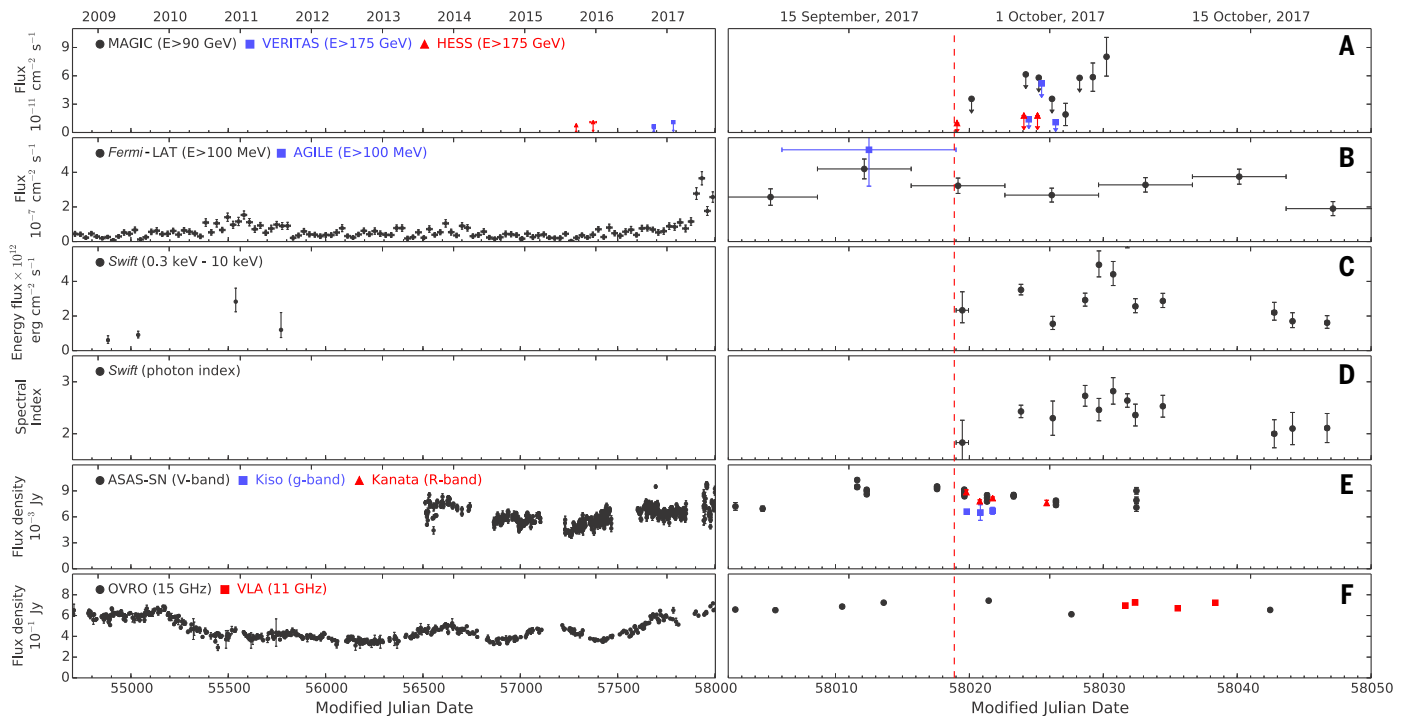

Fig. 3. Time-dependent multiwavelength observations of TXS 0506+056 before and after IceCube-170922A. Significant variability of the electromagnetic emission can be observed in all displayed energy bands, with the source being in a high-emission state around the time of the neutrino alert. From top to bottom: (A) VHE γ -ray observations by MAGIC, H.E.S.S., and VERITAS; (B) high-energy γ -ray observations by *Fermi*-LAT and *AGILE*; (C and D) x-ray observations by *Swift* XRT; (E) optical light curves from ASAS-SN, Kiso/KWFC, and Kanata/HONIR; and (F) radio observations by OVRO and VLA. The red

dashed line marks the detection time of the neutrino IceCube-170922A. The left set of panels shows measurements between MJD 54700 (22 August 2008) and MJD 58002 (6 September 2017). The set of panels on the right shows an expanded scale for time range MJD 58002 to MJD 58050 (24 October 2017). The *Fermi*-LAT light curve is binned in 28-day bins on the left panel, while finer 7-day bins are used on the expanded panel. A VERITAS limit from MJD 58019.40 (23 September 2017) of $2.1 \times 10^{-10} \text{ cm}^{-2} \text{ s}^{-1}$ is off the scale of the plot and not shown.

58019], ~4 hours after the circulation of the neutrino alert. A 1-hour follow-up observation of the neutrino alert under partial cloud coverage was performed using the Very Energetic Radiation Imaging Telescope Array System (VERITAS) γ -ray telescope array (33), located in Arizona, USA, later on the same day, ~12 hours after the IceCube detection. Both telescopes made additional observations on subsequent nights, but neither detected γ -ray emission from the source [see Fig. 3 and (25)]. Upper limits at 95% CL on the γ -ray flux were derived accordingly (assuming the measured spectrum, see below): $7.5 \times 10^{-12} \text{ cm}^{-2} \text{ s}^{-1}$ during the H.E.S.S. observation period and $1.2 \times 10^{-11} \text{ cm}^{-2} \text{ s}^{-1}$ during the VERITAS observations, both for energies $E > 175 \text{ GeV}$.

The Major Atmospheric Gamma Imaging Cherenkov (MAGIC) Telescopes (34) observed TXS 0506+056 for 2 hours on 24 September 2017 (MJD 58020) under nonoptimal weather conditions and then for a period of 13 hours from 28 September to 4 October 2017 (MJD 58024–58030) under good conditions. MAGIC consists of two 17-m telescopes, located at the Roque de los Muchachos Observatory on the Canary Island of La Palma (Spain).

No γ -ray emission from TXS 0506+056 was detected in the initial MAGIC observations on 24 September 2017, and an upper limit was derived on the flux above 90 GeV of $3.6 \times 10^{-11} \text{ cm}^{-2} \text{ s}^{-1}$

at 95% CL (assuming a spectrum $dN/dE \propto E^{-3.9}$). However, prompted by the *Fermi*-LAT detection of enhanced γ -ray emission, MAGIC performed another 13 hours of observations of the region starting 28 September 2017. Integrating the data, MAGIC detected a significant very-high-energy (VHE) γ -ray signal (35) corresponding to 374 ± 62 excess photons, with observed energies up to about 400 GeV. This represents a 6.2σ excess over expected background levels (25). The day-by-day light curve of TXS 0506+056 for energies above 90 GeV is shown in Fig. 3. The probability that a constant flux is consistent with the data is less than 1.35%. The measured differential photon spectrum (Fig. 4) can be described over the energy range of 80 to 400 GeV by a simple power law, $dN/dE \propto E^\gamma$, with a spectral index $\gamma = -3.9 \pm 0.4$ and a flux normalization of $(2.0 \pm 0.4) \times 10^{-10} \text{ TeV}^{-1} \text{ cm}^{-2} \text{ s}^{-1}$ at $E = 130 \text{ GeV}$. Uncertainties are statistical only. The estimated systematic uncertainties are <15% in the energy scale, 11 to 18% in the flux normalization, and ± 0.15 for the power-law slope of the energy spectrum (34). Further observations after 4 October 2017 were prevented by the full Moon.

An upper limit to the redshift of TXS 0506+056 can be inferred from VHE γ -ray observations using limits on the attenuation of the VHE flux due to interaction with the EBL. Details on the method are available in (25). The obtained upper

limit ranges from 0.61 to 0.98 at a 95% CL, depending on the EBL model used. These upper limits are consistent with the measured redshift of $z = 0.3365$ (28).

No γ -ray source above 1 TeV at the location of TXS 0506+056 was found in survey data of the High Altitude Water Cherenkov (HAWC) γ -ray observatory (36), either close to the time of the neutrino alert or in archival data taken since November 2014 (25).

VHE γ -ray observations are shown in Figs. 3 and 4. All measurements are consistent with the observed flux from MAGIC, considering the differences in exposure, energy range, and observation periods.

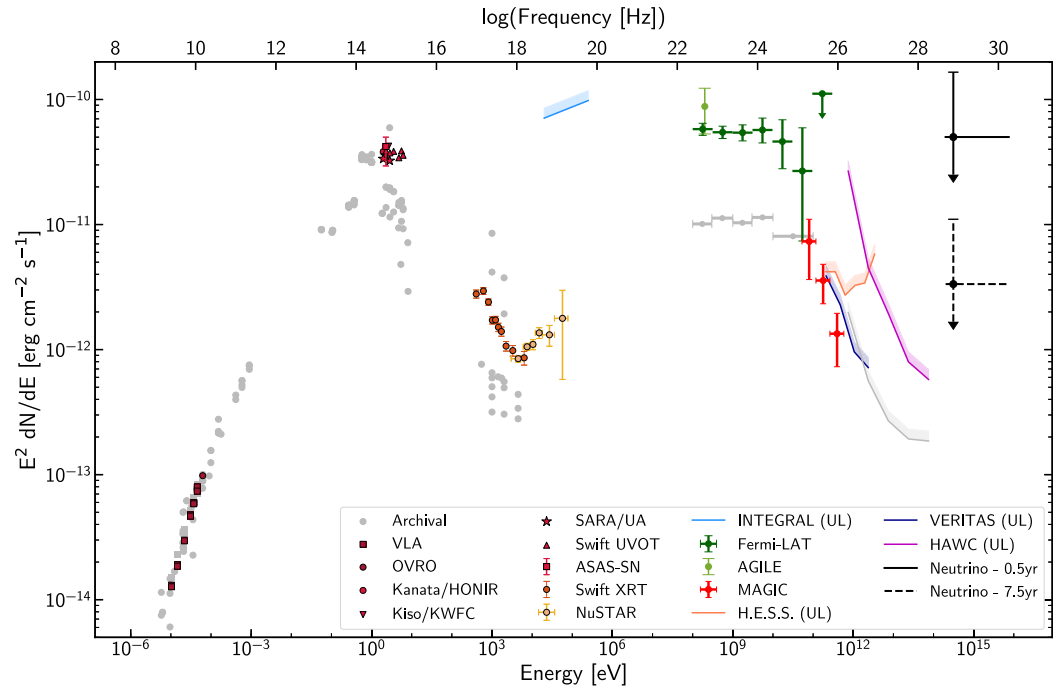

Radio, optical, and x-ray observations

The Karl G. Jansky Very Large Array (VLA) (37) observed TXS 0506+056 starting 2 weeks after the alert in several radio bands from 2 to 12 GHz (38), detecting significant radio flux variability and some spectral variability of this source. The source is also in the long-term blazar monitoring program of the Owens Valley Radio Observatory (OVRO) 40-m telescope at 15 GHz (39). The light curve shows a gradual increase in radio emission during the 18 months preceding the neutrino alert.

Optical observations were performed by the All-Sky Automated Survey for Supernovae (ASAS-SN) (40), the Liverpool Telescope (41), the

Fig. 4. Broadband spectral energy distribution for the blazar TXS 0506+056. The SED is

based on observations obtained within 14 days of the detection of the IceCube-170922A event. The $E^2 dN/dE$ vertical axis is equivalent to a vF_ν scale. Contributions are provided by the following instruments: VLA (38), OVRO (39), Kanata Hiroshima Optical and Near-Infrared camera (HONIR) (52), Kiso, and the Kiso Wide Field Camera (KWFC) (43), Southeastern Association for Research in Astronomy Observatory (SARA/UA) (53), ASAS-SN (54), *Swift* Ultraviolet and Optical Telescope (UVOT) and XRT (55), *NuSTAR* (56), *INTEGRAL* (57), *AGILE* (58), *Fermi*-LAT (16), MAGIC (35), VERITAS (59), H.E.S.S. (60), and HAWC (61). Specific observation dates and times are provided in (25). Differential flux upper limits (shown as colored bands and indicated as “UL” in the legend) are quoted at the 95% CL, while markers indicate significant detections. Archival observations are shown in gray to illustrate the historical flux level of the blazar in the radio-to-keV range as retrieved from the ASDC SED Builder (62), and in the γ -ray band as listed in the *Fermi*-LAT 3FGL catalog (23) and from an analysis of 2.5 years of HAWC data. The γ -ray observations have not been corrected for absorption owing to the EBL. SARA/UA, ASAS-SN, and Kiso/KWFC observations have not been corrected for Galactic attenuation. The electromagnetic SED displays a double-bump structure, one

peaking in the optical-ultraviolet range and the second one in the GeV range, which is characteristic of the nonthermal emission from blazars. Even within this 14-day period, there is variability observed in several of the energy bands shown (see Fig. 3), and the data are not all obtained simultaneously. Representative $v_\mu + \bar{\nu}_\mu$ neutrino flux upper limits that produce on average one detection like IceCube-170922A over a period of 0.5 (solid black line) and 7.5 years (dashed black line) are shown, assuming a spectrum of $dN/dE \propto E^{-2}$ at the most probable neutrino energy (311 TeV).

Kanata Telescope (42), the Kiso Schmidt Telescope (43), the high-resolution spectrograph (HRS) on the Southern African Large Telescope (SALT) (44), the Subaru telescope Faint Object Camera and Spectrograph (FOCAS) (45), and the X-SHOOTER instrument on the Very Large Telescope (VLT) (46). The V band flux of the source is the highest observed in recent years, and the spectral energy distribution has shifted toward blue wavelengths. Polarization was detected by Kanata in the R band at the level of 7%. Redshift determination for BL Lac objects is difficult owing to the nonthermal continuum from the nucleus outshining the spectral lines from the host galaxies. Attempts were made using optical spectra from the Liverpool, Subaru, and VLT telescopes to measure the redshift of TXS 0506+056, but only limits could be derived [see, e.g., (47)]. The redshift of TXS 0506+056 was later determined to be $z = 0.3365 \pm 0.0010$ using the Gran Telescopio Canarias (28).

X-ray observations were made by the X-Ray Telescope (XRT) on the *Neil Gehrels Swift Observatory* (0.3 to 10 keV) (48), *MAXI* Gas Slit Camera (GSC) (2 to 10 keV) (49), Nuclear Spectroscopic Telescope Array (*NuSTAR*) (3 to 79 keV) (50), and the International Gamma-Ray Astrophysics Laboratory (*INTEGRAL*) (20 to 250 keV) (51), with detections by *Swift* and *NuSTAR*. In a 2.1 square degree region around the neutrino alert, *Swift* identified nine x-ray sources, including TXS 0506+056.

Swift monitored the x-ray flux from TXS 0506+056 for 4 weeks after the alert, starting 23 September 2017 00:09:16 UT, finding clear evidence for spectral variability (see Fig. 3D). The strong increase in flux observed at VHE energies over several days up until MJD 58030 (4 October 2017) correlates well with an increase in the x-ray emission during this period of time. The spectrum of TXS 0506+056 observed in the week after the flare is compatible with the sum of two power-law spectra, a soft spectrum with index -2.8 ± 0.3 in the soft x-ray band covered by *Swift* XRT, and a hard spectrum with index -1.4 ± 0.3 in the hard x-ray band covered by *NuSTAR* (25). Extrapolated to 20 MeV, the *NuSTAR* hard-spectrum component connects smoothly to the plateau (index -2) component observed by the *Fermi*-LAT between 0.1 and 100 GeV and the soft VHE γ -ray component observed by MAGIC (compare Fig. 4). Taken together, these observations provide a mostly complete, contemporaneous picture of the source emissions from 0.3 keV to 400 GeV, more than nine orders of magnitude in photon energy.

Figures 3 and 4 summarize the multiwavelength light curves and the changes in the broadband spectral energy distribution (SED), compared to archival observations. Additional details about the radio, optical, and x-ray observations can be found in (25).

Chance coincidence probability

Data obtained from multiwavelength observations of TXS 0506+056 can be used to constrain the blazar-neutrino chance coincidence probability.

This coincidence probability is a measure of the likelihood that a neutrino alert like IceCube-170922A is correlated by chance with a flaring blazar, considering the large number of known γ -ray sources and the modest number of neutrino alerts.

Given the large number of potential neutrino source classes available, no a priori blazar-neutrino coincidence model was selected ahead of the alert. After the observation, however, several correlation scenarios were considered and tested to quantify the a posteriori significance of the observed coincidence. Testing multiple models is important as the specific assumptions about the correlation between neutrinos and γ -rays have an impact on the chance coincidence probability. In each case, the probability to obtain, by chance, a degree of correlation at least as high as that observed for IceCube-170922A was calculated using simulated neutrino alerts and the light curves of *Fermi*-LAT γ -ray sources. Given the continuous all-sky monitoring of the *Fermi*-LAT since 2008, all tests utilized 28-day binned γ -ray light curves above 1 GeV from 2257 extragalactic *Fermi*-LAT sources, derived in the same manner as used for the analysis of TXS 0506+056 γ -ray data.

To calculate the chance probabilities, a likelihood ratio test is used that allows different models of blazar-neutrino flux correlation to be evaluated in a consistent manner. All models assume that at least some of the observed γ -ray flux is produced in the same hadronic interactions that would produce high-energy neutrinos within the source. Our first model assumes that the neutrino flux is linearly correlated with the high-energy γ -ray energy flux (4). In this scenario, neutrinos are more likely to be produced during periods of bright, hard γ -ray emission. In the second model, the neutrino flux is modeled as strongly tied to variations in the observed γ -ray flux, regardless of the average flux of γ -rays. Here, a weak or a strong γ -ray source is equally likely to be a neutrino source if the neutrino is temporally correlated with variability in the γ -ray light curve. Third, we consider a correlation of the neutrino flux with the VHE γ -ray flux. Because hadronic acceleration up to a few PeV is required to explain the detected neutrino energy, VHE γ -ray sources are potential progenitors. Full details and results from these analyses are presented in (25).

The neutrino IceCube-170922A was found to arrive in a period of flaring activity in high-energy γ -rays. Prior to IceCube-170922A, nine public alerts had been issued by the IceCube real-time system. Additionally, 41 archival events have been identified among the IceCube data recorded since 2010, before the start of the real-time program in April 2016, which would have caused alerts if the real-time alert system had been in place. These events were also tested for coincidence with the γ -ray data.

Chance coincidence of the neutrino with the flare of TXS 0506+056 is disfavored at the 3σ level in any scenario where neutrino production is linearly correlated with γ -ray production or with γ -ray flux variations. This includes look-elsewhere corrections for all 10 alerts issued

previously by IceCube and the 41 archival events. One of the neutrino events that would have been sent as an alert and had a good angular resolution ($<5^\circ$) is in a spatial correlation with the γ -ray blazar 3FGL J1040.4+0615. However, this source was not in a particularly bright emission state at the detection time of the corresponding neutrino. Therefore, a substantially lower test statistic would be obtained in the chance correlation tests defined in this paper (25).

We have investigated how typical the blazar TXS 0506+056 is among those blazars that might have given rise to a coincident observation similar to the one reported here. A simulation that assumes that the neutrino flux is linearly correlated with the blazar γ -ray energy flux shows that in 14% of the signal realizations, we would find a neutrino coincident with a similarly bright γ -ray state as that observed for TXS 0506+056 (25). The detection of a single neutrino does not allow us to probe the details of neutrino production models or measure the neutrino-to- γ -ray production ratio. Further observations will be needed to unambiguously establish a correlation between high-energy neutrinos and blazars, as well as to understand the emission and acceleration mechanism in the event of a correlation.

Discussion

Blazars have often been suggested as potential sources of high-energy neutrinos. The calorimetric high-energy output of certain candidate blazars is high enough to explain individual observed IceCube events at 100-TeV to 1-PeV energies (63). Spatial coincidences between catalogs of blazars and neutrinos have been examined in (64), while (65) investigated one shower-like event with several thousand square degrees angular uncertainty observed in time coincidence with a blazar outburst. A track-like event, IceCube-160731, has been previously connected to a flaring γ -ray source (66). However, the limited evidence for a flaring source in the multiwavelength coverage did not permit an identification of the source type of the potential counterpart (66).

Owing to the precise direction of IceCube-170922A, combined with extensive multiwavelength observations, a chance correlation between a high-energy neutrino and the potential counterpart can be rejected at the 3σ level. Considering the association between IceCube-170922A and TXS 0506+056, γ -ray blazars are strong candidate sources for at least a fraction of the observed astrophysical neutrinos. Earlier studies of the cross-correlation between IceCube events and the γ -ray blazar population observed by *Fermi*-LAT demonstrated that these blazars can only produce a fraction of the observed astrophysical neutrino flux above 10 TeV (4). Although these limits constrain the contribution from blazars to the diffuse neutrino background, the potential association of one or two high-energy neutrinos to blazars over the total observing time of IceCube is fully compatible with the constraint.

Adopting standard cosmological parameters (67) $H_0 = 67.8$, $\Omega_m = 0.308$, $\Omega_\Lambda = 0.692$, where H_0 is the Hubble constant, Ω_m is the matter

density, and Ω_λ is the dark energy density, the observed redshift of $z = 0.3365$ implies an isotropic γ -ray luminosity between 0.1 and 100 GeV of 1.3×10^{47} erg s $^{-1}$ in the ± 2 weeks around the arrival time of the IceCube neutrino, and a luminosity of 2.8×10^{46} erg s $^{-1}$, averaged over all *Fermi*-LAT observations. Observations in the optical, x-ray, and VHE γ -ray bands show typical characteristics of blazar flares: strong variability on time scales of a few days and an indication of a shift of the synchrotron emission peak toward higher frequencies. VHE γ -ray emission is found to change by a factor of ~ 4 within just 3 days. Similarly, the high-energy γ -ray energy band shows flux variations up to a factor of ~ 5 from one week to the next.

No other neutrino event that would have passed the selection criteria for a high-energy alert was observed from this source since the start of IceCube observations in May 2010. The muon neutrino fluence for which we would expect to detect one high-energy alert event with IceCube in this period of time is 2.8×10^{-3} erg cm $^{-2}$. A power-law neutrino spectrum is assumed in this calculation with an index of -2 between 200 TeV and 7.5 PeV, the range between the 90% CL lower and upper limits for the energy of the observed neutrino [see (25) for details].

The fluence can be expressed as an integrated energy flux if we assume a time period during which the source was emitting neutrinos. For a source that emits neutrinos only during the ~ 6 -month period corresponding to the duration of the high-energy γ -ray flare, the corresponding average integrated muon neutrino energy flux would be 1.8×10^{-10} erg cm $^{-2}$ s $^{-1}$. Alternatively, the average integrated energy flux of a source that emits neutrinos over the whole observation period of IceCube (i.e., 7.5 years) would be 1.2×10^{-11} erg cm $^{-2}$ s $^{-1}$. These two benchmark cases are displayed in Fig. 4. In an ensemble of faint sources with a summed expectation of order 1, we would anticipate observing a neutrino even if the individual expectation value is $\ll 1$. This is expressed by the downward arrows on the neutrino flux points in Fig. 4.

The two cases discussed above correspond to average isotropic muon neutrino luminosities of 7.2×10^{46} erg s $^{-1}$ for a source that was emitting neutrinos in the ~ 6 -month period of the high-energy γ -ray flare, and 4.8×10^{45} erg s $^{-1}$ for a source that emitted neutrinos throughout the whole observation period. This is similar to the luminosity observed in γ -rays and thus broadly consistent with hadronic source scenarios (68).

A neutrino flux that produces a high-energy alert event can, over time, produce many lower-energy neutrino-induced muons in IceCube. A study of neutrino emission from TXS 0506+056 prior to the high-energy γ -ray flare, based on the investigation of these lower-energy events, is reported in a companion paper (26).

ACKNOWLEDGMENTS

MAGIC: We thank the Instituto de Astrofísica de Canarias for the excellent working conditions at the Observatorio del Roque de los Muchachos in La Palma. **AGILE:** We thank ASI personnel involved in the operations and data center of the *AGILE* mission. **ASAS-SN:** We thank Las Cumbres Observatory and its staff for their continued support of ASAS-SN. **HAWC:** Thanks to S. Delay, L. Daz, and E. Murrieta for technical support. **H.E.S.S.:** We appreciate the excellent work of the technical support staff in Berlin, Zeuthen, Heidelberg, Palaiseau, Paris, Saclay, Tübingen and in Namibia in the construction and operation of the equipment. **VERITAS:** We acknowledge the excellent work of the technical support staff at the Fred Lawrence Whipple Observatory and at the collaborating institutions in the construction and operation of the instrument. **VLA/17B-403 team:** We thank the NRAO for granting us DDT VLA time to observe this source and the NRAO staff for rapidly executing the observations.

Funding

IceCube Collaboration: The IceCube collaboration gratefully acknowledge the support from the following agencies and institutions: USA—U.S. National Science Foundation—Office of Polar Programs, U.S. National Science Foundation—Physics Division, Wisconsin Alumni Research Foundation, Center for High Throughput Computing (CHTC) at the University of Wisconsin—Madison, Open Science Grid (OSG), Extreme Science and Engineering Discovery Environment (XSEDE), U.S. Department of Energy National Energy Research Scientific Computing Center, Particle astrophysics research computing center at the University of Maryland, Institute for Cyber-Enabled Research at Michigan State University, and Astroparticle physics computational facility at Marquette University; Belgium—Funds for Scientific Research (FRS-FNRS and FWO), FWO Odysseus and Big Science programmes, and Belgian Federal Science Policy Office (Belspo); Germany—Bundesministerium für Bildung und Forschung (BMBF), Deutsche Forschungsgemeinschaft (DFG), Helmholtz Alliance for Astroparticle Physics (HAP), Initiative and Networking Fund of the Helmholtz Association, Deutsches Elektronen Synchrotron (DESY), and High Performance Computing cluster of the RWTH Aachen; Sweden—Swedish Research Council, Swedish Polar Research Secretariat, Swedish National Infrastructure for Computing (SNIC), and Knut and Alice Wallenberg Foundation; Australia—Australian Research Council; Canada—Natural Sciences and Engineering Research Council of Canada, Calcul Québec, Compute Ontario, Canada Foundation for Innovation, WestGrid, and Compute Canada; Denmark—Villum Fonden, Danish National Research Foundation (DNRF); New Zealand—Marsden Fund; Japan—Japan Society for Promotion of Science (JSPS) and Institute for Global Prominent Research (IGPR) of Chiba University; Korea—National Research Foundation of Korea (NRF); Switzerland—Swiss National Science Foundation (SNSF). **Fermi-LAT collaboration:** The *Fermi-LAT* Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Énergie Atomique and the Centre National de la Recherche Scientifique /Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden. Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France. This work performed in part under DOE Contract DE-AC02-76SF00515.

MAGIC collaboration: The financial support of the German BMBF and MPG, the Italian INFN and INAF, the Swiss National Fund SNF,

the ERDF under the Spanish MINECO (FPA2015-69818-P, FPA2012-36668, FPA2015-68378-P, FPA2015-69210-C6-2-R, FPA2015-69210-C6-4-R, FPA2015-69210-C6-6-R, AYA2015-71042-P, AYA2016-76012-C3-1-P, ESP2015-71662-C2-2-P, CSD2009-00064), and the Japanese JSPS and MEXT is gratefully acknowledged. This work was also supported by the Spanish Centro de Excelencia “Severo Ochoa” SEV-2012-0234 and SEV-2015-0548, and Unidad de Excelencia “Mara de Maetzu” MDM-2014-0369, by the Croatian Science Foundation (HrZZ) Project IP-2016-06-9782 and the University of Rijeka Project 13.12.1.3.02, by the DFG Collaborative Research Centers SFB823/C4 and SFB876/C3, the Polish National Research Centre grant UMO-2016/22/M/ST9/00382 and by the Brazilian MCTIC, CNPq and FAPERJ. **AGILE:** *AGILE* is an ASI space mission developed with scientific and programmatic support from INAF and INFN. Research partially supported through the ASI grant no. I/028/I/2.2. Part of this work is based on archival data, software or online services provided by the ASI Space Science Data Center (SSDC, previously known as ASDC). **ASAS-SN:** ASAS-SN is funded in part by the Gordon and Betty Moore Foundation through grant GBMF5490 to the Ohio State University, NSF grant AST-1515927, the Mt. Cuba Astronomical Foundation, the Center for Cosmology and AstroParticle Physics (CCAPP) at OSU, and the Chinese Academy of Sciences South America Center for Astronomy (CASSACA). A.F. was supported by the Initiative and Networking Fund of the Helmholtz Association. J.F.B. is supported by NSF grant PHY-1714479. S.D. acknowledges Project IC120009 supported by NSF. J.L.P. is supported by FONDECYT grant 1151445 and by the Ministry of Economy, Development, and Tourism’s Millennium Science Initiative through grant IC120009, awarded to The Millennium Institute of Astrophysics (MAS). This research was made possible through the use of the AAVSO Photometric All-Sky Survey (APASS), funded by the Robert Martin Ayers Sciences Fund. **HAWC:** HAWC acknowledges the support from: the US National Science Foundation (NSF) the US Department of Energy Office of High-Energy Physics; the Laboratory Directed Research and Development (LDRD) program of Los Alamos National Laboratory; Consejo Nacional de Ciencia y Tecnología (CONACyT), México (grants 271051, 232656, 260378, 179588, 239762, 254964, 271737, 258865, 243290, 132197, 281653) (Cátedras 873, 1563), Laboratorio Nacional HAWC de rayos gamma; L’OREAL Fellowship for Women in Science 2014; Red HAWC, México; DGAPA-UNAM (grants IG100317, IN111315, IN111716-3, IA102715, 109916, IA102917, IN112218); VIEP-BUAP; PIFI 2012, 2013, PROFOCIE 2014, 2015; Royal Society grant Newton Advanced Fellowship 180385; the University of Wisconsin Alumni Research Foundation; the Institute of Geophysics, Planetary Physics, and Signatures at Los Alamos National Laboratory; Polish Science Centre grant DEC-2014/13/B/ST9/945; Coordinación de la Investigación Científica de la Universidad Michoacana. **H.E.S.S.:** The support of the Namibian authorities and of the University of Namibia in facilitating the construction and operation of H.E.S.S. is gratefully acknowledged, as is the support by the German Ministry for Education and Research (BMBF), the Max Planck Society, the German Research Foundation (DFG), the Helmholtz Association, the Alexander von Humboldt Foundation, the French Ministry of Higher Education, Research and Innovation, the Centre National de la Recherche Scientifique (CNRS/IN2P3 and CNRS/INSU), the Commissariat à l’Énergie atomique et aux énergies alternatives (CEA), the UK Science and Technology Facilities Council (STFC), the Knut and Alice Wallenberg Foundation, the National Science Centre, Poland grant no. 2016/22/M/ST9/00382, the South African Department of Science and Technology and National Research Foundation, the University of Namibia, the National Commission on Research, Science & Technology of Namibia (NCRST), the Austrian Federal Ministry of Education, Science and Research and the Austrian Science Fund (FWF), the Australian Research Council (ARC), the Japan Society for the Promotion of Science and by the University of Amsterdam. This work benefited from services provided by the H.E.S.S. Virtual Organisation, supported by the national resource providers of the EGI Federation. **INTEGRAL:** *INTEGRAL* is an ESA space mission, with its instruments and science data center funded by the ESA member states (specifically the PI countries: Denmark, France, Germany, Italy, Switzerland, Spain), and with additional participation of Russia and the USA. The *INTEGRAL* SPI instrument was provided through Co-PI institutes IRAP (Toulouse/France) and MPE (Garching/Germany), the SPI project was coordinated and managed by CNES (Toulouse/France). The *INTEGRAL* IBIS instrument was provided through Co-PI institutes IAPS (Rome/Italy) and CEA (Saclay/France). The SPI-ACS detector system has been provided by MPE Garching/Germany. The SPI team is grateful to ASI, CEA, CNES, DLR, ESA, INTA, NASA, and OSTC for

their support. The Italian *INTEGRAL* team acknowledges the support of ASI/INAF agreement n. 2013-025-R.1. J.R. acknowledges support from the European Union’s Horizon 2020 Programme under the AHEAD project (grant no. 654215). R.D. acknowledges the German *INTEGRAL* support through DLR grants 50 OG 1101 and 1601. **Kanata, Kiso and Subaru observing teams:** Observations with the Kanata and Kiso Schmidt telescopes were supported by the Optical and Near-infrared Astronomy Inter-University Cooperation Program and the Grants-in-Aid of the Ministry of Education, Science, Culture, and Sport JP23740143, JP25800103, JP16H02158, JP17K14253, JP17H04830, JP26800103, JP24103003. This work was also based in part on data collected at Subaru Telescope, which is operated by the National Astronomical Observatory of Japan. **Kapteyn:** The Jacobus Kapteyn telescope is operated at the Observatorio del Roque de los Muchachos on the Spanish island of La Palma by the SARA consortium, whose member institutions (listed at <http://saraobservatory.org>) fund its operation. Refitting for remote operations and instrumentation were funded by the National Science Foundation under grant 1337566 to Texas A&M University–Commerce. **Liverpool Telescope:** The Liverpool Telescope is operated on the island of La Palma by Liverpool John Moores University in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias with financial support from the UK Science and Technology Facilities Council. **Swift/NuSTAR:** A.K. and D.F.C. acknowledge support from the National Aeronautics and Space Administration *Swift* Guest Investigator Program under grant NNX17AI95G. The *Swift* team at the Mission Operations Center (MOC) at Penn State acknowledges support from NASA contract NAS5-00136. *Swift* is supported at the University of Leicester by the UK Space Agency. **VERITAS:** This research is supported by grants from the U.S. Department of Energy Office of Science, the U.S. National Science Foundation and the Smithsonian Institution, and by NSERC in Canada. **VLA/17B-403** The National Radio Astronomy Observatory (NRAO) is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. A.J.T. is supported by a Natural Sciences and Engineering Research Council of Canada (NSERC) Post-Graduate Doctoral Scholarship (PGSD2-490318-2016). A.J.T. and G.R.S. are supported by NSERC Discovery Grants (RGPIN-402752-2011 and RGPIN-06569-2016). J.C.A.M.J. is the recipient of an Australian Research Council Future Fellowship (FT140101082). **Author contributions:** All authors meet the journal’s authorship criteria. **IceCube:** The IceCube Collaboration designed, constructed and now operates the IceCube Neutrino Observatory. Data processing and calibration, Monte Carlo simulations of the detector and of theoretical models, and data analyses were performed by a large number of collaboration members, who also discussed and approved the scientific results presented here. The paper was reviewed by the entire collaboration before publication, and all authors approved the final version of the manuscript. **Fermi-LAT:** The *Fermi-LAT* contact authors and internal reviewers are S.B., A.F., Y.T., K.B., E.C., and M.W. **MAGIC:** E.B. is the MAGIC multimessenger contact and PI of the neutrino follow-up program. K.S. is co-converter of the MAGIC transient working group. L.F. and M.P. are the main analysts of the MAGIC data. A.M. and E.P. derived an upper limit to the redshift inferred from MAGIC data. **AGILE:** All coauthors contributed to the scientific results presented in the paper. F.L. and M.T. wrote the part of the manuscript related to the *AGILE* results. **ASAS-SN:** A.F., B.J.S., and S.H. installed an automatic follow up to IceCube triggers which provided additional early data on this event. K.Z.S., C.S.K., J.F.B., T.A.T., T.W.S.H., S.D., J.L.P., and B.J.S. built the telescopes and developed the data processing pipelines. **HAWC:** T.W. is convener of the HAWC extragalactic working group. M.H. is the HAWC multimessenger contact. I.T., R.L., and I.M.C. were the main analysts of the HAWC data. **H.E.S.S.:** A.T. is convener of the H.E.S.S. extragalactic working group. F.S. is the H.E.S.S. multimessenger contact and PI of the neutrino follow-up program. C.H. is the main analyzer of the H.E.S.S. data presented here. S.O. provided a cross-check of the presented analysis. **INTEGRAL:** V.S. performed the *INTEGRAL* analysis. C.F. is the PI of *INTEGRAL* Science Data Center. R.D. is the co-PI of the SPI instrument. E.K. is *INTEGRAL* Project Scientist. P.L. and P.U. are co-PIs of *INTEGRAL*/IBIS instrument. S.M. is responsible for the *INTEGRAL*/IBAS. All of the collaborators provided contribution to the text. **Kanata, Kiso and Subaru observing teams:** Y.T.T., Y.U., and K.O. developed the follow-up strategy to search for IceCube counterparts. T.N. and M.K. conducted the near-infrared imaging and polarimetric observations of the TXS 0506+056 using the HONIR instrument on the Kanata telescope, which were processed by the data reduction system developed by R.I. The reduced

images were mainly examined by H.M. and H.N. M.Y. reduced the polarimetric data. K.S.K. supervised all of the above. T.M. conducted the optical imaging observations of TXS 0506+056 with the KWFC instrument on the Kiso Schmidt telescope and reduced the data. Y.M. conducted optical spectroscopic observations of the TXS 0506+056 with the FOCAS spectrograph on the 8.2 m Subaru telescope. The data are reduced and examined by M.Y. and T.M. **Kapteyn:** W.C.K. obtained and reduced the optical observations at the Kapteyn telescope. **Liverpool Telescope:** I.S. and C.C. obtained, reduced, and analyzed the Liverpool Telescope spectra. **Swift/NuSTAR:** A.K. led reduction of *Swift* XRT data, and J.J.D. led reduction of *NuSTAR* data. D.B.F. carried out the joint *Swift* XRT + *NuSTAR* analysis, and A.K. managed author contributions to this section. **VERITAS:** The construction, operation, and maintenance of the VERITAS telescopes, as well as the tools to analyze the VERITAS data, are the work of the the VERITAS Collaboration as a whole. The VERITAS Collaboration contacts for this paper are M.S. and D.A.W. **VLA/17B-403:** GRS wrote the Director's Discretionary Time proposal for the VLA observations. A.J.T. performed the VLA data reduction and analyses in consultation with the rest of the team. A.J.T. and G.R.S. wrote the VLA-related text in consultation with the rest of the team. G.R.S. contributed to writing the entire paper. **Competing interests:** All collaborations declare no competing interests.

Data and materials availability: IceCube: All IceCube data related to the the results presented in this paper are provided in the supplementary materials (25). **Fermi-LAT:** The *Fermi*-LAT data are available from the *Fermi* Science Support Center <http://fermi.gsfc.nasa.gov/ssc> and https://www.glast.stanford.edu/pub_data/1483/. **MAGIC:** The MAGIC data and analysis results are accessible at <https://magic.mpp.mpg.de/public/public-data/>. **AGILE:** The *AGILE* data are available at www.ssdsc.asi.it/mmia/index.php?mission=agilemmia. Data analysis software and calibrations are available at <http://agile.ssdsc.asi.it/publicsoftware.html>. **ASAS-SN:** The ASAS-SN light curves are available at <https://asas-sn.osu.edu>. **HAWC:** The HAWC data are available at <https://data.hawc-observatory.org/datasets/ic170922/index.php>. **H.E.S.S.:** The H.E.S.S. data are available at https://www.mpi-hd.mpg.de/hfm/HESS/pages/publications/auxiliary/auxinfo_TXS0506.html. **INTEGRAL:** The *INTEGRAL* data and analysis software are available at www.isdc.unige.ch/. **Kanata, Kiso and Subaru observing teams:** Data taken with the Kiso, Kanata, and Subaru telescopes are available in the archive SMOKA <https://smoka.nao.ac.jp/>, operated by the Astronomy Data Center, National Astronomical Observatory of Japan. The Subaru data were taken in the open-use program S16B-0711. **Kapteyn:** The Kapteyn data were taken from (53). **Liverpool Telescope:** The Liverpool Telescope data are available in the telescope archive at <http://telescope.livjm.ac.uk/cgi-bin/>

It_search. Swift/NuSTAR: The *Swift* data are available at www.swift.ac.uk/archive/obs.php. The initial tiling observations, shortly after the IceCube trigger, are targetIDs 10308-10326. The monitoring ObsIDs observed from 23 September to 23 October are 00010308001, 00083368001-006, 00010308008-013. The *NuSTAR* data are available at <https://heasarc.gsfc.nasa.gov/FTP/nustar/data/obs/03/9//90301618002/> under ObsID 90301618002. **VERITAS:** The VERITAS data are available at <https://veritas.sao.arizona.edu/veritas-science/veritas-results-mainmenu-72/490-ic-result-VLA/17B-403> team: The VLA data are available through the NRAO Science Data Archive <https://archive.nrao.edu/archive/advquery.jsp> under Project Code 17B-403.

Neutrino emission from a flaring blazar

Neutrinos interact only very weakly with matter, but giant detectors have succeeded in detecting small numbers of astrophysical neutrinos. Aside from a diffuse background, only two individual sources have been identified: the Sun and a nearby supernova in 1987. A multiteam collaboration detected a high-energy neutrino event whose arrival direction was consistent with a known blazar—a type of quasar with a relativistic jet oriented directly along our line of sight. The blazar, TXS 0506+056, was found to be undergoing a gamma-ray flare, prompting an extensive multiwavelength campaign. Motivated by this discovery, the IceCube collaboration examined lower-energy neutrinos detected over the previous several years, finding an excess emission at the location of the blazar. Thus, blazars are a source of astrophysical neutrinos.

Abstract

On 2017 August 17 a binary neutron star coalescence candidate (later designated GW170817) with merger time 12:41:04 UTC was observed through gravitational waves by the Advanced LIGO and Advanced Virgo detectors. The *Fermi* Gamma-ray Burst Monitor independently detected a gamma-ray burst (GRB 170817A) with a time delay of ~ 1.7 s with respect to the merger time. From the gravitational-wave signal, the source was initially localized to a sky region of 31 deg^2 at a luminosity distance of 40_{-8}^{+8} Mpc and with component masses consistent with neutron stars. The component masses were later measured to be in the range 0.86 to $2.26 M_{\odot}$. An extensive observing campaign was launched across the electromagnetic spectrum leading to the discovery of a bright optical transient (SSS17a, now with the IAU identification of AT 2017gfo) in NGC 4993 (at ~ 40 Mpc) less than 11 hours after the merger by the One-Meter, Two Hemisphere (1M2H) team using the 1 m Swope Telescope. The optical transient was independently detected by multiple teams within an hour. Subsequent observations targeted the object and its environment. Early ultraviolet observations revealed a blue transient that faded within 48 hours. Optical and infrared observations showed a redward evolution over ~ 10 days. Following early non-detections, X-ray and radio emission were discovered at the transient's position ~ 9 and ~ 16 days, respectively, after the merger. Both the X-ray and radio emission likely arise from a physical process that is distinct from the one that generates the UV/optical/near-infrared emission. No ultra-high-energy gamma-rays and no neutrino candidates consistent with the source were found in follow-up searches. These observations support the hypothesis that GW170817 was produced by the merger of two neutron stars in NGC 4993 followed by a short gamma-ray burst (GRB 170817A) and a kilonova/macronova powered by the radioactive decay of *r*-process nuclei synthesized in the ejecta.

Key words: gravitational waves – stars: neutron

1. Introduction

Over 80 years ago Baade & Zwicky (1934) proposed the idea of neutron stars, and soon after, Oppenheimer & Volkoff (1939) carried out the first calculations of neutron star models. Neutron stars entered the realm of observational astronomy in the 1960s by providing a physical interpretation of X-ray emission from Scorpius X-1 (Giacconi et al. 1962; Shklovsky 1967) and of radio pulsars (Gold 1968; Hewish et al. 1968; Gold 1969).

The discovery of a radio pulsar in a double neutron star system by Hulse & Taylor (1975) led to a renewed interest in binary stars and compact-object astrophysics, including the

development of a scenario for the formation of double neutron stars and the first population studies (Flannery & van den Heuvel 1975; Masevitch et al. 1976; Clark 1979; Clark et al. 1979; Dewey & Cordes 1987; Lipunov et al. 1987; for reviews see Kalogera et al. 2007; Postnov & Yungelson 2014). The Hulse-Taylor pulsar provided the first firm evidence (Taylor & Weisberg 1982) of the existence of gravitational waves (Einstein 1916, 1918) and sparked a renaissance of observational tests of general relativity (Damour & Taylor 1991, 1992; Taylor et al. 1992; Wex 2014). Merging binary neutron stars (BNSs) were quickly recognized to be promising sources of detectable gravitational waves, making them a primary target for ground-based interferometric detectors (see Abadie et al. 2010 for an overview). This motivated the development of accurate models for the two-body, general-relativistic dynamics (Blanchet et al. 1995; Buonanno & Damour 1999; Pretorius 2005; Baker et al. 2006; Campanelli et al. 2006; Blanchet 2014) that are critical for detecting and interpreting gravitational waves (Abbott et al. 2016c, 2016d, 2016e, 2017a, 2017c, 2017d).

Figure 1. Localization of the gravitational-wave, gamma-ray, and optical signals. The left panel shows an orthographic projection of the 90% credible regions from LIGO (190 deg²; light green), the initial LIGO-Virgo localization (31 deg²; dark green), IPN triangulation from the time delay between *Fermi* and *INTEGRAL* (light blue), and *Fermi*-GBM (dark blue). The inset shows the location of the apparent host galaxy NGC 4993 in the Swope optical discovery image at 10.9 hr after the merger (top right) and the DLT40 pre-discovery image from 20.5 days prior to merger (bottom right). The reticle marks the position of the transient in both images.

In the mid-1960s, gamma-ray bursts (GRBs) were discovered by the Vela satellites, and their cosmic origin was first established by Klebesadel et al. (1973). GRBs are classified as *long* or *short*, based on their duration and spectral hardness (Dezalay et al. 1992; Kouveliotou et al. 1993). Uncovering the progenitors of GRBs has been one of the key challenges in high-energy astrophysics ever since (Lee & Ramirez-Ruiz 2007). It has long been suggested that short GRBs might be related to neutron star mergers (Goodman 1986; Paczynski 1986; Eichler et al. 1989; Narayan et al. 1992).

In 2005, the field of short gamma-ray burst (sGRB) studies experienced a breakthrough (for reviews see Nakar 2007; Berger 2014) with the identification of the first host galaxies of sGRBs and multi-wavelength observation (from X-ray to optical and radio) of their afterglows (Berger et al. 2005; Fox et al. 2005; Gehrels et al. 2005; Hjorth et al. 2005b; Villasenor et al. 2005). These observations provided strong hints that sGRBs might be associated with mergers of neutron stars with other neutron stars or with black holes. These hints included: (i) their association with both elliptical and star-forming galaxies (Barthelmy et al. 2005; Prochaska et al. 2006; Berger et al. 2007; Ofek et al. 2007; Troja et al. 2008; D’Avanzo et al. 2009; Fong et al. 2013), due to a very wide range of delay times, as predicted theoretically (Bagot et al. 1998; Fryer et al. 1999; Belczynski et al. 2002); (ii) a broad distribution of spatial offsets from host-galaxy centers (Berger 2010; Fong & Berger 2013; Tunnicliffe et al. 2014), which was predicted to arise from supernova kicks (Narayan et al. 1992; Bloom et al. 1999); and (iii) the absence of associated supernovae (Fox et al. 2005; Hjorth et al. 2005c, 2005a; Soderberg et al. 2006; Kocevski et al. 2010; Berger et al. 2013a). Despite these strong hints, proof that sGRBs were powered by neutron star mergers remained elusive, and interest intensified in following up gravitational-wave detections electromagnetically (Metzger & Berger 2012; Nissanke et al. 2013).

Evidence of beaming in some sGRBs was initially found by Soderberg et al. (2006) and Burrows et al. (2006) and confirmed

by subsequent sGRB discoveries (see the compilation and analysis by Fong et al. 2015 and also Troja et al. 2016). Neutron star binary mergers are also expected, however, to produce isotropic electromagnetic signals, which include (i) early optical and infrared emission, a so-called kilonova/macronova (hereafter kilonova; Li & Paczyński 1998; Kulkarni 2005; Rosswog 2005; Metzger et al. 2010; Roberts et al. 2011; Barnes & Kasen 2013; Kasen et al. 2013; Tanaka & Hotokezaka 2013; Grossman et al. 2014; Barnes et al. 2016; Tanaka 2016; Metzger 2017) due to radioactive decay of rapid neutron-capture process (*r*-process) nuclei (Lattimer & Schramm 1974, 1976) synthesized in dynamical and accretion-disk-wind ejecta during the merger; and (ii) delayed radio emission from the interaction of the merger ejecta with the ambient medium (Nakar & Piran 2011; Piran et al. 2013; Hotokezaka & Piran 2015; Hotokezaka et al. 2016). The late-time infrared excess associated with GRB 130603B was interpreted as the signature of *r*-process nucleosynthesis (Berger et al. 2013b; Tanvir et al. 2013), and more candidates were identified later (for a compilation see Jin et al. 2016).

Here, we report on the global effort⁹⁵⁸ that led to the first joint detection of gravitational and electromagnetic radiation from a single source. An ~ 100 s long gravitational-wave signal (GW170817) was followed by an sGRB (GRB 170817A) and an optical transient (SSS17a/AT 2017gfo) found in the host galaxy NGC 4993. The source was detected across the electromagnetic spectrum—in the X-ray, ultraviolet, optical, infrared, and radio bands—over hours, days, and weeks. These observations support the hypothesis that GW170817 was produced by the merger of two neutron stars in NGC 4993, followed by an sGRB and a kilonova powered by the radioactive decay of *r*-process nuclei synthesized in the ejecta.

⁹⁵⁸ A follow-up program established during initial LIGO-Virgo observations (Abadie et al. 2012) was greatly expanded in preparation for Advanced LIGO-Virgo observations. Partners have followed up binary black hole detections, starting with GW150914 (Abbott et al. 2016a), but have discovered no firm electromagnetic counterparts to those events.

2. A Multi-messenger Transient

On 2017 August 17 12:41:06 UTC the *Fermi* Gamma-ray Burst Monitor (GBM; Meegan et al. 2009) onboard flight software triggered on, classified, and localized a GRB. A Gamma-ray Coordinates Network (GCN) Notice (Fermi-GBM 2017) was issued at 12:41:20 UTC announcing the detection of the GRB, which was later designated GRB 170817A (von Kienlin et al. 2017). Approximately 6 minutes later, a gravitational-wave candidate (later designated GW170817) was registered in low latency (Cannon et al. 2012; Messick et al. 2017) based on a single-detector analysis of the Laser Interferometer Gravitational-wave Observatory (LIGO) Hanford data. The signal was consistent with a BNS coalescence with merger time, t_c , 12:41:04 UTC, less than 2 s before GRB 170817A. A GCN Notice was issued at 13:08:16 UTC. Single-detector gravitational-wave triggers had never been disseminated before in low latency. Given the temporal coincidence with the *Fermi*-GBM GRB, however, a GCN Circular was issued at 13:21:42 UTC (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017a) reporting that a highly significant candidate event consistent with a BNS coalescence was associated with the time of the GRB⁹⁵⁹. An extensive observing campaign was launched across the electromagnetic spectrum in response to the *Fermi*-GBM and LIGO–Virgo detections, and especially the subsequent well-constrained, three-dimensional LIGO–Virgo localization. A bright optical transient (SSS17a, now with the IAU identification of AT 2017gfo) was discovered in NGC 4993 (at ~ 40 Mpc) by the 1M2H team (August 18 01:05 UTC; Coulter et al. 2017a) less than 11 hr after the merger.

2.1. Gravitational-wave Observation

GW170817 was first detected online (Cannon et al. 2012; Messick et al. 2017) as a single-detector trigger and disseminated through a GCN Notice at 13:08:16 UTC and a GCN Circular at 13:21:42 UTC (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017a). A rapid re-analysis (Nitz et al. 2017a, 2017b) of data from LIGO-Hanford, LIGO-Livingston, and Virgo confirmed a highly significant, coincident signal. These data were then combined to produce the first three-instrument skymap (Singer & Price 2016; Singer et al. 2016) at 17:54:51 UTC (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017b), placing the source nearby, at a luminosity distance *initially* estimated to be 40_{-8}^{+8} Mpc in an elongated region of ≈ 31 deg² (90% credibility), centered around R.A. $\alpha(\text{J2000.0}) = 12^{\text{h}}57^{\text{m}}$ and decl. $\delta(\text{J2000.0}) = -17^{\circ}51'$. Soon after, a coherent analysis (Veitch et al. 2015) of the data from the detector network produced a skymap that was distributed at 23:54:40 UTC (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017c), consistent with the initial one: a ≈ 34 deg² sky region at 90% credibility centered around $\alpha(\text{J2000.0}) = 13^{\text{h}}09^{\text{m}}$ and $\delta(\text{J2000.0}) = -25^{\circ}37'$.

The offline gravitational-wave analysis of the LIGO-Hanford and LIGO-Livingston data identified GW170817 with a false-alarm rate of less than one per 8.0×10^4 (Abbott et al. 2017c). This analysis uses post-Newtonian waveform models (Blanchet et al. 1995, 2004, 2006; Bohé et al. 2013) to construct a matched-filter search (Sathyaprakash & Dhurandhar 1991; Cutler et al. 1993; Allen et al. 2012) for gravitational waves from the coalescence of compact-object binary systems in the (detector frame) total mass range 2–500 M_{\odot} . GW170817 lasted for ~ 100 s in the detector sensitivity band. The signal reached Virgo first,

then LIGO-Livingston 22 ms later, and after 3 ms more, it arrived at LIGO-Hanford. GW170817 was detected with a combined signal-to-noise ratio across the three-instrument network of 32.4. For comparison, GW150914 was observed with a signal-to-noise ratio of 24 (Abbott et al. 2016c).

The properties of the source that generated GW170817 (see Abbott et al. 2017c for full details; here, we report parameter ranges that span the 90% credible interval) were derived by employing a coherent Bayesian analysis (Veitch et al. 2015; Abbott et al. 2016b) of the three-instrument data, including marginalization over calibration uncertainties and assuming that the signal is described by waveform models of a binary system of compact objects in quasi-circular orbits (see Abbott et al. 2017c and references therein). The waveform models include the effects introduced by the objects' intrinsic rotation (spin) and tides. The source is located in a region of 28 deg² at a distance of 40_{-14}^{+8} Mpc, see Figure 1, consistent with the early estimates disseminated through GCN Circulares (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017b, 2017c). The misalignment between the total angular momentum axis and the line of sight is $\leq 56^{\circ}$.

The (source-frame⁹⁶⁰) masses of the primary and secondary components, m_1 and m_2 , respectively, are in the range $m_1 \in (1.36\text{--}2.26)M_{\odot}$ and $m_2 \in (0.86\text{--}1.36)M_{\odot}$. The chirp mass,⁹⁶¹ \mathcal{M} , is the mass parameter that, at the leading order, drives the frequency evolution of gravitational radiation in the inspiral phase. This dominates the portion of GW170817 in the instruments' sensitivity band. As a consequence, it is the best measured mass parameter, $\mathcal{M} = 1.188_{-0.002}^{+0.004} M_{\odot}$. The total mass is $2.82_{-0.09}^{+0.47} M_{\odot}$, and the mass ratio m_2/m_1 is bound to the range 0.4–1.0. These results are consistent with a binary whose components are neutron stars. White dwarfs are ruled out since the gravitational-wave signal sweeps through 200 Hz in the instruments' sensitivity band, implying an orbit of size ~ 100 km, which is smaller than the typical radius of a white dwarf by an order of magnitude (Shapiro & Teukolsky 1983). However, for this event gravitational-wave data *alone* cannot rule out objects more compact than neutron stars such as quark stars or black holes (Abbott et al. 2017c).

2.2. Prompt Gamma-Ray Burst Detection

The first announcement of GRB 170817A came from the GCN Notice (Fermi-GBM 2017) automatically generated by *Fermi*-GBM at 12:41:20 UTC, just 14 s after the detection of the GRB at $T_0 = 12:41:06$ UTC. GRB 170817A was detected by the *International Gamma-Ray Astrophysics Laboratory* (*INTEGRAL*) spacecraft using the Anti-Coincidence Shield (von Kienlin et al. 2003) of the spectrometer on board *INTEGRAL* (SPI), through an offline search initiated by the LIGO–Virgo and *Fermi*-GBM reports. The final *Fermi*-GBM localization constrained GRB 170817A to a region with highest probability at $\alpha(\text{J2000.0}) = 12^{\text{h}}28^{\text{m}}$ and $\delta(\text{J2000.0}) = -30^{\circ}$ and 90% probability region covering ~ 1100 deg² (Goldstein et al. 2017a). The difference between the binary merger and the

⁹⁵⁹ The trigger was recorded with LIGO–Virgo ID G298048, by which it is referred throughout the GCN Circulares.

⁹⁶⁰ Any mass parameter $m^{(\text{det})}$ derived from the observed signal is measured in the detector frame. It is related to the mass parameter, m , in the source frame by $m^{(\text{det})} = (1+z)m$, where z is the source's redshift. Here, we always report source-frame mass parameters, assuming standard cosmology (Ade et al. 2016) and correcting for the motion of the solar System barycenter with respect to the cosmic microwave background (Fixsen 2009). From the gravitational-wave luminosity distance measurement, the redshift is determined to be $z = 0.008_{-0.003}^{+0.002}$. For full details see Abbott et al. (2016b, 2017c, 2017e).

⁹⁶¹ The binary's chirp mass is defined as $\mathcal{M} = (m_1 m_2)^{3/5} / (m_1 + m_2)^{1/5}$.

Figure 2. Timeline of the discovery of GW170817, GRB 170817A, SSS17a/AT 2017gfo, and the follow-up observations are shown by messenger and wavelength relative to the time t_c of the gravitational-wave event. Two types of information are shown for each band/messenger. First, the shaded dashes represent the times when information was reported in a GCN Circular. The names of the relevant instruments, facilities, or observing teams are collected at the beginning of the row. Second, representative observations (see Table 1) in each band are shown as solid circles with their areas approximately scaled by brightness; the solid lines indicate when the source was detectable by at least one telescope. Magnification insets give a picture of the first detections in the gravitational-wave, gamma-ray, optical, X-ray, and radio bands. They are respectively illustrated by the combined spectrogram of the signals received by LIGO-Hanford and LIGO-Livingston (see Section 2.1), the *Fermi*-GBM and *INTEGRAL*/SPI-ACS lightcurves matched in time resolution and phase (see Section 2.2), 1.5×1.5 postage stamps extracted from the initial six observations of SSS17a/AT 2017gfo and four early spectra taken with the SALT (at $t_c + 1.2$ days; Buckley et al. 2017; McCully et al. 2017b), ESO-NTT (at $t_c + 1.4$ days; Smartt et al. 2017), the SOAR 4 m telescope (at $t_c + 1.4$ days; Nicholl et al. 2017d), and ESO-VLT-XShooter (at $t_c + 2.4$ days; Smartt et al. 2017) as described in Section 2.3, and the first X-ray and radio detections of the same source by *Chandra* (see Section 3.3) and JVLA (see Section 3.4). In order to show representative spectral energy distributions, each spectrum is normalized to its maximum and shifted arbitrarily along the linear y-axis (no absolute scale). The high background in the SALT spectrum below 4500 Å prevents the identification of spectral features in this band (for details McCully et al. 2017b).

GRB is $T_0 - t_c = 1.734 \pm 0.054$ s (Abbott et al. 2017g). Exploiting the difference in the arrival time of the gamma-ray signals at *Fermi*-GBM and *INTEGRAL* SPI-ACS (Svinkin et al. 2017c) provides additional significant constraints on the gamma-ray localization area (see Figure 1). The IPN localization capability will be especially important in the case of future gravitational-wave events that might be less well-localized by LIGO-Virgo.

Standard follow-up analyses (Goldstein et al. 2012; Paciesas et al. 2012; Gruber et al. 2014) of the *Fermi*-GBM trigger determined the burst duration to be $T_{90} = 2.0 \pm 0.5$ s, where T_{90} is defined as the duration over which 90% of the burst fluence is accumulated in the energy range of 50–300 keV. From the *Fermi*-GBM T_{90} measurement, GRB 170817A was classified as an sGRB with 3:1 odds over being a long GRB. The classification of GRB 170817A as an sGRB is further supported by incorporating the hardness ratio of the burst and comparing it to the *Fermi*-GBM catalog (Goldstein et al. 2017a). The SPI-ACS duration for GRB 170817A of 100 ms is consistent with an sGRB classification within the instrument’s historic sample (Savchenko et al. 2012).

The GRB had a peak photon flux measured on a 64 ms timescale of 3.7 ± 0.9 photons $s^{-1} cm^{-2}$ and a fluence over the T_{90} interval of $(2.8 \pm 0.2) \times 10^{-7}$ erg cm^{-2} (10–1000 keV; (Goldstein et al. 2017a). GRB 170817A is the closest sGRB with measured redshift. By usual measures, GRB 170817A is sub-luminous, a tantalizing observational result that is explored in Abbott et al. (2017g) and Goldstein et al. (2017a).

Detailed analysis of the *Fermi*-GBM data for GRB 170817A revealed two components to the burst: a main pulse encompassing the GRB trigger time from $T_0 - 0.320$ s to $T_0 + 0.256$ s followed by a weak tail starting at $T_0 + 0.832$ s and extending to $T_0 + 1.984$ s. The spectrum of the main pulse of GRB 170817A is best fit with a Comptonized function (a power law with an exponential cutoff) with a power-law photon index of -0.62 ± 0.40 , peak energy $E_{\text{peak}} = 185 \pm 62$ keV, and time-averaged flux of $(3.1 \pm 0.7) \times 10^{-7}$ erg $cm^{-2} s^{-1}$. The weak tail that follows the main pulse, when analyzed independently, has a localization consistent with both the main pulse and the gravitational-wave position. The weak tail, at 34% the fluence of the main pulse, extends the T_{90} beyond the main pulse and has a softer, blackbody spectrum with $kT = 10.3 \pm 1.5$ keV (Goldstein et al. 2017a).

Using the *Fermi*-GBM spectral parameters of the main peak and T_{90} interval, the integrated fluence measured by *INTEGRAL* SPI-ACS is $(1.4 \pm 0.4) \times 10^{-7}$ erg cm^{-2} (75–2000 keV), compatible with the *Fermi*-GBM spectrum. Because SPI-ACS is most sensitive above 100 keV, it detects only the highest-energy part of the main peak near the start of the longer *Fermi*-GBM signal (Abbott et al. 2017f).

2.3. Discovery of the Optical Counterpart and Host Galaxy

The announcements of the *Fermi*-GBM and LIGO-Virgo detections, and especially the well-constrained, three-dimensional LIGO-Virgo localization, triggered a broadband observing campaign in search of electromagnetic counterparts. A large number of teams across the world were mobilized using ground- and space-based telescopes that could observe the region identified by the gravitational-wave detection. GW170817 was localized to the southern sky, setting in the early evening for the northern hemisphere

telescopes, thus making it inaccessible to the majority of them. The LIGO-Virgo localization region (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017b, 2017c) became observable to telescopes in Chile about 10 hr after the merger with an altitude above the horizon of about 45° .

The One-Meter, Two-Hemisphere (1M2H) team was the first to discover and announce (August 18 01:05 UTC; Coulter et al. 2017a) a bright optical transient in an *i*-band image acquired on August 17 at 23:33 UTC ($t_c + 10.87$ hr) with the 1 m Swope telescope at Las Campanas Observatory in Chile. The team used an observing strategy (Gehrels et al. 2016) that targeted known galaxies (from White et al. 2011b) in the three-dimensional LIGO-Virgo localization taking into account the galaxy stellar mass and star formation rate (Coulter et al. 2017). The transient, designated Swope Supernova Survey 2017a (SSS17a), was $i = 17.057 \pm 0.018$ mag⁹⁶² (August 17 23:33 UTC, $t_c + 10.87$ hr) and did not match any known asteroid or supernova. SSS17a (now with the IAU designation AT 2017gfo) was located at $\alpha(J2000.0) = 13^h09^m48^s.085 \pm 0.018$, $\delta(J2000.0) = -23^\circ22'53''343 \pm 0.218$ at a projected distance of $10''6$ from the center of NGC 4993, an early-type galaxy in the ESO 508 group at a distance of $\simeq 40$ Mpc (Tully–Fisher distance from Freedman et al. 2001), consistent with the gravitational-wave luminosity distance (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017b).

Five other teams took images of the transient within an hour of the 1M2H image (and before the SSS17a announcement) using different observational strategies to search the LIGO-Virgo sky localization region. They reported their discovery of the same optical transient in a sequence of GCNs: the Dark Energy Camera (01:15 UTC; Allam et al. 2017), the Distance Less Than 40 Mpc survey (01:41 UTC; Yang et al. 2017a), Las Cumbres Observatory (LCO; 04:07 UTC; Arcavi et al. 2017a), the Visible and Infrared Survey Telescope for Astronomy (VISTA; 05:04 UTC; Tanvir et al. 2017a), and MASTER (05:38 UTC; Lipunov et al. 2017d). Independent searches were also carried out by the Rapid Eye Mount (REM-GRAWITA, optical, 02:00 UTC; Melandri et al. 2017a), *Swift* UVOT/XRT (ultraviolet, 07:24 UTC; Evans et al. 2017a), and Gemini-South (infrared, 08:00 UT; Singer et al. 2017a).

The Distance Less Than 40 Mpc survey (DLT40; L. Tartaglia et al. 2017, in preparation) team independently detected SSS17a/AT 2017gfo, automatically designated DLT17ck (Yang et al. 2017a) in an image taken on August 17 23:50 UTC while carrying out high-priority observations of 51 galaxies (20 within the LIGO-Virgo localization and 31 within the wider *Fermi*-GBM localization region; Valenti et al. 2017, accepted). A confirmation image was taken on August 18 00:41 UTC after the observing program had cycled through all of the high-priority targets and found no other transients. The updated magnitudes for these two epochs are $r = 17.18 \pm 0.03$ and 17.28 ± 0.04 mag, respectively.

SSS17a/AT 2017gfo was also observed by the VISTA in the second of two 1.5 deg^2 fields targeted. The fields were chosen to be within the high-likelihood localization region of GW170817 and to contain a high density of potential host galaxies (32 of the 54 entries in the list of Cook et al. 2017a). Observations began during evening twilight and were repeated twice to give a short temporal baseline over which to search for

⁹⁶² All apparent magnitudes are AB and corrected for the Galactic extinction in the direction of SSS17a ($E(B - V) = 0.109$ mag; Schlafly & Finkbeiner 2011).

variability (or proper motion of any candidates). The magnitudes of the transient source in the earliest images taken in the near-infrared were measured to be $K_s = 18.63 \pm 0.05$, $J = 17.88 \pm 0.03$, and $Y = 17.51 \pm 0.02$ mag.

On August 17 23:59 UTC, the MASTER-OAFA robotic telescope (Lipunov et al. 2010), covering the sky location of GW170817, recorded an image that included NGC 4993. The autodetection software identified MASTER OT J130948.10-232253.3, the bright optical transient with the unfiltered magnitude $W = 17.5 \pm 0.2$ mag, as part of an automated search performed by the MASTER Global Robotic Net (Lipunov et al. 2017a, 2017d).

The Dark Energy Camera (DECam; Flaugher et al. 2015) Survey team started observations of the GW170817 localization region on August 17 23:13 UTC. DECam covered 95% of the probability in the GW170817 localization area with a sensitivity sufficient to detect a source up to 100 times fainter than the observed optical transient. The transient was observed on 2017 August 18 at 00:05 UTC and independently detected at 00:42 UTC (Allam et al. 2017). The measured magnitudes of the transient source in the first images were $i = 17.30 \pm 0.02$, $z = 17.45 \pm 0.03$. A complete analysis of DECam data is presented in Soares-Santos et al. (2017).

Las Cumbres Observatory (LCO; Brown et al. 2013) surveys started their observations of individual galaxies with their global network of 1 and 2 m telescopes upon receipt of the initial *Fermi*-GBM localization. Approximately five hours later, when the LIGO-Virgo localization map was issued, the observations were switched to a prioritized list of galaxies (from Dalya et al. 2016) ranked by distance and luminosity (Arcavi et al. 2017, in preparation). In a 300 s w -band exposure beginning on August 18 00:15 UTC, a new transient, corresponding to AT 2017gfo/SSS17a/DLT17ck, was detected near NGC 4993 (Arcavi et al. 2017a). The transient was determined to have $w = 17.49 \pm 0.04$ mag (Arcavi et al. 2017e).

These early photometric measurements, from the optical to near-infrared, gave the first broadband spectral energy distribution of AT 2017gfo/SSS17a/DLT17ck. They do not distinguish the transient from a young supernova, but they serve as reference values for subsequent observations that reveal the nature of the optical counterpart as described in Section 3.1. Images from the six earliest observations are shown in the inset of Figure 2.

3. Broadband Follow-up

While some of the first observations aimed to tile the error region of the GW170817 and GRB 170817A localization areas, including the use of galaxy targeting (White et al. 2011a; Dalya et al. 2016; D. Cook & M. Kasliwal 2017, in preparation; S. R. Kulkarni et al. 2017, in preparation), most groups focused their effort on the optical transient reported by Coulter et al. (2017) to define its nature and to rule out that it was a chance coincidence of an unrelated transient. The multi-wavelength evolution within the first 12–24 hr, and the subsequent discoveries of the X-ray and radio counterparts, proved key to scientific interpretation. This section summarizes the plethora of key observations that occurred in different wavebands, as well as searches for neutrino counterparts.

3.1. Ultraviolet, Optical, and Infrared

The quick discovery in the first few hours of Chilean darkness, and the possibility of fast evolution, prompted the need for the ultraviolet–optical–infrared follow-up community to have access to both space-based and longitudinally separated ground-based facilities. Over the next two weeks, a network of ground-based telescopes, from 40 cm to 10 m, and space-based observatories spanning the ultraviolet (UV), optical (O), and near-infrared (IR) wavelengths followed up GW170817. These observations revealed an exceptional electromagnetic counterpart through careful monitoring of its spectral energy distribution. Here, we first consider photometric and then spectroscopic observations of the source.

Regarding photometric observations, at $t_c + 11.6$ hr, the *Magellan*-Clay and *Magellan*-Baade telescopes (Drout et al. 2017a; Simon et al. 2017) initiated follow-up observations of the transient discovered by the Swope Supernova Survey from the optical (g band) to NIR (K_s band). At $t_c + 12.7$ hr and $t_c + 12.8$ hr, the Rapid Eye Mount (REM)/ROS2 (Melandri et al. 2017b) detected the optical transient and the Gemini-South FLAMINGO2 instrument first detected near-infrared K_s -band emission constraining the early optical to infrared color (Kasliwal et al. 2017; Singer et al. 2017a), respectively. At $t_c + 15.3$ hr, the *Swift* satellite (Gehrels 2004) detected bright, ultraviolet emission, further constraining the effective temperature (Evans et al. 2017a, 2017b). The ultraviolet evolution continued to be monitored with the *Swift* satellite (Evans et al. 2017b) and the *Hubble Space Telescope* (*HST*; Adams et al. 2017; Cowperthwaite et al. 2017b; Kasliwal et al. 2017).

Over the course of the next two days, an extensive photometric campaign showed a rapid dimming of this initial UV–blue emission and an unusual brightening of the near-infrared emission. After roughly a week, the redder optical and near-infrared bands began to fade as well. Ground- and space-based facilities participating in this photometric monitoring effort include (in alphabetic order): CTIO1.3 m, DECam (Cowperthwaite et al. 2017b; Nicholl et al. 2017a, 2017d), IRSF, the Gemini-South FLAMINGO2 (Singer et al. 2017a, 2017b; Chornock et al. 2017b; Troja et al. 2017b, 2017d), Gemini-South GMOS (Troja et al. 2017b), GROND (Chen et al. 2017; Wiseman et al. 2017), *HST* (Cowperthwaite et al. 2017b; Levan & Tanvir 2017; Levan et al. 2017a; Tanvir & Levan 2017; Troja et al. 2017a), *i*Telescope.Net telescopes (Im et al. 2017a, 2017b), the Korea Microlensing Telescope Network (KMTNet; Im et al. 2017c, 2017d), LCO (Arcavi et al. 2017b, 2017c, 2017e), the Lee Sang Gak Telescope (LSGT)/SNUCAM-II, the *Magellan*-Baade and *Magellan*-Clay 6.5 m telescopes (Drout et al. 2017a; Simon et al. 2017), the Nordic Optical Telescope (Malesani et al. 2017a), Pan-STARRS1 (Chambers et al. 2017a, 2017b, 2017c, 2017d), REM/ROS2 and REM/REMIR (Melandri et al. 2017a, 2017c), SkyMapper (Wolf et al. 2017), Subaru Hyper Suprime-Cam (Yoshida et al. 2017a, 2017b, 2017c, 2017d; Tominaga et al. 2017), ESO-VISTA (Tanvir et al. 2017a), ESO-VST/OmegaCAM (Grado et al. 2017a, 2017b), and ESO-VLT/FORS2 (D’Avanzo et al. 2017).

One of the key properties of the transient that alerted the worldwide community to its unusual nature was the rapid luminosity decline. In bluer optical bands (i.e., in the g band), the transient showed a fast decay between daily photometric measurements (Cowperthwaite et al. 2017b; Melandri et al. 2017c). Pan-STARRS (Chambers et al. 2017c) reported

photometric measurements in the optical/infrared *izy* bands with the same cadence, showing fading by 0.6 mag per day, with reliable photometry from difference imaging using already existing sky images (Chambers et al. 2016; Cowperthwaite et al. 2017b). Observations taken every 8 hr by LCO showed an initial rise in the *w* band, followed by rapid fading in all optical bands (more than 1 mag per day in the blue) and reddening with time (Arcavi et al. 2017e). Accurate measurements from Subaru (Tominaga et al. 2017), LSGT/SNUCAM-II and KMTNet (Im et al. 2017c), ESO-VLT/FORS2 (D’Avanzo et al. 2017), and DECam (Cowperthwaite et al. 2017b; Nicholl et al. 2017b) indicated a similar rate of fading. On the contrary, the near-infrared monitoring reports by GROND and Gemini-South showed that the source faded more slowly in the infrared (Chornock et al. 2017b; Wiseman et al. 2017) and even showed a late-time plateau in the Ks band (Singer et al. 2017b). This evolution was recognized by the community as quite unprecedented for transients in the nearby (within 100 Mpc) universe (e.g., Siebert et al. 2017).

Table 1 reports a summary of the imaging observations, which include coverage of the entire gravitational-wave sky localization and follow-up of SSS17a/AT2017gfo. Figure 2 shows these observations in graphical form.

Concerning spectroscopic observations, immediately after discovery of SSS17a/AT2017gfo on the Swope 1 m telescope, the same team obtained the first spectroscopic observations of the optical transient with the LDSS-3 spectrograph on the 6.5 m *Magellan*-Clay telescope and the MagE spectrograph on the 6.5 m *Magellan*-Baade telescope at Las Campanas Observatory. The spectra, just 30 minutes after the first image, showed a blue and featureless continuum between 4000 and 10000 Å, consistent with a power law (Drout et al. 2017a; Shappee et al. 2017). The lack of features and blue continuum during the first few hours implied an unusual, but not unprecedented transient since such characteristics are common in cataclysmic-variable stars and young core-collapse supernovae (see, e.g., Li et al. 2011a, 2011b).

The next 24 hr of observation were critical in decreasing the likelihood of a chance coincidence between SSS17a/AT2017gfo, GW170817, and GRB 170817A. The SALT-RSS spectrograph in South Africa (Buckley et al. 2017; McCully et al. 2017b; Shara et al. 2017), ePESSTO with the EFOSC2 instrument in spectroscopic mode at the ESO New Technology Telescope (NTT, in La Silla, Chile; Lyman et al. 2017), the X-shooter spectrograph on the ESO Very Large Telescope (Pian et al. 2017b) in Paranal, and the Goodman Spectrograph on the 4 m SOAR telescope (Nicholl et al. 2017c) obtained additional spectra. These groups reported a rapid fall off in the blue spectrum without any individual features identifiable with line absorption common in supernova-like transients (see, e.g., Lyman et al. 2017). This ruled out a young supernova of any type in NGC 4993, showing an exceptionally fast spectral evolution (Drout et al. 2017; Nicholl et al. 2017d). Figure 2 shows some representative early spectra (SALT spectrum is from Buckley et al. 2017; McCully et al. 2017b; ESO spectra from Smartt et al. 2017; SOAR spectrum from Nicholl et al. 2017d). These show rapid cooling, and the lack of commonly observed ions from elements abundant in supernova ejecta, indicating this object was unprecedented in its optical and near-infrared emission. Combined with the rapid fading, this was broadly indicative of a possible kilonova (e.g., Arcavi et al. 2017e; Cowperthwaite et al. 2017b; McCully et al. 2017b;

Kasen et al. 2017; Kasliwal et al. 2017; Kilpatrick et al. 2017b; Nicholl et al. 2017d; Smartt et al. 2017). This was confirmed by spectra taken at later times, such as with the Gemini Multi-Object Spectrograph (GMOS; Kasliwal et al. 2017; McCully et al. 2017b; Troja et al. 2017a, 2017b), the LDSS-3 spectrograph on the 6.5 m *Magellan*-Clay telescope at Las Campanas Observatory (Drout et al. 2017; Shappee et al. 2017), the LCO FLOYDS spectrograph at Faulkes Telescope South (McCully et al. 2017a, 2017b), and the AAOmega spectrograph on the 3.9 m Anglo-Australian Telescope (Andreoni et al. 2017), which did not show any significant emission or absorption lines over the red featureless continuum. The optical and near-infrared spectra over these few days provided convincing arguments that this transient was unlike any other discovered in extensive optical wide-field surveys over the past decade (see, e.g., Siebert et al. 2017).

The evolution of the spectral energy distribution, rapid fading, and emergence of broad spectral features indicated that the source had physical properties similar to models of kilonovae (e.g., Metzger et al. 2010; Kasen et al. 2013; Barnes & Kasen 2013; Tanaka & Hotokezaka 2013; Grossman et al. 2014; Metzger & Fernández 2014; Barnes et al. 2016; Tanaka 2016; Kasen et al. 2017; Kilpatrick et al. 2017b; Metzger 2017). These show a very rapid shift of the spectral energy distribution from the optical to the near-infrared. The FLAMINGOS2 near-infrared spectrograph at Gemini-South (Chornock et al. 2017c; Kasliwal et al. 2017) shows the emergence of very broad features in qualitative agreement with kilonova models. The ESO-VLT/X-shooter spectra, which simultaneously cover the wavelength range 3200–24800 Å, were taken over 2 weeks with a close to daily sampling (Pian et al. 2017a; Smartt et al. 2017) and revealed signatures of the radioactive decay of *r*-process nucleosynthesis elements (Pian et al. 2017a). Three epochs of infrared grism spectroscopy with the *HST* (Cowperthwaite et al. 2017b; Levan & Tanvir 2017; Levan et al. 2017a; Tanvir & Levan 2017; Troja et al. 2017a)⁹⁶³ identified features consistent with the production of lanthanides within the ejecta (Levan & Tanvir 2017; Tanvir & Levan 2017; Troja et al. 2017a).

The optical follow-up campaign also includes linear polarimetry measurements of SSS17a/AT2017gfo by ESO-VLT/FORS2, showing no evidence of an asymmetric geometry of the emitting region and lanthanide-rich late kilonova emission (Covino et al. 2017). In addition, the study of the galaxy with the MUSE Integral Field Spectrograph on the ESO-VLT (Levan et al. 2017b) provides simultaneous spectra of the counterpart and the host galaxy, which show broad absorption features in the transient spectrum, combined with emission lines from the spiral arms of the host galaxy (Levan & Tanvir 2017; Tanvir & Levan 2017).

Table 2 reports the spectroscopic observations that have led to the conclusion that the source broadly matches kilonovae theoretical predictions.

3.2. Gamma-Rays

The fleet of ground- and space-based gamma-ray observatories provided broad temporal and spectral coverage of the source location. Observations spanned ~ 10 orders of magnitude in energy and covered the position of SSS17a/AT2017gfo from a few hundred seconds before the GRB 170817A trigger time (T_0) to days afterward. Table 3 lists, in chronological order, the results reporting observation

⁹⁶³ *HST* Program GO 14804 Levan, GO 14771 Tanvir, and GO 14850 Troja.

Table 1

A Partial Summary of Photometric Observations up to 2017 September 5 UTC with at Most Three Observations per Filter per Telescope/Group, i.e., the Earliest, the Peak, and the Latest in Each Case

time, flux upper limits, and the energy range of the observations, which are summarized here.

At the time of GRB 170817A, three out of six spacecraft of the Inter Planetary Network (Hurley et al. 2013) had a

favorable orientation to observe the LIGO-Virgo skymap. However, based on the *Fermi*-GBM (Goldstein et al. 2017b) and *INTEGRAL* analyses, GRB 170817A was too weak to be detected by *Konus-Wind* (Svinkin et al. 2017a). Using the

Note.

^a Assuming no shielding by the structures of ISS.

Earth Occultation technique (Wilson-Hodge et al. 2012), *Fermi*-GBM placed limits on persistent emission for the 48 hr period centered at the *Fermi*-GBM trigger time over the 90% credible region of the GW170817 localization. Using the offline targeted search for transient signals (Blackburn et al. 2015), *Fermi*-GBM also set constraining upper limits on precursor and extended emission associated with GRB 170817A (Goldstein et al. 2017b). *INTEGRAL* (Winkler et al. 2003) continued uninterrupted observations after GRB 170817A for 10 hr. Using the PiCSIT (Labanti et al. 2003) and SPI-ACS detectors, the presence of a steady source 10 times weaker than the prompt emission was excluded (Savchenko et al. 2017).

The High Energy telescope on board *Insight*-HXMT monitored the entire GW170817 skymap from $T_0 - 650$ s to $T_0 + 450$ s but, due to the weak and soft nature of GRB 170817A, did not detect any significant excess at T_0 (Liao et al. 2017). Upper limits from 0.2–5 MeV for GRB 170817A and other emission episodes are reported in Li et al. (2017).

The Calorimetric Electron Telescope (CALET) Gamma-ray Burst Monitor (CGBM) found no significant excess around T_0 . Upper limits may be affected due to the location of SSS17a/AT2017gfo being covered by the large structure of the International Space Station at the time of GRB 170817A (Nakahira et al. 2017). *AstroSat* CZTI (Singh et al. 2014; Bhalerao et al. 2017) reported upper limits for the 100 s interval centered on T_0 (Balasubramanian et al. 2017); the position of SSS17a/AT2017gfo was occulted by the Earth, however, at the time of the trigger.

For the AstroRivelatore Gamma a Immagini Leggero (AGILE) satellite (Tavani et al. 2009) the first exposure of the GW170817 localization region by the Gamma Ray Imaging Detector (GRID), which was occulted by the Earth at the time of GRB 170817A, started at $T_0 + 935$ s. The GRID observed the field before and after T_0 , typically with 150 s exposures. No gamma-ray source was detected above 3σ in the energy range 30 MeV–30 GeV (V. Verrecchia et al. 2017, in preparation).

At the time of the trigger, *Fermi* was entering the South Atlantic Anomaly (SAA) and the Large Area Telescope (LAT) was not collecting science data (*Fermi*-GBM uses different SAA boundaries and was still observing). *Fermi*-LAT resumed data taking at roughly $T_0 + 1153$ s, when 100% of the low-latency GW170817 skymap (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017b) was in the field of view for ~ 1000 s. No significant source of high-energy emission was detected. Additional searches over different timescales were performed for the entire time span of LAT data, and no significant excess was detected at the position of SSS17a/AT2017gfo (Kocevski et al. 2017).

The High Energy Stereoscopic System (H.E.S.S.) array of imaging atmospheric Cherenkov telescopes observed from August 17 18:00 UTC with three pointing positions. The first, at $T_0 + 5.3$ hr, covered SSS17a/AT2017gfo. Observations repeated the following nights until the location moved outside the visibility window, with the last pointing performed on August 22 18:15 UTC. A preliminary analysis with an energy threshold of ~ 500 GeV revealed no significant gamma-ray emission (de Naurois et al. 2017), confirmed by the final, offline analysis (see H. Abdalla et al. (H.E.S.S. Collaboration) 2017, in preparation, for more results).

For the High-Altitude Water Cherenkov (HAWC) Observatory (Abeysekara et al. 2017) the LIGO-Virgo localization

region first became visible on August 17 between 19:57 and 23:25 UTC. SSS17a/AT2017gfo was observed for 2.03 hr starting at 20:53 UTC. Upper limits from HAWC for energies > 40 TeV assuming an $E^{-2.5}$ spectrum are reported in Martinez-Castellanos et al. (2017).

INTEGRAL (3 keV–8 MeV) carried out follow-up observations of the LIGO-Virgo localization region, centered on the optical counterpart, starting 24 hr after the event and spanning 4.7 days. Hard X-ray emission is mostly constrained by IBIS (Ubertini et al. 2003), while above 500 keV SPI (Vedrenne et al. 2003) is more sensitive. Besides the steady flux limits reported in Table 3, these observations exclude delayed bursting activity at the level of giant magnetar flares. No gamma-ray lines from a kilonova or $e^{+/-}$ pair plasma annihilation were detected (see Savchenko et al. 2017).

3.3. Discovery of the X-Ray Counterpart

While the UV, optical, and IR observations mapped the emission from the sub-relativistic ejecta, X-ray observations probed a different physical regime. X-ray observations of GRB afterglows are important to constrain the geometry of the outflow, its energy output, and the orientation of the system with respect to the observers' line of sight.

The earliest limits at X-ray wavelengths were provided by the Gas Slit Camera (GSC) of the *Monitor of All-Sky X-ray Image* (*MAXI*; Matsuoka et al. 2009). Due to an unfavorable sky position, the location of GW170817 was not observed by *MAXI* until August 17 17:21 UTC ($T_0 + 0.19$ days). No X-ray emission was detected at this time to a limiting flux of 8.6×10^{-9} erg cm $^{-2}$ s $^{-1}$ (2–10 keV; Sugita et al. 2017; S. Sugita 2017, in preparation). *MAXI* obtained three more scans over the location with no detections before the more sensitive pointed observations began.

In addition, the Super-*AGILE* detector (Feroci et al. 2007) on board the *AGILE* mission (Tavani et al. 2009) observed the location of GW170817 starting at August 18 01:16:34.84 UTC ($T_0 + 0.53$ days). No X-ray source was detected at the location of GW170817, with a 3σ upper limit of 3.0×10^{-9} erg cm $^{-2}$ s $^{-1}$ (18–60 keV; V. Verrecchia et al. 2017, in preparation).

The first pointed X-ray observations of GW170817 were obtained by the X-Ray Telescope (Burrows et al. 2005) on the *Swift* satellite (Gehrels 2004) and the *Nuclear Spectroscopic Telescope ARray* (*NuSTAR*; Harrison et al. 2013), beginning at $T_0 + 0.62$ days and $T_0 + 0.70$ days, respectively. No X-ray emission was detected at the location of GW170817 to limiting fluxes of 2.7×10^{-13} erg cm $^{-2}$ s $^{-1}$ (0.3–10.0 keV; Evans et al. 2017a, 2017b) and 2.6×10^{-14} erg cm $^{-2}$ s $^{-1}$ (3.0–10.0 keV; Evans et al. 2017a, 2017b). *Swift* continued to monitor the field, and after stacking several epochs of observations, a weak X-ray source was detected near the location of GW170817 at a flux of 2.6×10^{-14} erg cm $^{-2}$ s $^{-1}$ (Evans et al. 2017c).

INTEGRAL (see Section 3.2) performed pointed follow-up observations from one to about six days after the trigger. The X-ray monitor JEM-X (Lund et al. 2003) constrained the average X-ray luminosity at the location of the optical transient to be $< 2 \times 10^{-11}$ erg cm $^{-2}$ s $^{-1}$ (3–10.0 keV) and $< 7 \times 10^{-12}$ erg cm $^{-2}$ s $^{-1}$ (10–25 keV; Savchenko et al. 2017).

Chandra obtained a series of observations of GW170817 beginning at August 19 17:10 UTC ($T_0 + 2.2$ days) and continuing until the emission from NGC 4993 became unobservable because of SSS17a/AT2017gfo's proximity to

the Sun (Fong et al. 2017; Haggard et al. 2017b; Margutti et al. 2017a; Troja et al. 2017c, 2017e). Two days post-trigger, Margutti et al. (2017a) reported an X-ray non-detection for SSS17a/AT 2017gfo in a $\simeq 25$ ks *Chandra* exposure,⁹⁶⁴ along with the detection of an extended X-ray source whose position was consistent with the host NGC 4993 (Margutti et al. 2017b). Refined astrometry from subsequent *Swift* observations confirmed that the previously reported candidate was indeed associated with the host nucleus (Evans et al. 2017a, 2017b).

Nine days post-trigger, Troja et al. (2017c) reported the discovery of the X-ray counterpart with *Chandra*. In a 50 ks exposure observation, they detected significant X-ray emission at the same position of the optical/IR counterpart (Troja et al. 2017a; top right panel in Figure 2)⁹⁶⁵. Fifteen days post-trigger, two additional 50 ks *Chandra* observations were made, which confirmed the continued presence of X-ray emission. Based on the first of these two observations^{966,967}: Fong et al. (2017) reported the detection of the X-ray counterpart and the presence of an additional X-ray point source in the near vicinity (Margutti et al. 2017b), and Troja et al. (2017e) reported a flux of 4.5×10^{-15} erg cm⁻² s⁻¹ for the X-ray counterpart. One day later, Haggard et al. (2017b) reported another deep observation showing continued distinct X-ray emission coincident with SSS17a/AT 2017gfo, NGC 4993, and the additional point source (Haggard et al. 2017a, 2017b).¹⁰

Neither *Swift* nor *Chandra* can currently observe GW170817 because it is too close to the Sun ($<47^\circ$ for *Swift*, $<46^\circ$ for *Chandra*). Hence, until early 2017 December, *NuSTAR* is the only sensitive X-ray observatory that can continue to observe the location of GW170817.

All X-ray observations of GW170817 are summarized in Table 4.

3.4. Discovery of the Radio Counterpart

Radio emission traces fast-moving ejecta from a neutron star coalescence, providing information on the energetics of the explosion, the geometry of the ejecta, as well as the environment of the merger. The spectral and temporal evolution of such emission, coupled with X-ray observations, are likely to constrain several proposed models (see, e.g., Nakar & Piran 2011; Piran et al. 2013; Hotokezaka & Piran 2015; Hotokezaka et al. 2016; Gottlieb et al. 2017).

Prior to detection of SSS17a/AT 2017gfo, a blind radio survey of cataloged galaxies in the gravitational-wave localization volume commenced with the Australia Telescope Compact Array (ATCA; Wilson et al. 2011), and observed the merger events' location on 2017 August 18 at 01:46 UTC (Kaplan et al. 2017a). In addition, the Long Wavelength Array 1 (LWA1; Ellingson et al. 2013) followed up the gravitational-wave localization with observations at $t_c + 6.5$ hr, then on 2017 August 23 and 30 (Callister et al. 2017a; Callister et al. 2017b) using four beams (one centered on NGC 4993, one off-center, and two off NGC 4993). These observations set 3σ upper limits for the appearance of a radio source in the beam centered on NGC 4993, about 8 hours after the GW event, as ~ 200 Jy at 25 MHz and ~ 100 Jy at 45 MHz.

The first reported radio observations of the optical transient SSS17a/AT 2017gfo's location occurred on August 18 at 02:09:00 UTC (T0+13.5 hr) with the Karl G. Jansky Very Large Array (VLA) by Alexander et al. (2017d).⁹⁶⁸ Initially attributed to the optical transient, this radio source was later established to be an AGN in the nucleus of the host galaxy, NGC 4993 (Alexander et al. 2017e, 2017c). Subsequent observations with several radio facilities spanning a wide range of radio and millimeter frequencies continued to detect the AGN, but did not reveal radio emission at the position of the transient (Alexander et al. 2017f; Bannister et al. 2017b; Corsi et al. 2017a, 2017b, 2017c; De et al. 2017a, 2017b; Kaplan et al. 2017a; Lynch et al. 2017a, 2017b, 2017c; Mooley et al. 2017a; Resmi et al. 2017).

The first radio counterpart detection consistent with the *HST* position (refined by *Gaia* astrometry) of SSS17a/AT 2017gfo (Adams et al. 2017) was obtained with the VLA on 2017 September 2 and 3 at two different frequencies (≈ 3 GHz and ≈ 6 GHz) via two independent observations: the Jansky VLA mapping of Gravitational Wave bursts as Afterglows in Radio (JAGWAR⁹⁶⁹; Mooley et al. 2017b) and VLA/16A-206⁹⁷⁰ (Corsi et al. 2017d). Marginal evidence for radio excess emission at the location of SSS17a/AT 2017gfo was also confirmed in ATCA images taken on September 5 at similar radio frequencies (≈ 7.25 GHz; Murphy et al. 2017). Subsequent repeated detections spanning multiple frequencies have confirmed an evolving transient (Hallinan et al. 2017a, 2017b; Corsi et al. 2017d; Mooley et al. 2017b). Independent observations carried out on 2017 September 5 with the same frequency and exposure time used by Corsi et al. (2017d) did not detect any emission to a 5σ limit⁹⁷¹ (Alexander et al. 2017a), but this group also subsequently detected the radio counterpart on 2017 September 25 (Alexander et al. 2017b, 2017c).

SSS17a/AT 2017gfo, as well as other parts of the initial gravitational-wave localization area, were and are also being continuously monitored at a multitude of different frequencies with the Atacama Large Millimeter/submillimeter Array (ALMA; Wootten & Thompson 2009; Schulze et al. 2017; Kim et al. 2017, in preparation; Alexander et al. 2017c; Williams et al. 2017a), the Australian Square Kilometre Array Pathfinder (ASKAP; Johnston et al. 2007), ASKAP-Fast Radio Burst (Bannister et al. 2017a, 2017c), ATCA, Effelsberg-100 m (Barr et al. 2013), the Giant Metrewave Radio Telescope (GMRT; Swarup et al. 1991), the Low-Frequency Array (LOFAR; van Haarlem et al. 2013), the Long Wavelength Array (LWA1), MeerKAT (Goedhart et al. 2017a), the Murchison Widefield Array (MWA; Tingay et al. 2013), Parkes-64 m (SUPERB; Bailes et al. 2017a; Keane et al. 2017), Sardinia Radio Telescope (SRT; Prandoni et al. 2017), VLA, VLA Low Band Ionosphere and Transient Experiment (VLITE; Clarke & Kassim 2016), and also using the very long baseline interferometry (VLBI) technique with e-MERLIN (Moldon et al. 2017a, 2017b), the European VLBI Network (Paragi et al. 2017a, 2017b), and the Very Long Baseline Array (VLBA; Deller et al. 2017a, 2017b). The latter have the potential to resolve (mildly) relativistic ejecta on a timescale of months.

Table 5 summarizes the radio observations of GW170817.

⁹⁶⁴ *Chandra* OBSID-18955, PI: Fong.

⁹⁶⁵ *Chandra* OBSID-19294, PI: Troja.

⁹⁶⁶ *Chandra* OBSID-20728, PI: Troja (Director's Discretionary Time observation distributed also to Haggard, Fong, and Margutti).

⁹⁶⁷ *Chandra* OBSID-18988, PI: Haggard.

⁹⁶⁸ VLA/17A-218, PI: Fong.

⁹⁶⁹ VLA/17A-374, PI: Mooley.

⁹⁷⁰ VLA/16A-206, PI: Corsi.

⁹⁷¹ VLA/17A-231, PI: Alexander.

Table 4
X-Ray Monitoring and Evolution of GW170817

Observatory	UT Date (Start)	Time since GW trigger (days)	f_x (erg cm ⁻² s ⁻¹)	L_x (erg s ⁻¹)	Energy (keV)	GCN/Reference
<i>MAXI</i>	Aug 17 17:21:54 UTC	0.19	$<8.6 \times 10^{-9}$	$<1.65 \times 10^{45}$	2–10	S. Sugita et al. (2017, in preparation)

3.5. Neutrinos

The detection of GW170817 was rapidly followed up by the IceCube (Aartsen et al. 2017) and ANTARES (Ageron et al. 2011) neutrino observatories and the Pierre Auger Observatory (Aab et al. 2015a) to search for coincident, high-energy (GeV–EeV) neutrinos emitted in the relativistic outflow produced by the BNS merger. The results from these observations, described briefly below, can be used to constrain the properties of relativistic outflows driven by the merger (A. Albert et al. 2017, in preparation).

In a search for muon–neutrino track candidates (Aartsen et al. 2016), and contained neutrino events of any flavor (Aartsen et al. 2015), IceCube identified no neutrinos that were directionally coincident with the final localization of GW170817 at 90% credible level, within ± 500 s of the merger (Bartos et al. 2017a, 2017b). Additionally, no MeV supernova neutrino burst signal was detected coincident with the merger. Following the identification via electromagnetic observations of the host galaxy of the event, IceCube also carried out an extended search in the direction of NGC 4993 for neutrinos within the 14 day period following the merger, but found no significant neutrino emission (A. Albert et al. 2017, in preparation).

A neutrino search for upgoing high-energy muon neutrinos was carried out using the online ANTARES data stream (Ageron et al. 2017a). No upgoing neutrino candidates were found over a $t_c \pm 500$ s time window. The final localization of GW170817 (LIGO Scientific Collaboration & Virgo Collaboration et al. 2017c) was above the ANTARES horizon at the time of the GW event. A search for downgoing muon neutrinos was thus performed, and no neutrinos were found over $t_c \pm 500$ s (Ageron et al. 2017b). A search for neutrinos originating from below the ANTARES horizon, over an extended period of 14 days after the merger, was also performed, without yielding significant detection (A. Albert et al. 2017, in preparation).

The Pierre Auger Observatory carried out a search for ultra-high-energy (UHE) neutrinos above $\sim 10^{17}$ eV using its Surface Detector (Aab et al. 2015a). UHE neutrino-induced extensive air showers produced either by interactions of downward-going neutrinos in the atmosphere or by decays of tau leptons originating from tau neutrino interactions in the Earth’s crust can be efficiently identified above the background of the more numerous ultra-high-energy cosmic rays (Aab et al. 2015b). Remarkably, the position of the transient in NGC 4993 was just between $0^\circ.3$ and $3^\circ.2$ below the horizon during $t_c \pm 500$ s. This region corresponds to the most efficient geometry for Earth-skimming tau neutrino detection at 10^{18} eV energies. No neutrino candidates were found in $t_c \pm 500$ s (Alvarez-Muniz et al. 2017) nor in the 14 day period after it (A. Albert et al. 2017, in preparation).

4. Conclusion

For the first time, gravitational and electromagnetic waves from a single source have been observed. The gravitational-wave observation of a binary neutron star merger is the first of its kind. The electromagnetic observations further support the interpretation of the nature of the binary, and comprise three components at different wavelengths: (i) a prompt sGRB that demonstrates that BNS mergers are the progenitor of at least a fraction of such bursts; (ii) an ultraviolet, optical, and infrared transient (kilonova), which allows for the identification of the host galaxy and is associated with the aftermath of the BNS

merger; and (iii) delayed X-ray and radio counterparts that provide information on the environment of the binary. These observations, described in detail in the companion articles cited above, offer a comprehensive, sequential description of the physical processes related to the merger of a binary neutron star. Table 6 collects all of the Gamma-ray Coordinates Network (GCN) notices and circulars related to GW170817 through 2017 October 1 UTC. The results of this campaign demonstrate the importance of collaborative gravitational-wave, electromagnetic, and neutrino observations and mark a new era in multi-messenger, time-domain astronomy.

(*IM2H*) We thank J. McIver for alerting us to the LVC circular. We thank J. Mulchaey (Carnegie Observatories director), L. Infante (Las Campanas Observatory director), and the entire Las Campanas staff for their extreme dedication, professionalism, and excitement, all of which were critical in the discovery of the first gravitational-wave optical counterpart and its host galaxy as well as the observations used in this study. We thank I. Thompson and the Carnegie Observatory Time Allocation Committee for approving the Swope Supernova Survey and scheduling our program. We thank the University of Copenhagen, DARK Cosmology Centre, and the Niels Bohr International Academy for hosting D.A.C., R.J.F., A.M.B., E.R., and M.R.S. during the discovery of GW170817/SSS17a. R.J.F., A.M.B., and E.R. were participating in the Kavli Summer Program in Astrophysics, “Astrophysics with gravitational wave detections.” This program was supported by the the Kavli Foundation, Danish National Research Foundation, the Niels Bohr International Academy, and the DARK Cosmology Centre. The UCSC group is supported in part by NSF grant AST–1518052, the Gordon & Betty Moore Foundation, the Heising-Simons Foundation, generous donations from many individuals through a UCSC Giving Day grant, and from fellowships from the Alfred P. Sloan Foundation (R.J.F.), the David and Lucile Packard Foundation (R.J.F. and E.R.) and the Niels Bohr Professorship from the DNRF (E.R.). A.M.B. acknowledges support from a UCMEXUS-CONACYT Doctoral Fellowship. Support for this work was provided by NASA through Hubble Fellowship grants HST–HF–51348.001 (B.J.S.) and HST–HF–51373.001 (M.R.D.) awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS5–26555. This paper includes data gathered with the 1 meter Swope and 6.5 meter Magellan Telescopes located at Las Campanas Observatory, Chile.

(*AGILE*) The AGILE Team thanks the ASI management, the technical staff at the ASI Malindi ground station, the technical support team at the ASI Space Science Data Center, and the Fucino AGILE Mission Operation Center. AGILE is an ASI space mission developed with programmatic support by INAF and INFN. We acknowledge partial support through the ASI grant No. I/028/12/2. We also thank INAF, Italian Institute of Astrophysics, and ASI, Italian Space Agency.

(*ANTARES*) The ANTARES Collaboration acknowledges the financial support of: Centre National de la Recherche Scientifique (CNRS), Commissariat à l’énergie atomique et aux énergies alternatives (CEA), Commission Européenne (FEDER fund and Marie Curie Program), Institut Universitaire de France (IUF), IdEx program and UnivEarthS Labex program at Sorbonne Paris Cité (ANR-10-LABX-0023 and ANR-11-IDEX-0005-02), Labex OCEVU (ANR-11-LABX-0060) and the A*MIDEX project (ANR-11-IDEX-0001-02), Région

Île-de-France (DIM-ACAV), Région Alsace (contrat CPER), Région Provence-Alpes-Côte d'Azur, Département du Var and Ville de La Seyne-sur-Mer, France; Bundesministerium für Bildung und Forschung (BMBF), Germany; Istituto Nazionale di Fisica Nucleare (INFN), Italy; Nederlandse organisatie voor Wetenschappelijk Onderzoek (NWO), the Netherlands; Council of the President of the Russian Federation for young scientists and leading scientific schools supporting grants, Russia; National Authority for Scientific Research (ANCS), Romania; Ministerio de Economía y Competitividad (MINECO): Plan Estatal de Investigación (refs. FPA2015-65150-C3-1-P, -2-P and -3-P; MINECO/FEDER), Severo Ochoa Centre of Excellence and MultiDark Consolider (MINECO), and Prometeo and Grisolia programs (Generalitat Valenciana), Spain; Ministry of Higher Education, Scientific Research and Professional Training, Morocco. We also acknowledge the technical support of Ifremer, AIM and Foselev Marine for the sea operation and the CC-IN2P3 for the computing facilities.

(AST3) The AST3 project is supported by the National Basic Research Program (973 Program) of China (Grant Nos. 2013CB834901, 2013CB834900, 2013CB834903), and the Chinese Polar Environment Comprehensive Investigation & Assessment Program (grant No. CHINARE2016-02-03-05). The construction of the AST3 telescopes has received fundings from Tsinghua University, Nanjing University, Beijing Normal University, University of New South Wales, and Texas A&M University, the Australian Antarctic Division, and the National Collaborative Research Infrastructure Strategy (NCRIS) of Australia. It has also received funding from Chinese Academy of Sciences through the Center for Astronomical Mega-Science and National Astronomical Observatory of China (NAOC).

(Auger) The successful installation, commissioning, and operation of the Pierre Auger Observatory would not have been possible without the strong commitment and effort from the technical and administrative staff in Malargüe. We are very grateful to the following agencies and organizations for financial support: Argentina—Comisión Nacional de Energía Atómica; Agencia Nacional de Promoción Científica y Tecnológica (ANPCyT); Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET); Gobierno de la Provincia de Mendoza; Municipalidad de Malargüe; NDM Holdings and Valle Las Leñas; in gratitude for their continuing cooperation over land access; Australia—the Australian Research Council; Brazil—Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq); Financiadora de Estudos e Projetos (FINEP); Fundação de Amparo à Pesquisa do Estado de Rio de Janeiro (FAPERJ); São Paulo Research Foundation (FAPESP) grant Nos. 2010/07359-6 and 1999/05404-3; Ministério da Ciência, Tecnologia, Inovações e Comunicações (MCTIC); Czech Republic—grant Nos. MSMT CR LG15014, LO1305, LM2015038 and CZ.02.1.01/0.0/0.0/16_013/0001402; France—Centre de Calcul IN2P3/CNRS; Centre National de la Recherche Scientifique (CNRS); Conseil Régional Ile-de-France; Département Physique Nucléaire et Corpusculaire (PNC-IN2P3/CNRS); Département Sciences de l'Univers (SDU-INSU/CNRS); Institut Lagrange de Paris (ILP) grant No. LABEX ANR-10-LABX-63 within the Investissements d'Avenir Programme Grant No. ANR-11-IDEX-0004-02; Germany—Bundesministerium für Bildung und Forschung (BMBF); Deutsche Forschungsgemeinschaft (DFG); Finanzministerium Baden-Württemberg; Helmholtz Alliance for Astroparticle Physics (HAP); Helmholtz-Gemeinschaft Deutscher Forschungszentren (HGF); Ministerium für Innovation,

Wissenschaft und Forschung des Landes Nordrhein-Westfalen; Ministerium für Wissenschaft, Forschung und Kunst des Landes Baden-Württemberg; Italy—Istituto Nazionale di Fisica Nucleare (INFN); Istituto Nazionale di Astrofisica (INAF); Ministero dell'Istruzione, dell'Università e della Ricerca (MIUR); CETEMPS Center of Excellence; Ministero degli Affari Esteri (MAE); Mexico—Consejo Nacional de Ciencia y Tecnología (CONACYT) No. 167733; Universidad Nacional Autónoma de México (UNAM); PAPIIT DGAPA-UNAM; The Netherlands – Ministerie van Onderwijs, Cultuur en Wetenschap; Nederlandse Organisatie voor Wetenschappelijk Onderzoek (NWO); Stichting voor Fundamenteel Onderzoek der Materie (FOM); Poland—National Centre for Research and Development, grant Nos. ERA-NET-ASPERA/01/11 and ERA-NET-ASPERA/02/11; National Science Centre, grant Nos. 2013/08/M/ST9/00322, 2013/08/M/ST9/00728, and HARMONIA 5–2013/10/M/ST9/00062, UMO-2016/22/M/ST9/00198; Portugal—Portuguese national funds and FEDER funds within Programa Operacional Factores de Competitividade through Fundação para a Ciência e a Tecnologia (COMPETE); Romania—Romanian Authority for Scientific Research ANCS; CNDI-UEFISCDI partnership projects grant Nos. 20/2012 and 194/2012 and PN 16 42 01 02; Slovenia—Slovenian Research Agency; Spain—Comunidad de Madrid; Fondo Europeo de Desarrollo Regional (FEDER) funds; Ministerio de Economía y Competitividad; Xunta de Galicia; European Community 7th Framework Program grant No. FP7-PEOPLE-2012-IEF-328826; USA—Department of Energy, Contract Nos. DE-AC02-07CH11359, DE-FR02-04ER41300, DE-FG02-99ER41107, and DE-SC0011689; National Science Foundation, grant No. 0450696; The Grainger Foundation; Marie Curie-IRSES/EPLANET; European Particle Physics Latin American Network; European Union 7th Framework Program, grant No. PIRSES-2009-GA-246806; European Union's Horizon 2020 research and innovation programme (grant No. 646623); and UNESCO.

(Australian Radio) T.M. acknowledges the support of the Australian Research Council through grant FT150100099. S.O. acknowledges the Australian Research Council grant Laureate Fellowship FL15010014. D.L.K. and I.S.B. are additionally supported by NSF grant AST-141242. P.A.B. and the DFN team acknowledge the Australian Research Council for support under their Australian Laureate Fellowship scheme. The Australia Telescope Compact Array is part of the Australia Telescope National Facility, which is funded by the Australian Government for operation as a National Facility managed by CSIRO. This scientific work makes use of the Murchison Radio-astronomy Observatory, operated by CSIRO. We acknowledge the Wajarri Yamatji people as the traditional owners of the Observatory site. Support for the operation of the MWA is provided by the Australian Government (NCRIS), under a contract to Curtin University administered by Astronomy Australia Limited. We acknowledge the Pawsey Supercomputing Centre, which is supported by the Western Australian and Australian Governments. The Australian SKA Pathfinder is part of the Australia Telescope National Facility, which is managed by CSIRO. Operation of ASKAP is funded by the Australian Government with support from the National Collaborative Research Infrastructure Strategy. ASKAP uses the resources of the Pawsey Supercomputing Centre. Establishment of ASKAP, the Murchison Radio-astronomy Observatory and the Pawsey Supercomputing Centre are initiatives of the Australian Government, with support from

the Government of Western Australia and the Science and Industry Endowment Fund. Parts of this research were conducted by the Australian Research Council Centre of Excellence for All-sky Astrophysics in 3D (ASTRO 3D) through project number CE170100013.

(*Berger Time-Domain Group*) The Berger Time-Domain Group at Harvard is supported in part by the NSF through grants AST-1411763 and AST-1714498, and by NASA through grants NNX15AE50G and NNX16AC22G.

(*Bootes*) A.J.C.T. acknowledges support from the Spanish Ministry Project AYA 2015-71718-R (including FEDER funds) and Junta de Andalucía Proyecto de Excelencia TIC-2839. I.H.P. acknowledges the support of the National Research Foundation (NRF-2015R1A2A1A01006870). S.J. acknowledges the support of Korea Basic Science Research Program (NRF2014R1A6A3A03057484 and NRF-2015R1D1A4A01020961). The BOOTES-5/JGT observations were carried out at Observatorio Astronómico Nacional in San Pedro Mártir (OAN-SPM, México), operated by Instituto de Astronomía, UNAM and with support from Consejo Nacional de Ciencia y Tecnología (México) through the Laboratorios Nacionales Program (México), Instituto de Astrofísica de Andalucía (IAA-CSIC, Spain) and Sungkyunkwan University (SKKU, South Korea). We also thank the staff of OAN-SPM for their support in carrying out the observations.

(*CAASTRO*) Parts of this research were conducted by the Australian Research Council Centre of Excellence for All-sky Astrophysics (CAASTRO), through project number CE110001020. The national facility capability for SkyMapper has been funded through ARC LIEF grant LE130100104 from the Australian Research Council, awarded to the University of Sydney, the Australian National University, Swinburne University of Technology, the University of Queensland, the University of Western Australia, the University of Melbourne, Curtin University of Technology, Monash University, and the Australian Astronomical Observatory. SkyMapper is owned and operated by The Australian National University's Research School of Astronomy and Astrophysics.

(*CALET*) The CALET team gratefully acknowledges support from NASA, ASI, JAXA, and MEXT KAKENHI grant numbers JP 17H06362, JP26220708, and JP17H02901.

(*Chandra/McGill*) This work was supported in part by Chandra Award Number GO7-18033X, issued by the Chandra X-ray Observatory Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of the National Aeronautics Space Administration (NASA) under contract NAS8-03060. D.H., M.N., and J.J.R. acknowledge support from a Natural Sciences and Engineering Research Council of Canada (NSERC) Discovery Grant and a Fonds de recherche du Québec–Nature et Technologies (FRQNT) Nouveaux Chercheurs Grant. P.A.E. acknowledges UKSA support. J.A.K. acknowledges the support of NASA grant NAS5-00136. D.H. also acknowledges support from the Canadian Institute for Advanced Research (CIFAR).

(*CZTI/AstroSat*) CZTI is built by a TIFR-led consortium of institutes across India, including VSSC, ISAC, IUCAA, SAC, and PRL. The Indian Space Research Organisation funded, managed, and facilitated the project.

(*DLT40*) D.J.S. acknowledges support for the DLT40 program from NSF grant AST-1517649.

(*EuroVLBI*) The European VLBI Network is a joint facility of independent European, African, Asian, and North American

radio astronomy institutes. Scientific results from data presented in this publication are derived from the following EVN project code: RP029. e-MERLIN is a National Facility operated by the University of Manchester at Jodrell Bank Observatory on behalf of STFC. The collaboration between LIGO/Virgo and EVN/e-MERLIN is part of a project that has received funding from the European Unions Horizon 2020 research and innovation programme under grant agreement No. 653477.

(*ePESSTO*) We acknowledge ESO programs 199.D-0143 and 099.D-0376. PS1 and ATLAS are supported by NASA grants NNX08AR22G, NNX12AR65G, NNX14AM74G, and NNX12AR55G. We acknowledge the Leibniz-Prize to Prof. G. Hasinger (DFG grant HA 1850/28-1), EU/FP7-ERC grants 291222, 615929, 647208, 725161, STFC grants ST/P000312/1 and ERF ST/M005348/1, ST/P000495/1. Marie Skłodowska-Curie grant No 702538. Polish NCN grant OPUS 2015/17/B/ST9/03167, Knut and Alice Wallenberg Foundation. PRIN-INAF 2014. David and Ellen Lee Prize Postdoctoral Fellowship at the California Institute of Technology. Alexander von Humboldt Sofja Kovalevskaja Award. Royal Society—Science Foundation Ireland Vilho, Yrjö and Kalle Väisälä Foundation. FONDECYT grant number 3160504. US NSF grant AST-1311862. Swedish Research Council and the Swedish Space Board. The Quantum Universe I-Core program, the ISF, BSF, and Kimmel award. IRC grant GOIPG/2017/1525. Australian Research Council CAASTRO CE110001020 and grant FT160100028. We acknowledge Millennium Science Initiative grant IC120009.

(*Fermi-GBM*) B.C., V.C., A.G., and W.S.P. gratefully acknowledge NASA funding through contract NNM13AA43C. M.S.B., R.H., P.J., C.A.M., S.P., R.D.P., M.S., and P.V. gratefully acknowledge NASA funding from cooperative agreement NNM11AA01A. E.B. is supported by an appointment to the NASA Postdoctoral Program at the Goddard Space Flight Center, administered by Universities Space Research Association under contract with NASA. D.K., C.A.W.H., C.M. H., and J.R. gratefully acknowledge NASA funding through the *Fermi*-GBM project. Support for the German contribution to GBM was provided by the Bundesministerium für Bildung und Forschung (BMBF) via the Deutsches Zentrum für Luft und Raumfahrt (DLR) under contract number 50 QV 0301. A. v.K. was supported by the Bundesministeriums für Wirtschaft und Technologie (BMWi) through DLR grant 50 OG 1101. S. M.B. acknowledges support from Science Foundation Ireland under grant 12/IP/1288.

(*Fermi-LAT*) The *Fermi*-LAT Collaboration acknowledges support for LAT development, operation, and data analysis from NASA and DOE (United States), CEA/Irfu and IN2P3/CNRS (France), ASI and INFN (Italy), MEXT, KEK, and JAXA (Japan), and the K.A. Wallenberg Foundation, the Swedish Research Council and the National Space Board (Sweden). Science analysis support in the operations phase from INAF (Italy) and CNES (France) is also gratefully acknowledged. This work performed in part under DOE Contract DE-AC02-76SF00515.

(*FRBSG*) S.L.L. is supported by NSF grant PHY-1607291 (LIU). Construction of the LWA has been supported by the Office of Naval Research under Contract N00014-07-C-0147. Support for operations and continuing development of the LWA1 is provided by the National Science Foundation

under grants AST-1139963 and AST-1139974 of the University Radio Observatory program.

(*GRAWITA*) We acknowledge INAF for supporting the project “Gravitational Wave Astronomy with the first detections of adLIGO and adVIRGO experiments—GRAWITA” PI: E. Brocato. Observations are made with ESO Telescopes at the Paranal Observatory under programmes ID 099.D-0382 (PI: E. Pian), 099.D-0622 (PI: P. D’Avanzo), 099.D-0191 (PI: A. Grado), 099.D-0116 (PI: S. Covino) and with the REM telescope at the ESO La Silla Observatory under program ID 35020 (PI: S. Campana). We thank the ESO operation staff for excellent support of this program. The Sardinia Radio Telescope (SRT) is funded by the Department of University and Research (MIUR), the Italian Space Agency (ASI), and the Autonomous Region of Sardinia (RAS) and is operated as National Facility by the National Institute for Astrophysics (INAF). Z.J. is supported by the External Cooperation Program of BIC (number 114332KYSB20160007). J.M. is supported by the Hundred Talent Program, the Major Program of the Chinese Academy of Sciences (KJZD-EW-M06), the National Natural Science Foundation of China 11673062, and the Oversea Talent Program of Yunnan Province. R.L.C. Starling, K.W., A.B.H., N.R.T., and C.G.M. are supported by the STFC (Science and Technology Facilities Council). D.K., acknowledges the financial support from the Slovenian Research Agency (P1-0188). S.K. and A.N.G. acknowledge support by grant DFG Kl 766/16-3. D.G. acknowledges the financial support of the UnivEarthS Labex program at Sorbonne Paris Cité (ANR-10-LABX-0023 and ANR-11-IDEX-0005-02). K.T. was supported by JSPS grant 15H05437 and by a JST Consortia grant.

(*GROND*) Part of the funding for GROND was generously granted from the Leibniz-Prize to Prof. G. Hasinger (DFG grant HA 1850/28-1). “We acknowledge the excellent help in obtaining GROND data from Angela Hempel, Markus Rabus and Régis Lachaume on La Silla.”

(*GROWTH*, *JAGWAR*, *Caltech-NRAO*, *TTU-NRAO*, and *NuSTAR*) This work was supported by the GROWTH (Global Relay of Observatories Watching Transients Happen) project funded by the National Science Foundation under PIRE grant No. 1545949. GROWTH is a collaborative project among California Institute of Technology (USA), University of Maryland College Park (USA), University of Wisconsin–Milwaukee (USA), Texas Tech University (USA), San Diego State University (USA), Los Alamos National Laboratory (USA), Tokyo Institute of Technology (Japan), National Central University (Taiwan), Indian Institute of Astrophysics (India), Inter-University Center for Astronomy and Astrophysics (India), Weizmann Institute of Science (Israel), The Oskar Klein Centre at Stockholm University (Sweden), Humboldt University (Germany), Liverpool John Moores University (UK). A.H. acknowledges support by the I-Core Program of the Planning and Budgeting Committee and the Israel Science Foundation. T.M. acknowledges the support of the Australian Research Council through grant FT150100099. Parts of this research were conducted by the Australian Research Council Centre of Excellence for All-sky Astrophysics (CAASTRO), through project number CE110001020. The Australia Telescope Compact Array is part of the Australia Telescope National Facility which is funded by the Australian Government for operation as a National Facility managed by CSIRO. D.L.K. is additionally supported by NSF grant AST-1412421.

A.A.M. is funded by the Large Synoptic Survey Telescope Corporation in support of the Data Science Fellowship Program. P.C.Y., C.C.N., and W.H.I. thank the support from grants MOST104-2923-M-008-004-MY5 and MOST106-2112-M-008-007. A.C. acknowledges support from the National Science Foundation CAREER award 1455090, “CAREER: Radio and gravitational-wave emission from the largest explosions since the Big Bang.” T.P. acknowledges the support of Advanced ERC grant TReX. B.E.C. thanks SMARTS 1.3 m Queue Manager Bryndis Cruz for prompt scheduling of the SMARTS observations. Basic research in radio astronomy at the Naval Research Laboratory (NRL) is funded by 6.1 Base funding. Construction and installation of VLITE was supported by NRL Sustainment Restoration and Maintenance funding. K.P.M.’s research is supported by the Oxford Centre for Astrophysical Surveys, which is funded through the Hintze Family Charitable Foundation. J.S. and A. G. are grateful for support from the Knut and Alice Wallenberg Foundation. GREAT is funded by the Swedish Research Council (V.R.). E.O.O. is grateful for the support by grants from the Israel Science Foundation, Minerva, Israeli ministry of Science, the US-Israel Binational Science Foundation, and the I-CORE Program of the Planning and Budgeting Committee and The Israel Science Foundation. We thank the staff of the GMRT that made these observations possible. The GMRT is run by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. AYQH was supported by a National Science Foundation Graduate Research Fellowship under grant No. DGE-1144469. S.R. has been supported by the Swedish Research Council (VR) under grant number 2016 03657 3, by the Swedish National Space Board under grant number Dnr. 107/16 and by the research environment grant “Gravitational Radiation and Electromagnetic Astrophysical Transients (GREAT)” funded by the Swedish Research council (V.R.) under Dnr. 2016-06012. We acknowledge the support of the Science and Engineering Research Board, Department of Science and Technology, India and the Indo-US Science and Technology Foundation for the GROWTH-India project.

(*HAWC*) We acknowledge the support from: the US National Science Foundation (NSF); the US Department of Energy Office of High-Energy Physics; the Laboratory Directed Research and Development (LDRD) program of Los Alamos National Laboratory; Consejo Nacional de Ciencia y Tecnología (CONACyT), Mexico (grants 271051, 232656, 167281, 260378, 179588, 239762, 254964, 271737, 258865, 243290); Red HAWC, Mexico; DGAPA-UNAM (grants RG100414, IN111315, IN111716-3, IA102715, 109916); VIEP-BUAP; the University of Wisconsin Alumni Research Foundation; the Institute of Geophysics, Planetary Physics, and Signatures at Los Alamos National Laboratory; Polish Science Centre grant DEC-2014/13/B/ST9/945. We acknowledge the support of the Science and Engineering Research Board, Department of Science and Technology, India and the Indo-US Science and Technology Foundation for the GROWTH-India project.

(*H.E.S.S.*) The support of the Namibian authorities and of the University of Namibia in facilitating the construction and operation of H.E.S.S. is gratefully acknowledged, as is the support by the German Ministry for Education and Research (BMBF), the Max Planck Society, the German Research Foundation (DFG), the Alexander von Humboldt Foundation, the Deutsche Forschungsgemeinschaft, the French Ministry for Research, the CNRS-IN2P3 and the Astroparticle

Interdisciplinary Programme of the CNRS, the U.K. Science and Technology Facilities Council (STFC), the INPN of the Charles University, the Czech Science Foundation, the Polish National Science Centre, the South African Department of Science and Technology and National Research Foundation, the University of Namibia, the National Commission on Research, Science and Technology of Namibia (NCRST), the Innsbruck University, the Austrian Science Fund (FWF), and the Austrian Federal Ministry for Science, Research and Economy, the University of Adelaide and the Australian Research Council, the Japan Society for the Promotion of Science and by the University of Amsterdam. We appreciate the excellent work of the technical support staff in Berlin, Durham, Hamburg, Heidelberg, Palaiseau, Paris, Saclay, and in Namibia in the construction and operation of the equipment. This work benefited from services provided by the H.E.S.S. Virtual Organisation, supported by the national resource providers of the EGI Federation.

(Insight-HXMT) The *Insight-HXMT* team acknowledges the support from the China National Space Administration (CNSA), the Chinese Academy of Sciences (CAS; grant No. XDB23040400), and the Ministry of Science and Technology of China (MOST; grant No. 2016YFA0400800).

(IceCube) We acknowledge the support from the following agencies: U.S. National Science Foundation-Office of Polar Programs, U.S. National Science Foundation-Physics Division, University of Wisconsin Alumni Research Foundation, the Grid Laboratory of Wisconsin (GLOW) grid infrastructure at the University of Wisconsin—Madison, the Open Science Grid (OSG) grid infrastructure; U.S. Department of Energy, and National Energy Research Scientific Computing Center, the Louisiana Optical Network Initiative (LONI) grid computing resources; Natural Sciences and Engineering Research Council of Canada, WestGrid and Compute/Calcul Canada; Swedish Research Council, Swedish Polar Research Secretariat, Swedish National Infrastructure for Computing (SNIC), and Knut and Alice Wallenberg Foundation, Sweden; German Ministry for Education and Research (BMBF), Deutsche Forschungsgemeinschaft (DFG), Helmholtz Alliance for Astroparticle Physics (HAP), Initiative and Networking Fund of the Helmholtz Association, Germany; Fund for Scientific Research (FNRS-FWO), FWO Odysseus programme, Flanders Institute to encourage scientific and technological research in industry (IWT), Belgian Federal Science Policy Office (Belspo); Marsden Fund, New Zealand; Australian Research Council; Japan Society for Promotion of Science (JSPS); the Swiss National Science Foundation (SNSF), Switzerland; National Research Foundation of Korea (NRF); Villum Fonden, Danish National Research Foundation (DNRF), Denmark.

(IKI-GW) A.S.P., A.A.V., E.D.M., and P.Y.u.M. acknowledge the support from the Russian Science Foundation (grant 15-12-30015). V.A.K., A.V.K., and I.V.R. acknowledge the Science and Education Ministry of Kazakhstan (grant No. 0075/GF4). R.I. is grateful to the grant RUSTAVELI FR/379/6-300/14 for partial support. We acknowledge the excellent help in obtaining Chilescope data from Sergei Pogrebsskiy and Ivan Rubzov.

(INTEGRAL) This work is based on observations with INTEGRAL, an ESA project with instruments and science data center funded by ESA member states (especially the PI countries: Denmark, France, Germany, Italy, Switzerland, Spain), and with the participation of Russia and the USA. The INTEGRAL SPI project has been completed under the responsibility and leadership of CNES. The SPI-ACS detector

system has been provided by MPE Garching/Germany. The SPI team is grateful to ASI, CEA, CNES, DLR, ESA, INTA, NASA, and OSTC for their support. The Italian INTEGRAL team acknowledges the support of ASI/INAF agreement No. 2013-025-R.1. R.D. and A.v.K. acknowledge the German INTEGRAL support through DLR grant 50 OG 1101. A.L. and R.S. acknowledge the support from the Russian Science Foundation (grant 14-22-00271). A.D. is funded by Spanish MINECO/FEDER grant ESP2015-65712-C5-1-R.

(IPN) K.H. is grateful for support under NASA grant NNX15AE60G. R.L.A. and D.D.F. are grateful for support under RFBF grant 16-29-13009-ofi-m.

(J-GEM) MEXT KAKENHI (JP17H06363, JP15H00788, JP24103003, JP10147214, JP10147207), JSPS KAKENHI (JP16H02183, JP15H02075, JP15H02069, JP26800103, JP25800103), Inter-University Cooperation Program of the MEXT, the NINS program for cross-disciplinary science study, the Toyota Foundation (D11-R-0830), the Mitsubishi Foundation, the Yamada Science Foundation, Inoue Foundation for Science, the National Research Foundation of South Africa.

(KU) The Korea-Uzbekistan Consortium team acknowledges the support from the NRF grant No. 2017R1A3A3001362, and the KASI grant 2017-1-830-03. This research has made use of the KMTNet system operated by KASI.

(Las Cumbres) Support for I.A. and J.B. was provided by NASA through the Einstein Fellowship Program, grants PF6-170148 and PF7-180162, respectively. D.A.H., C.M., and G.H. are supported by NSF grant AST-1313484. D.P. and D.M. acknowledge support by Israel Science Foundation grant 541/17. This work makes use of observations from the LCO network.

(LIGO and Virgo) The authors gratefully acknowledge the support of the United States National Science Foundation (NSF) for the construction and operation of the LIGO Laboratory and Advanced LIGO as well as the Science and Technology Facilities Council (STFC) of the United Kingdom, the Max-Planck-Society (MPS), and the State of Niedersachsen/Germany for support of the construction of Advanced LIGO and construction and operation of the GEO600 detector. Additional support for advanced LIGO was provided by the Australian Research Council. The authors gratefully acknowledge the Italian Istituto Nazionale di Fisica Nucleare (INFN), the French Centre National de la Recherche Scientifique (CNRS) and the Foundation for Fundamental Research on Matter supported by the Netherlands Organisation for Scientific Research, for the construction and operation of the Virgo detector and the creation and support of the EGO consortium. The authors also gratefully acknowledge research support from these agencies as well as by the Council of Scientific and Industrial Research of India, the Department of Science and Technology, India, the Science & Engineering Research Board (SERB), India, the Ministry of Human Resource Development, India, the Spanish Agencia Estatal de Investigación, the Vicepresidència i Conselleria d'Innovació Recerca i Turisme and the Conselleria d'Educació i Universitat del Govern de les Illes Balears, the Conselleria d'Educació Investigació Cultura i Esport de la Generalitat Valenciana, the National Science Centre of Poland, the Swiss National Science Foundation (SNSF), the Russian Foundation for Basic Research, the Russian Science Foundation, the European Commission, the European Regional Development Funds (ERDF), the Royal Society, the Scottish Funding Council, the Scottish Universities Physics Alliance, the Hungarian Scientific Research Fund (OTKA), the Lyon Institute of Origins

(LIO), the National Research, Development and Innovation Office Hungary (NKFI), the National Research Foundation of Korea, Industry Canada and the Province of Ontario through the Ministry of Economic Development and Innovation, the Natural Science and Engineering Research Council Canada, the Canadian Institute for Advanced Research, the Brazilian Ministry of Science, Technology, Innovations, and Communications, the International Center for Theoretical Physics South American Institute for Fundamental Research (ICTP-SAIFR), the Research Grants Council of Hong Kong, the National Natural Science Foundation of China (NSFC), the China National Space Administration (CNSA) and the Chinese Academy of Sciences (CAS), the Ministry of Science and Technology of China (MOST), the Leverhulme Trust, the Research Corporation, the Ministry of Science and Technology (MOST), Taiwan and the Kavli Foundation. The authors gratefully acknowledge the support of the NSF, STFC, MPS, INFN, CNRS, and the State of Niedersachsen/Germany for provision of computational resources. The *MAXI* team acknowledges the support by JAXA, RIKEN, and MEXT KAKENHI grant number JP 17H06362. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. The European VLBI Network is a joint facility of independent European, African, Asian, and North American radio astronomy institutes. Scientific results from data presented in this publication are derived from the following EVN project code: RP029. e-MERLIN is a National Facility operated by the University of Manchester at Jodrell Bank Observatory on behalf of STFC. The collaboration between LIGO/Virgo and EVN/e-MERLIN is part of a project that has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 653477. We thank Britt Griswold (NASA/GSFC) for graphic arts. P.G.J. acknowledges ERC-Consolidator grant No. 647208. We thank the GMRT staff for prompt scheduling of these observations. The GMRT is run by the National Center for Radio Astrophysics of the Tata Institute of Fundamental Research. INAF, Italian Institute of Astrophysics ASI, Italian Space Agency. This work is part of the research program Innovational Research Incentives Scheme (Vernieuwingsimpuls), which is financed by the Netherlands Organization for Scientific Research through the NWO VIDI grant No. 639.042.612-Nissanke and NWO TOP grant No. 62002444-Nissanke. We thank ESO for granting full access to all the LVC MoU partners of the observations of GW170817 obtained with NACO and VISIR under the Observatory program 60.A-9392.

(*LOFAR*) LOFAR, the Low-Frequency Array designed and constructed by ASTRON, has facilities in several countries that are owned by various parties (each with their own funding sources) and that are collectively operated by the International LOFAR Telescope (ILT) foundation under a joint scientific policy. P.G.J. acknowledges support from ERC grant number 647208. R.F. was partially funded by ERC Advanced Investigator Grant 267607 “4 PI SKY.”

(*MASTER*) Development Programme of Lomonosov Moscow State University, Sergey Bodrov of Moscow Union OPTICA, Russian Scientific Foundation 16-12-00085, National Research Foundation of South Africa, Russian Federation Ministry of Education and Science (14.B25.31.0010, 14.593.21.0005, 3.10131.2017/NM), RFBR 17-52-80133

(*MAXI*) The *MAXI* team acknowledges support by JAXA, RIKEN, and MEXT KAKENHI grant number JP 17H06362.

(*Nordic Optical Telescope*) J.P.U.F. acknowledges the Carlsberg foundation for funding for the NTE project. D.X. acknowledges the support by the One-Hundred-Talent Program of the Chinese Academy of Sciences (CAS) and by the Strategic Priority Research Program “Multi-wavelength Gravitational Wave Universe” of the CAS (No. XDB23000000). Based on observations made with the Nordic Optical Telescope (program 55-013), operated by the Nordic Optical Telescope Scientific Association.

(*OzGrav*) Part of this research was funded by the Australian Research Council Centre of Excellence for Gravitational Wave Discovery (OzGrav), CE170100004 and the Australian Research Council Centre of Excellence for All-sky Astrophysics (CAASTRO), CE110001020. J.C. acknowledges the Australian Research Council Future Fellowship grant FT130101219. Research support to I.A. is provided by the Australian Astronomical Observatory (AAO). A.T.D. acknowledges the support of an Australian Research Council Future Fellowship (FT150100415). Based in part on data acquired through the Australian Astronomical Observatory. We acknowledge the traditional owners of the land on which the AAT stands, the Gamilaraay people, and pay our respects to elders past and present. The Etelman/VIRT team acknowledge NASA grant NNX13AD28A.

(*Pan-STARRS*) The Pan-STARRS1 observations were supported in part by NASA grant No. NNX14AM74G issued through the SSO Near Earth Object Observations Program and the Queen's University Belfast. The Pan-STARRS1 Surveys were made possible through contributions by the Institute for Astronomy, the University of Hawaii, the Pan-STARRS Project Office, the Max-Planck Society and its participating institutes, the Max Planck Institute for Astronomy, Heidelberg and the Max Planck Institute for Extraterrestrial Physics, Garching, The Johns Hopkins University, Durham University, the University of Edinburgh, the Queen's University Belfast, the Harvard-Smithsonian Center for Astrophysics, the LCO Global Telescope Network Incorporated, the National Central University of Taiwan, the Space Telescope Science Institute, and the National Aeronautics and Space Administration under grant No. NNX08AR22G issued through the Planetary Science Division of the NASA Science Mission Directorate, the National Science Foundation grant No. AST-1238877, the University of Maryland, Eotvos Lorand University (ELTE), and the Los Alamos National Laboratory. The Pan-STARRS1 Surveys are archived at the Space Telescope Science Institute (STScI) and can be accessed through MAST, the Mikulski Archive for Space Telescopes. Additional support for the Pan-STARRS1 public science archive is provided by the Gordon and Betty Moore Foundation.

(*Pi of the Sky*) The Pi of the Sky team is grateful for the support of the ESAt/INTA-CEDEA personnel in Mazagón, Huelva (Spain). Analysis of the Pi of the Sky data was based on the LUIZA software developed within the GLORIA project, funded from the European Union Seventh Framework Programme (FP7/2007-2013) under grant 283783.

(*SALT*) D.B., S.M.C., E.R.C., S.B.P., P.V., and T.W. acknowledge support from the South African National Research Foundation. M.M.S. gratefully acknowledges the support of the late Paul Newman and the Newmans Own Foundation. We are most grateful for the DDT allocation for the SALT observations.

(*SKA*) R.F. was partially funded by ERC Advanced Investigator Grant 267607 “4 PI SKY.”

(*Swift*) Funding for the *Swift* mission in the UK is provided by the UK Space Agency. The *Swift* team at the MOC at Penn State acknowledges support from NASA contract NAS5-00136. The Italian *Swift* team acknowledge support from ASI-INAF grant I/004/11/3.

(*TOROS*) We thank support from the USA Air Force Office of International Scientific Research (AFOSR/IO), the Dirección de Investigación de la Universidad de La Serena, the Consejo Nacional de Investigaciones Científicas y Técnicas de Argentina, the FAPESP, and the Observatorio Nacional-MCT of Brasil.

(*TTU Group*) A.C. and N.T.P. acknowledge support from the NSF CAREER Award 1455090: “CAREER: Radio and gravitational-wave emission from the largest explosions since the Big Bang.” The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.

(*VINROUGE*) Based on observations made with ESO telescopes at the La Silla Paranal Observatory under programmes ID 099.D-0668, 099.D-0116, 099.D-0622, 179.A-2010, and 198.D-2010; and with the NASA/ESA *Hubble Space Telescope* observations under programs GO 14771, GO 14804, GO 14850. The VISTA observations were processed by C.G.F. at the Cambridge Astronomy Survey Unit (CASU), which is funded by the UK Science and Technology Research Council under grant ST/N005805/1. This research used resources provided by the Los Alamos National Laboratory Institutional Computing Program, which is supported by the U.S. Department of Energy National Nuclear Security Administration under Contract No. DE-AC52-06NA25396. We acknowledge support to the following bodies: the ERC (grant No. 725246); STFC via grant ST/P000495/1; VILLUM FONDEN (investigator grant project number 16599); the Spanish project AYA 2014-58381-P; the Juan de la Cierva Incorporación fellowship IJCI-2014-21669; the Juan de la Cierva Incorporación fellowship IJCI-2015-26153; the NRFK grant No. 2017R1A3A3001362; grants GO718062A and HSTG014850001A; the Swedish Research Council (VR) under grant number 2016-03657-3; the Swedish National Space Board under grant number Dnr. 107/16; the research environment grant “Gravitational Radiation and Electromagnetic Astrophysical Transients (GREAT)” under Dnr 2016-06012; UKSA.

(*Zadko*) The Zadko Telescope was made possible by a philanthropic donation by James Zadko to the University of Western Australia (UWA). Zadko Telescope operations are supported by UWA and the Australian Research Council Centre of Excellence OzGrav CE170100004. The TAROT network of telescopes is supported by the French Centre National de la Recherche Scientifique (CNRS), the Observatoire de la Côte d’Azur (OCA), and we thank the expertise and support of the Observatoire des Sciences de l’Univers, Institut Pythéas, Aix-Marseille University. The FIGARONet network is supported under the Agence Nationale de la Recherche (ANR) grant 14-CE33. The paper-writing team would like to thank Britt Griswold (NASA/GSFC) and Aaron Geller (Northwestern/NUIT/CIERA) for assistance with graphics.

ABSTRACT

The IceCube Collaboration has previously discovered a high-energy astrophysical neutrino flux using neutrino events with interaction vertices contained within the instrumented volume of the IceCube detector. We present a complementary measurement using charged current muon neutrino events where the interaction vertex can be outside this volume. As a consequence of the large muon range the effective area is significantly larger but the field of view is restricted to the Northern Hemisphere. IceCube data from 2009 through 2015 have been analyzed using a likelihood approach based on the reconstructed muon energy and zenith angle. At the highest neutrino energies between 194 TeV and 7.8 PeV a significant astrophysical contribution is observed, excluding a purely atmospheric origin of these events at 5.6σ significance. The data are well described by an isotropic, unbroken power-law flux with a normalization at 100 TeV neutrino energy of $(0.90_{-0.27}^{+0.30}) \times 10^{-18} \text{ GeV}^{-1} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$ and a hard spectral index of $\gamma = 2.13 \pm 0.13$. The observed spectrum is harder in comparison to previous IceCube analyses with lower energy thresholds which may indicate a break in the astrophysical neutrino spectrum of unknown origin. The highest-energy event observed has a reconstructed muon energy of (4.5 ± 1.2) PeV which implies a probability of less than 0.005% for this event to be of atmospheric origin. Analyzing the arrival directions of all events with reconstructed muon energies above 200 TeV no correlation with known γ -ray sources was found. Using the high statistics of atmospheric neutrinos we report the current best constraints on a prompt atmospheric muon neutrino flux originating from charmed meson decays which is below 1.06 in units of the flux normalization of the model in Enberg et al.

Key words: astroparticle physics – methods: data analysis – neutrinos

1. INTRODUCTION

The detection of high-energy cosmic neutrinos as cosmic messengers has been an important goal of astroparticle physics. Being stable, electrically neutral particles, high-energy neutrinos are able to propagate almost undisturbed through the universe from their production sites to Earth keeping their directional and energy information. Hence, they constitute excellent cosmic messenger particles, particularly at the highest

energies. They arise from weak decays of hadrons, mostly pions and kaons, which are expected to be produced by hadronic interactions of cosmic rays in the surrounding matter of the cosmic-ray accelerator. Their observation will help to elucidate the unknown sources of high-energy cosmic rays (Gaisser et al. 1995; Learned & Mannheim 2000; Becker 2008).

Already in the 1960s the observation of high-energy neutrinos had been discussed by Greisen (1960), Markov

(1960), and Reines (1960), shortly after the discovery of the neutrino by Reines & Cowan (1956). The proposed method was the detection of up-going muons as a signature of a charged-current (CC) muon neutrino interaction below the detector. Soon it was realized that the expected astrophysical fluxes are small and cubic-kilometer-sized detectors would be needed to accomplish the goal, see e.g., Roberts (1992). The construction of large Cherenkov detectors by instrumenting optically transparent natural media, i.e., deep oceans, lakes, and glaciers with photo-sensors (Belolaptikov et al. 1997; Andres et al. 2000; Ageron et al. 2011) proved to be a key concept. The largest instrument to date is the IceCube Neutrino Observatory at the geographic South Pole (Achterberg et al. 2006).

Main backgrounds to the search for astrophysical neutrinos are high-energy atmospheric neutrinos and muons produced by cosmic-ray interactions in the Earth’s atmosphere.

In 2013, a diffuse all-flavor flux of high-energy astrophysical neutrinos was discovered (Aartsen et al. 2013a, 2014b). The analysis selected events due to high-energy neutrinos which interact within the detector by using its outer layers as a veto. This strategy enables a full-sky sensitivity for all neutrino flavors. The veto not only rejects atmospheric muons entering the detector from the outside extremely efficiently, but also atmospheric neutrinos from above the detector which are produced together with muons.

In this analysis we focus on up-going muons which arise from charged-current interactions of muon neutrinos both inside and outside the detector. By allowing neutrinos to interact outside the instrumented volume a larger effective area is achieved. However, at the same time it is necessary to restrict the analysis to the Northern Hemisphere where the Earth filters atmospheric muons efficiently. Furthermore, the analysis is mainly sensitive to a muon neutrino flux because of the large muon range. Nevertheless this strategy will impose further constraints on possible models (Cholis & Hooper 2013; He et al. 2013; Kalashev et al. 2013; Laha et al. 2013; Razzaque 2013; Roulet et al. 2013; Stecker 2013; Anchordoqui et al. 2014; Gonzalez-Garcia et al. 2014; Murase et al. 2014; Tamborra et al. 2014; Bechtol et al. 2015; Senno et al. 2016) that have been proposed to explain the observed astrophysical neutrino flux.

This analysis is based on a high-purity and high-statistics selection of about 350,000 well-reconstructed up-going muon events from six years of IceCube operation, improving the statistics compared to previous analyses (Aartsen et al. 2014c, 2015c) by almost an order of magnitude.

Even when individual astrophysical neutrino sources cannot be identified because they are too weak, their cumulative flux can be measured as a diffuse flux. The signature of an astrophysical neutrino signal with respect to the background of atmospheric neutrinos is illustrated in Figure 1. Astrophysical neutrinos from cosmic accelerators are generically expected to have a hard energy spectrum as originally predicted by Fermi: $dN_\nu/dE \simeq \phi_0 \cdot E^{-2}$. However, the spectral index depends in detail on the source properties and the acceleration mechanism (Bell 2013; Kashti & Waxman 2005; Klein et al. 2013). Recent IceCube analyses (Kopper et al. 2015; Aartsen et al. 2015a, 2015b; Lesiak-Bzdak et al. 2015) yielded a softer spectrum with a spectral index between 2.5 and 2.7.

The energy spectrum of the atmospheric neutrino background is about one power steeper than the primary cosmic-ray spectrum ($dN_{CR}/dE \propto E^{-2.7..3.1}$), with the exception of prompt

neutrinos from heavy meson decays, which follow the primary spectrum more closely. The astrophysical signal appears as an excess above energies of about 100 TeV. As shown, the zenith distribution differs for signal and backgrounds which themselves depend on the energy. At the highest energies the Earth becomes increasingly opaque to neutrinos and the signal is dominated by events near the horizon.

The identification of an astrophysical signal is based on a two-dimensional likelihood fit in zenith and energy. It follows the methods of the previous analyses (Aartsen et al. 2014c, 2015c) which are improved with respect to the treatment of systematic uncertainties.

The data selection is described in Section 2. The method is described in Section 3. The results of the analysis with respect to the astrophysical signal are presented in Section 4, where we discuss the fit results, tests of alternative hypotheses and investigations on the most energetic event (Schoenen & Raedel 2015). In Section 5 we present investigations on the directions of recorded events and the attempt to correlate these directions with astrophysical objects. In Section 6 we discuss implications of this analysis for the expected flux of high-energy prompt atmospheric neutrinos from the decay of charmed mesons and obtain the currently most constraining exclusion limit.

2. DATA SAMPLE

2.1. IceCube Detector

The IceCube Neutrino Observatory is a cubic-kilometer-sized Cherenkov detector embedded in the ice at the geographic South Pole (Achterberg et al. 2006). It has been designed to detect neutrinos above TeV energies by measuring the Cherenkov light produced by charged particles produced in neutrino interactions. A total of 5160 optical photomultiplier tubes (PMTs) instrument 86 cable strings with a vertical spacing of 17 m at depths between 1450 and 2450 m beneath the surface of the glacial ice sheet (Abbasi et al. 2010). Each PMT is housed in a digital optical module (DOM), consisting of a pressure-resistant sphere, digitization/calibration electronics, and calibration LEDs (Abbasi et al. 2009).

The strings are deployed in a hexagonal pattern with an inter-string spacing of about 125 m except for the central eight strings which have a smaller spacing of about 60 m and also a smaller vertical DOM spacing.

The detector was completed in 2010 December; prior to that, data were recorded with partially installed detector configurations. In the remainder of the paper we differentiate the partial detector configurations by the number of strings, e.g., IC59 for the 59-string configuration. The complete detector with 86 strings is referred to by the year the data taking started, e.g., IC2011. The analysis presented here uses data taken from 2009 May until 2015 May which includes the partial detector configurations IC59, IC79 and the seasons IC2011–2014 of the completed detector.

2.2. Event Selection

The events that trigger IceCube are predominantly down-going atmospheric muons produced in cosmic-ray air showers. The standard trigger condition for high-energy neutrino analyses in IceCube requires a minimum of eight DOMs recording light within a time window of 5 μ s, which results in a rate above 2 kHz. The triggering DOMs must be in a local

Figure 1. Distribution of the expected neutrino energy (left) and zenith angle (right) for the data selection of this analysis. Shown are the distributions of conventional atmospheric neutrinos (Honda et al. 2007), prompt atmospheric neutrinos (Enberg et al. 2008) where both are corrected for the cosmic-ray spectrum in Gaisser (2012), and a benchmark astrophysical signal $10^{-18} \text{ GeV}^{-1} \text{ cm}^{-2} \text{ sr}^{-1} \text{ s}^{-1} (E_\nu/100 \text{ TeV})^{-2}$.

coincidence with either their neighboring or next-to-nearest neighboring DOMs.

For each trigger the digitized PMT waveforms of the detected Cherenkov-light signals are sent to the surface where the number of photons as well as their arrival times are extracted. This information is used to reconstruct the energy and geometry of the event (Ahrens et al. 2004; Abbasi et al. 2013; Aartsen et al. 2014a).

The data processing schemes were improved during the construction of IceCube and the event selection has been optimized for each detector configuration. Data are processed and reconstructed at the South Pole in real time. A filter criterion, optimized for high-energy track-like signatures, requires a minimum amount of detected total charge and a good quality of the track reconstruction. This reduces the data stream to about 34 Hz that is sent off-site via satellite for further data processing. These events are still dominated by down-going atmospheric muon events. In order to select high-energy up-going muons with high purity and high efficiency, more sophisticated reconstruction algorithms are applied and high-quality events are selected.

The neutrino event selections are based on Monte Carlo (MC) generated neutrinos and atmospheric muons. Note that there are differences in the MC used for the different seasons due to improving simulation code and models which is accounted for in the likelihood fit (see Section 3.2). The simulation of neutrinos is performed by injecting a neutrino at the Earth’s surface and propagating it through the Earth. The neutrino interaction in ice or rock is simulated (Gazizov & Kowalski 2005) with the deep inelastic scattering cross section calculated using the CTEQ5 parton distribution functions (Lai et al. 2000) or the updated HERA1.5 PDFs (Cooper-Sarkar et al. 2011). At the energies of interest the cross sections differ by less than 5%. Each simulated neutrino is forced to interact in the vicinity of the instrumented volume. The volume is scaled as a function of the neutrino energy to include the maximum range of the muon produced in the interaction. The muon is propagated through the detector taking into account energy losses and decay (Chirkin & Rhode 2004; Koehne et al. 2013).
