issued before September 2017 no signal was detected by MAGIC within the 50% containment radius reported by IceCube (15).

Table S1: **Neutrino alerts selected as MAGIC targets.** For each set of targeted observations, the position, directional uncertainty and reported deposited energy from the neutrino alert are listed. Additionally, MAGIC zenith angle ranges and times over which observations were made are listed.

IceCube-	160427A	160731A	170321A	170922A
<i>From IceCube:</i>

<i>MAGIC data taking:</i>				
Zenith angle range [deg]	18 - 26	45-65	45-60	22-52
Effective observation time [h]	1.85	1.3	1.0	12.9

MAGIC performed the first observations of the reported IceCube-170922A event direction for 2 hours on 24 September, 2017 (32 hours after the IceCube alert was issued), under non-optimal weather conditions. The standard MAGIC analysis framework MARS was used for the data analysis (34). After data quality selection, 1.07 hours of observations were used to derive an upper limit on the TXS 0506+056 flux above 90 GeV of $3.56 \times 10^{-11} \text{ cm}^{-2} \text{ s}^{-1}$ at 95% C.L. The upper limit was calculated (83) assuming a 30% systematic uncertainty in the estimated γ -ray detection efficiency of MAGIC. Observations were resumed on 28 September, 2017. With good observational conditions, data from 28 September, 2017 and 29 September, 2017 revealed hints of a signal, with an excess observed at the $\sim 3.5 \sigma$ significance level. The significance of this signal grew steadily over the following nights, motivating the long exposure. Analysis cuts optimized for Crab Nebula detection above 90 GeV were applied to the data. Integrating 12.9 hours of good quality data, MAGIC detected a clear signal with 374 ± 62 excess events at the location of the blazar TXS 0506+056 (RA: 77.36 deg, Dec: +5.69 deg (J2000) (19)). The combined signal is shown in Figure S3. The day-to-day results from the MAGIC observations are provided in Table S2. Observations with a detection significance of less than 2σ are reported as flux upper limits at 95% C.L., again including a 30% systematic uncertainty on the detection efficiency.

The MAGIC VHE γ -ray observations can be used to determine an upper limit for the redshift of TXS 0506+056 constraining the attenuation of the VHE flux due to interaction with the EBL (10, 11). These redshift limits are derived from assumed properties of the intrinsic spectrum, the measured VHE spectrum from MAGIC and models for the EBL. Here, the intrinsic spectrum is assumed to be a simple power-law $dN/dE \propto E^\gamma$, with the index constrained to be $\gamma < -1.5$. For each assumed redshift value, the VHE gamma-ray spectrum is evaluated including attenuation with the EBL and the expected rate of γ -ray events is calculated using the

MAGIC instrument response. A likelihood test is constructed by comparing the expected event rates to those observed in the source region and in the background control regions. The likelihood (L) is maximized by allowing the intrinsic spectral model parameters to vary and treating uncertainties in the cosmic-ray induced background as nuisance parameters. Performing a scan in redshift, at each step the profile likelihood following (84) is used to derive an upper limit to the source redshift at 95% C.L. When the maximum likelihood value is obtained for $z=0$, the so-called "bounded likelihood" approach is followed, *i.e.* the increase in $-2 \ln \mathcal{L}$ is computed relative to its value at $z=0$. The dominant experimental systematics are evaluated by varying the simulated total light throughput of the instrument (including effects in the atmosphere) by $\pm 15\%$. The most conservative value derived from all realizations is taken as a result for the upper limit.

For TXS 0506+056, the redshift upper limit ranges from 0.61 to 0.67 at 95% C.L, adopting the EBL models from (85–87). More conservative are the results obtained using the models from (88–90) for which the redshift upper limit ranges from 0.83 to 0.98 at 95% C.L. Considering a lower confidence level of 90% C.L. the results are in better agreement, the full range of upper limits values for all EBL models considered here being 0.41 to 0.57. Conservatively, the resulting 95% confidence level upper limit on the source redshift is $z < 0.98$ taking into account a 15% systematic uncertainty on the total light throughput of the instrument (11). These results are consistent with the measured redshift of $z=0.3365$ (28).

Table S2: **MAGIC nightly observations of TXS 0506+056.** Summary of MAGIC observations for each night’s observation of TXS 0506+056, including: date corresponding to the middle of the observation window; effective observation time after quality cuts; integral photon flux above 90 GeV, with flux upper limits (indicated by $<$) given at 95% C.L.; and per-night significance.

Date MJD	Effective time [hours]	Flux $>$ 90 GeV [ph cm $^{-2}$ s $^{-1}$]	Significance σ
58020.16	1.07	$< 3.6 \times 10^{-11}$	0
58024.21	1.25	$< 6.2 \times 10^{-11}$	1.8
58025.18	2.9	$< 5.8 \times 10^{-11}$	1.0
58026.17	3.0	$< 3.6 \times 10^{-11}$	0.95
58027.18	2.9	$1.9 \pm 1.2 \times 10^{-11}$	2.5
58028.23	0.8	$< 5.8 \times 10^{-11}$	1.7
58029.22	1.3	$5.9 \pm 1.5 \times 10^{-11}$	4.3
58030.24	0.65	$8.0 \pm 2.0 \times 10^{-11}$	5.4

H.E.S.S. The High Energy Stereoscopic System (H.E.S.S.) of imaging atmospheric Cherenkov telescopes has been routinely performing follow-up observations of high-energy neutrinos detected by IceCube and ANTARES since 2015. The H.E.S.S. system has been designed to automatically react to neutrino alerts, allowing for a search for VHE γ -ray sources in coincidence with a neutrino detection on timescales that range from a few tens of seconds to several

days (91). In the past, several neutrino alerts were followed up by H.E.S.S. (92). All follow-up observations of IceCube alerts performed by H.E.S.S. are summarized in Table S3.

Table S3: Neutrino follow-up observations performed by H.E.S.S. IceCube-170922A represents the IceCube alert which was followed up with the longest exposure and the shortest delay. The long exposure was taken following the *Fermi*-LAT announcement of TXS 0506+056 being in a high emission state (16).

Date	Alert identifier	Delay of observations	Duration of observations
Apr 27, 2016	IceCube-160427A	2d 15h	2h
Jul 31, 2016	IceCube-160731A	16h	2h
Nov 3, 2016	IceCube-161103A	12h	2h
Sep 22, 2017	IceCube-170922A	4h	3h 14m

H.E.S.S. performed follow-up observations towards the direction of the blazar TXS 0506+056 during the nights of 22 September, 2017 and 23 September, 2017 after the detection of a high-energy neutrino by IceCube. Initial observations started ~ 4 hours after the circulation of the neutrino alert (18). A preliminary on-site analysis did not reveal any significant γ -ray emission (60) for this data set. A second set of observations was acquired during the nights of 27 September, 2017 and 28 September, 2017 following the announcement of *Fermi*-LAT that TXS 0506+056 was in an active state and positionally coincident with the direction of the neutrino event (16). In total 3.25 hours of high-quality observations including the central large telescope (CT5) were obtained at zenith angles ranging from 31 deg to 46 deg.

The 3.25 hours of CT5 data were analyzed in mono mode using the Model Analysis (93) with *loose* cuts to achieve a low energy threshold. No γ -ray emission at a significant level was detected and upper limits on the VHE γ -ray flux have been calculated. The best fit spectral index of -3.9 as measured from the MAGIC data was used as the spectral assumption. Limits at 95% C.L. were derived using the Rolke method (94) and assuming a systematic uncertainty of 30%. Negative excess fluctuations of the measured counts in the signal region were taken into account by replacing them with the measured background counts, scaled with the signal region exposure time.

The limits and fluxes were calculated for each night of the data set individually. They are shown in Figure 3 and summarized in Table S4 above an energy threshold of 175 GeV. The table and figure also include flux upper limits from two archival observation campaigns from September 2015 and December 2015 to January 2016. Additionally, differential flux upper limits were calculated for the whole 3.25 hour dataset. They are depicted in Figure 4 and summarized in Table S5. All results have been cross-checked with an independent calibration and analysis chain (95), which showed consistent results.

Table S4: **Flux upper limits from H.E.S.S. for TXS 0506+056.** Archival and nightly γ -ray flux upper limits at 95% confidence level for TXS 0506+056 derived from the H.E.S.S. observations assuming an $E^{-3.9}$ energy spectrum.

MJD [days]	Observation time [h]	Flux > 175 GeV [ph cm ⁻² s ⁻¹]
57286 – 57288	5.4	$< 7.2 \times 10^{-12}$
57358 – 57390	4.4	$< 1.1 \times 10^{-11}$
58019.07	1.35	$< 1.0 \times 10^{-11}$
58024.08	0.48	$< 1.8 \times 10^{-11}$
58025.08	1.65	$< 1.8 \times 10^{-11}$

Table S5: **H.E.S.S. differential γ -ray flux upper limits for TXS 0506+056.** Flux upper limits (f_γ) at 95% C.L. obtained for the full TXS 0506+056 H.E.S.S. data set and assuming an $E^{-3.9}$ energy spectrum. E_{\min} and E_{\max} define the energy range over which the differential flux upper limit is derived.

E_{\min} [TeV]	E_{\max} [TeV]	f_γ [cm ⁻² s ⁻¹ TeV ⁻¹]
0.16	0.28	$< 6.6 \times 10^{-11}$
0.28	0.48	$< 2.1 \times 10^{-11}$
0.48	0.85	$< 4.5 \times 10^{-12}$
0.85	1.50	$< 1.8 \times 10^{-12}$
1.50	2.63	$< 5.9 \times 10^{-13}$
2.63	4.62	$< 3.3 \times 10^{-13}$

VERITAS The Very Energetic Radiation Imaging Telescope Array System (VERITAS) (33), was used to perform follow-up observations of IceCube-170922A. Observations started on 23 September 2017 at 09:06 UTC, 12.2 hours after the IceCube detection, accumulating an exposure of one hour under partial cloud coverage in normal observation mode. Additional VERITAS observations were collected following the *Fermi*-LAT report of the detection of a hard GeV γ -ray flare from the blazar TXS 0506+056 located within the neutrino error region. Five additional hours were collected during the period between 28 September 2017 at 08:57 UTC and 30 September 2017 at 11:04 UTC (5.5 to 7.6 days after the neutrino detection), resulting in a total exposure of 5.5 hours for the entire data set after quality cuts.

An analysis of the data optimized for soft-spectrum sources shows no evidence of γ -ray emission at the blazar location or anywhere else in the 3.5 deg VERITAS field of view. The integral γ -ray flux upper limit derived from the VERITAS observations at the TXS 0506+056 position is $1.2 \times 10^{-11} \text{ cm}^{-2} \text{ s}^{-1}$ at 95% C.L. above an energy threshold of 175 GeV assuming the power-law photon spectral index of -3.9 from the MAGIC data.

All limits were calculated using the method described in (84) with the requirement of a minimum of 10 events present in the off-source region to reduce the uncertainty in the estimation of the background rate. The systematic uncertainty in the energy scale of VERITAS is 15% to 20% (96). Differential γ -ray flux upper limits are listed in Table S7 at 95% C.L. for observations obtained within two weeks of the neutrino alert. These observations, with the addition of historical observations of the blazar TXS 0506+056 performed by VERITAS prior to the detection of IceCube-170922A, were used to calculate light-curve integral flux upper limits above a threshold of 175 GeV which are listed in Table S6. For observation periods where the VERITAS energy threshold was higher than 175 GeV, the upper limits were scaled to this value by conservatively assuming a photon spectral index of -4.3 based on a 1σ deviation of the index from the MAGIC data (-3.9 ± 0.4).

VERITAS observations of IceCube-170922A were performed as part of the VERITAS neutrino follow-up program (97). Prompt follow-up observations performed by VERITAS under this program in response to alerts prior to the IceCube-170922A are included in Table S8.

HAWC The High-Altitude Water Cherenkov (HAWC) γ -ray observatory (36) has a very wide field of view (~ 2 sr) and operates with $>95\%$ uptime, enabling it to survey $2/3$ of the sky above ~ 1 TeV. The IceCube-170922A location was not in the field of view of HAWC at the time of the event. Three time periods were searched for VHE γ -rays with no evidence for a source in any of the studies. For all these searches, the 95% C.L. upper limits on the flux above 1 TeV assume a spectral index of -3.9 . The 1 TeV threshold for flux limits was chosen so that the limit depends very weakly on the spectral index.

First, a time integrated search at the location of TXS 0506+056 was made using archival data from 26 November 2014 to 27 August 2017. The upper limit on the flux is $1.6 \times 10^{-13} \text{ cm}^{-2} \text{ s}^{-1}$. Second, the transits of TXS 0506+056, in HAWC, right before and right after the time stamp of IceCube-170922A (22 September 2017, from 08:37:15 to 14:29:45 UTC and 23 Septem-

Table S6: **Flux upper limits from VERITAS for TXS 0506+056.** Nightly γ -ray flux upper limits at 95% confidence level from VERITAS above an energy threshold of 175 GeV, assuming an $E^{-3.9}$ energy spectrum.

MJD [days]	Time window (half width) [days]	Flux > 175 GeV [ph cm ⁻² s ⁻¹]
57685.4392	± 0.0104	$< 6.8 \times 10^{-12}$
57686.4500	± 0.0200	$< 5.7 \times 10^{-12}$
57786.1544	± 0.0142	$< 1.1 \times 10^{-11}$
58019.3971	± 0.0124	$< 2.1 \times 10^{-10}$
58024.4380	± 0.0653	$< 1.4 \times 10^{-11}$
58025.3932	± 0.0219	$< 5.2 \times 10^{-11}$
58026.4399	± 0.0211	$< 1.1 \times 10^{-11}$

Table S7: **VERITAS differential γ -ray flux upper limits for TXS 0506+056.** Differential γ -ray flux upper limits (f_γ) derived from VERITAS observations of the TXS 0506+056 blazar position. E_{\min} and E_{\max} define the energy range over which the differential flux upper limit is derived and are based on observations obtained within 2 weeks of the neutrino alert.

E_{\min} [TeV]	E_{\max} [TeV]	f_γ [cm ⁻² s ⁻¹ TeV ⁻¹]
0.141	0.316	$< 5.4 \times 10^{-11}$
0.316	0.708	$< 6.4 \times 10^{-12}$
0.708	1.585	$< 5.3 \times 10^{-13}$
1.585	3.548	$< 8.0 \times 10^{-14}$

ber 2017, from 08:33:19 to 14:25:49 UTC) were used. The upper limit on the flux is 3.6×10^{-12} cm⁻² s⁻¹. Finally, data from 9 September 2017 09:28:22 to 19 September 2017 14:41:33 UTC and from 21 September 2017 08:41:11 to 6 October 2017 13:34:43 UTC was used (the time gap was due to a power outage after Mexico’s earthquake on 19 September 2017), roughly coinciding with the *Fermi*-LAT reported flare (16), results in an upper limit of the flux of 2.1×10^{-12} cm⁻² s⁻¹. Quasi-differential upper limits on $E^2 dN/dE$ using HAWC data are presented in Figure 4 using the method described in (99).

Radio, optical and X-ray observations

VLA The Karl G. Jansky Very Large Array (VLA) (37) was used to obtain radio frequency observations of the blazar TXS 0506+056, following its identification as the potential astrophysical origin of IceCube-170922A (18). The VLA observations were taken over six epochs between 5 October 2017 and 21 November 2017, in *S* (2 – 4 GHz), *C* (4 – 8 GHz) and *X* (8 – 12 GHz) bands. The array was split into 3 sub-arrays, with 8 antennas observing at *C* band, 9 antennas at *X* band, and 10 antennas observing at *S* band, to simultaneously sample the source

Table S8: **Neutrino follow-up observations performed by VERITAS.**

IceCube Alert ID	UTC Date	Obs delay [hr]	Exposure [hr]	VERITAS publication
IceCube-160427A	27 April 2016	0.05	3.15	(98)
IceCube-161103A	3 November 2016	0.06	1.5	-
IceCube-170321A	21 March 2017	19.3	0.5	-
IceCube-170922A	22 September 2017	12.2	5.5	(59)

flux density across the three receiver sets. The antennas for each sub-array were selected so that all sub-arrays had similar beam patterns. A total of 10.8 minutes on target were acquired in each band, per epoch, cycling continuously between the calibrator (1 min) and target (5.4 min). All observations were made with the 8-bit samplers, using 2 base-bands with 8 spectral windows of 64 2 MHz channels each, giving a total bandwidth of 1.024 GHz per base-band. The flagging, calibration, and imaging were carried out within the Common Astronomy Software Application package (CASA, v5.1.1; (100)) using standard procedures.

For all sub-arrays, 3C 138 (QSO J0521+166) was applied as the flux calibrator, and QSO J0502+0609 as the phase calibrator. When imaging, a natural weighting scheme was used to maximize sensitivity. A phase-only self-calibration was performed on the data (with 10 second solution intervals) to correct for phase de-correlation of the unresolved emission. No self-calibration was performed when the preliminary flux densities of the first 4 epochs were reported in (38). As expected, phase de-correlation was strongest at higher frequencies, and on 6 October 2017, that was measured to have significantly stronger tropospheric contribution to the interferometric phase.

TXS 0506+056 was detected significantly in all bands/epochs. Observation times and flux densities for TXS 0506+056 are shown in Table S9, where a point source was fitted in the image plane (with the CASA imfit task) to obtain each of these measurements. The reported uncertainties on the flux density do not include the $\sim 5\%$ systematic uncertainty on the absolute flux scale calibration. This uncertainty should be included when comparing these flux density measurements to those with other facilities. Flux densities and the measured $\nu^{\sim 0.2}$ spectra were relatively constant from 5 - 12 October 2017 (epochs 1–4). The source brightened slightly above 4 GHz on 24 October 2017. The final data (on 21 November 2017) indicate a ($\sim 20\%$) brighter source at frequencies below 6 GHz, and spectral steepening at higher frequencies ($\nu^{\sim 0.2}$ at lower frequencies and $\nu^{\sim -0.1}$ at higher frequencies). This peak may be due to synchrotron self-absorption. An injection of energy (*e.g.*, jet ejecta) that moves downstream and reaches the radio photosphere for $\nu \sim 10$ GHz by 21 November 2017, could provide a spectral turnover.

ASAS-SN The All-Sky Automated Survey for Supernovae (ASAS-SN) consists of two units — one at Haleakala, Hawaii and one at Cerro Tololo in Chile — each comprising four robotic 14 cm telescopes. ASAS-SN has been monitoring the visible sky to ~ 17 mag in the *V* band on a 2–3 day cadence (101).

An initially extracted light curve spanning from August 2013 to October 2017 from the ASAS-SN Sky Patrol (40) interface indicated that TXS 0506+056 had brightened by $\Delta V \sim 0.5$ mag over the 50 days prior to the neutrino event (54). While the source shows significant variability, the recent data indicate this is the brightest this object has been in several years. This source was observed at higher cadence compared to the regular survey for a few days after the neutrino detection thanks to automated ASAS-SN target-of-opportunity observations triggered by the public IceCube alerts.

The ASAS-SN V band light curve is shown in Figure 3 and is extracted using aperture photometry on the difference images and combining the multiple images obtained at each epoch. Proximity to the Sun prevented observations from April to July 2017. The source had a relatively steady flux of $V \sim 14.5$ mag in the previous observing season (August 2016 to April 2017) and brightened from a minimum of $V \simeq 15.0$ mag in the season before that (July 2015 to March 2016). ASAS-SN images have $\sim 15''$ FWHM PSF. There is a modest dilution of the variability amplitude through the contributions of a nearby source to the photometry aperture.

Kanata/HONIR TXS 0506+056 was monitored in the imaging mode with the Hiroshima Optical and Near-InfraRed camera (HONIR) (42) installed at the Cassegrain focus of the 1.5-m Kanata telescope at the Higashi-Hiroshima Observatory, starting ~ 20 hours after the IceCube-170922A alert. Polarimetric observation with HONIR was also performed since 30 September 2017, revealing that TXS 0506+056 was highly polarized ($\sim 7\%$ in R band). The magnitude was measured by relative photometry with respect to the nearby reference stars listed in the AAVSO Photometric All-Sky Survey (102). For polarimetry of TXS 0506+056, strongly-polarized standard stars (BD +64 106 and BD +59 389; (103)), and several unpolarized standard stars, were observed for calibration. The instrumental polarization for HONIR was confirmed to be negligibly small ($\lesssim 0.1\%$), and no correction was applied. The foreground Galactic extinction ($E_{B-V} = 0.096$, (104)) indicates that the interstellar polarization is $p_R \leq 0.9\%$ (105), suggesting the observed large polarization is predominantly intrinsic to the blazar. Possible blazar candidates were selected from flat spectrum radio sources of $\alpha > -0.5$ (where α is a spectral index defined as $F_\nu \propto \nu^\alpha$) from 0.15 GHz TGSS (106) and 1.4 GHz NVSS (107) catalogs. Four flat-radio-spectrum objects (including TXS 0506+056) found within the IceCube-170922A error region were examined. Visual inspection of differenced images taken on 23 September 2017 and 24 September 2017 showed a clear fading of blazar TXS 0506+056 (52).

Kiso/KWFC Monitoring observations of TXS 0506+056 in optical g , r , and i bands commenced after the neutrino alert with the Kiso Wide Field Camera (43) attached to the 1.05 m Kiso Schmidt telescope. The point spread function sizes are 4-6 arcsec FWHM, well separated from a nearby bright star in the KWFC images. The data were reduced in the same manner as that for a previous supernova survey (108). Compared with previous observations (109), the flux of the object increased by approximately 1.0 mag and remained in a bright phase until at least November 2017.

Figure S4: **Liverpool Telescope measured spectrum of TXS 0506+056.** Spectrum of TXS 0506+056 obtained with the low resolution ($R \approx 350$) spectrograph SPRAT on the Liverpool Telescope on 29 September 2017. The spectrum shows a smooth continuum typical of a BL Lac object, with absorption features that are telluric or attributable to Galactic interstellar Na I absorption.

Liverpool Telescope Low resolution (resolving power ~ 350 , $4000 - 8000 \text{ \AA}$) optical spectra of TXS 0506+056 were obtained with the SPRAT spectrograph of the 2.0 m Liverpool Telescope (41) on 29 September 2017 02:31 UTC and 30 September 2017 02:15 UTC. The spectra, shown in Figure S4, showed no sign of variation and are typical of a BL Lac object, showing a smooth continuum. The only feature seen is attributable to Galactic interstellar Na I absorption. No redshift measurement is possible from the optical spectra. Both spectra have a flat spectral energy distribution with $F_\lambda \sim 4 \times 10^{-15} \text{ ergs s}^{-1} \text{ cm}^{-2} \text{ \AA}^{-1}$, which is bluer than the (similarly featureless) spectrum presented in (110), indicating a likely “bluer-when-brighter” behavior.

Subaru/FOCAS Low resolution (resolving power ~ 400 in $4700-8200 \text{ \AA}$ and ~ 1200 in $7500-10500 \text{ \AA}$) optical spectra were obtained with the Faint Object Camera and Spectrograph (45) on the 8.2-m Subaru telescope on 30 September 2017 and 1 October 2017, respectively, and are shown in Figure S5. The data was reduced with IRAF software in the standard manner (111). The signal-to-noise ratios are roughly 350 per pixel. The spectra are almost featureless smooth continua over the entire wavelength range except for a weak emission line is marginally detected around $8,800 \text{ \AA}$, corresponding [NII] detected in (28).

Figure S5: **Subaru/FOCAS spectra of TXS 0506+056.** Normalized spectra taken with FOCAS on the 8.2-m Subaru telescope on 30 September 2017 (blue) and 1 October 2017 (red), in two different settings of the grism and order-sort filters. Note that some atmospheric absorption effects remain. The [NII] line detected by Paiano et al. (28) is marginally detected as shown in the inset figure.

Swift and NuSTAR *Swift* carried out rapid-response follow-up observations of IceCube-170922A as a mosaic of 19 pointings beginning 3.25 hours after the neutrino detection, lasting 22.5 hours, and accumulating approximately 800 s exposure per pointing. The tiled *Swift* XRT observations together cover a roughly circular region centered on RA, Dec (J2000) = (77.2866 deg, +5.7537 deg), with radius of approximately 0.8 deg and sky area 2.1 deg². XRT data was analyzed automatically as data was received at the University of Leicester, via the reduction routines described in (112, 113). Nine sources were detected in the covered region down to a typical achieved depth of 3.8×10^{-13} erg cm⁻² s⁻¹ (0.3 keV – 10.0 keV). All of the detected sources were identified as counterparts to known and cataloged stars, X-ray sources, or radio sources (114). Source 2 from these observations, located 0.077 deg from the center of the neutrino localization, was identified as the likely X-ray counterpart to TXS 0506+056.

Following the *Fermi*-LAT report that TXS 0506+056 was in an enhanced GeV-flaring state, a *Swift* monitoring campaign was initiated (55) and a single *NuSTAR* observation (56) was requested. *Swift* monitoring observations began on 27 September 2017 with 12 epochs (and 24.7 ks total exposure time) completed by 23 October 2017 (Table S10). *NuSTAR* observations over 02:23 to 17:48 UTC on 29 September 2017 yielded 23.9 ks (24.5 ks) exposure in the A (B) units, respectively, after processing with *NuSTAR* standard software tools (115) (SAAMODE=strict). With count rates of 21.3 ct ks⁻¹ (20.8 ct ks⁻¹) in the A (B) units, TXS 0506+056 is well detected in these data.

For joint analysis purposes, the *Swift* XRT data from the 27 September 2017 and 30 Septem-

Figure S6: **Swift-XRT and NuSTAR observations of TXS 0506+056.** The spectrum of TXS 0506+056 from a joint fit to Swift-XRT data with the NuSTAR spectrum of TXS 0506+056. Swift-XRT data are shown with orange markers and the two NuSTAR units are shown with blue and green markers.

ber 2017 monitoring observations were selected; processing of these data occurred with the online tools of the UK *Swift* Science Data Centre (112), yielding a 6.9 ks exposure, with the source exhibiting a count rate of 88 ct ks^{-1} .

The resulting TXS 0506+056 spectrum over 0.3 keV – 100 keV is adequately fit with a double power-law spectral model with the galactic hydrogen column density (N_{H}) fixed at the expected Galactic value, $N_{\text{H}} = 1.11 \times 10^{21} \text{ cm}^{-2}$ (Fig. S6).

The soft power-law component has the photon index $\Gamma_s = -2.78 \pm 0.30$ and yields a flux of $(1.78 \pm 0.41) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ over 0.3 keV – 10 keV, while the hard power-law component has the photon index $\Gamma_h = -1.43 \pm 0.25$ and yields a flux of $(4.7 \pm 2.4) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ over 3 keV – 100 keV. The hard power-law component that dominates over the NuSTAR bandpass extrapolates to $\nu F_\nu = 5.8 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ at $E_\gamma = 20 \text{ MeV}$, consistent with the flux observed over the *Fermi*-LAT bandpass (0.1 GeV – 100 GeV) at that epoch.

To characterize the X-ray flux and spectral variability of TXS 0506+056, we performed a power-law fit to each individual *Swift* XRT observation (Table S10), as well as to the summed spectrum from all listed epochs. The 14 October 2017 observation is excluded from the spectral analysis due to low exposure time. The summed spectrum (24.7 ks total exposure) is adequately fitted with a single power-law spectral model having $N_{\text{H}} = 1.11 \times 10^{21} \text{ cm}^{-2}$, resulting in a pho-

ton index $\Gamma = -2.46 \pm 0.06$ and mean flux of $3.06 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ (0.3 keV – 10.0 keV). This source has been observed on multiple previous occasions with the *Swift* XRT (113). In past observations, TXS 0506+056 exhibits a typical count rate of 40 ct ks⁻¹, with one observation at approximately 90 ct ks⁻¹. The source was therefore in an active X-ray flaring state by comparison to historical X-ray measurements (cf. Figure 3).

Individual monitoring observations show evidence of spectral variability; photon indices and X-ray flux measurements for each epoch are provided in Table S10, and the variations in photon index are shown in Figure 3. The χ^2 statistic for photon index variations (compared to a fixed $\Gamma = -2.46$ from the summed spectrum) is 33.91 for 11 degrees of freedom ($p = 3.7 \times 10^{-4}$).

INTEGRAL The *INTEGRAL* observatory (51) has surveyed the sky in hard X-rays and soft γ -rays at energies above 20 keV since October 2002. At the time of the IceCube-170922A detection, *INTEGRAL* was performing a slew between two pointings, and the sensitivity to emission from the IceCube neutrino direction depends on time. Combining data from the Spectrometer on *INTEGRAL* - Anti-Coincidence Shield (SPI-ACS) and Imager on Board the *INTEGRAL* Satellite - Veto (IBIS/Veto) instruments, we set a limit on the 8-second peak flux at any time within ± 30 minutes from the time of the alert at a level of $10^{-7} \text{ erg cm}^{-2} \text{ s}^{-1}$, assuming a power-law spectrum with a slope of -2 (57).

The location of IceCube-170922A was serendipitously in the field of view of *INTEGRAL* from 30 September 2017, 05:36:04 UTC (MJD 58026.23) to 24 October 2017, 16:20:25 UTC (MJD 58050.68). Due to the large off-axis angle, the resulting effective exposure was only 32 ks. In the combined mosaicked images of *INTEGRAL* Soft Gamma-Ray Imager data we did not detect the source, and set an upper limit (3σ C.L.) on the average flux from the position of TXS 0506+056 of $7.1 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 20 keV – 80 keV energy range and $9.8 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 80 keV – 250 keV energy range.

Neutrino-blazar coincidence analysis

In order to calculate the chance probability of a coincidence between a neutrino alert, such as IceCube-170922A, and a flaring blazar, several hypothesis tests have been performed covering a range of assumptions on the spatial and temporal signal distribution and neutrino emission scenarios. For each hypothesis we create a test statistic (TS) that we use in a likelihood ratio test to compare the signal hypothesis to the null hypothesis. In each case our null hypothesis assumes no correlation between a cataloged γ -ray source and high-energy neutrino events (including atmospheric neutrinos and misidentified muons, and the astrophysical neutrinos). The signal hypothesis assumes that neutrino events originate from cataloged *Fermi*-LAT blazars, given a particular model for the correlation between the neutrino and γ -ray emission.

As a common framework for all the analyses, we start with an unbinned likelihood function defined in a similar way to previous IceCube point source analyses (3, 4):

$$\mathcal{L} = \prod_i^N \left(\frac{n_s}{N} \mathcal{S} + \left(1 - \frac{n_s}{N}\right) \mathcal{B} \right), \quad (\text{S1})$$

with signal and background probability density functions (PDFs) denoted as \mathcal{S} and \mathcal{B} , respectively. N is the total number of events and n_s the number of signal events. Additionally, there is one constrained nuisance parameter included in the likelihood for the γ -ray energy flux (or flux ratio) normalization of each source using the method from (116), treating the flux error as a normal distribution. Including the nuisance factor does not have a significant influence on the results. In the simple case considered here, only a single event enters the analysis, i.e. $N = 1$.

We define a test statistic of the form

$$TS = 2 \log \frac{\mathcal{L}(n_s = 1)}{\mathcal{L}(n_s = 0)} = 2 \log \frac{\mathcal{S}}{\mathcal{B}}. \quad (\text{S2})$$

In this definition the likelihood ratio test reduces to a test between two fixed alternate hypotheses and TS can take negative values for background-like events. The signal PDF consists of three independent parts, a spatial factor, a flux weight factor, and a factor for the detector acceptance:

$$\mathcal{S}(\vec{x}, t) = \sum_s \frac{1}{2\pi\sigma^2} e^{-|\vec{x}_s - \vec{x}|^2 / (2\sigma^2)} w_s(t) w_{\text{acc}}(\theta_s), \quad (\text{S3})$$

where the sum runs over all 2257 extragalactic *Fermi*-LAT sources, s . Their light curves were constructed as described above for the analysis of the *Fermi*-LAT light curves for TXS 0506+056, where 28-day wide bins are used to characterize the γ -ray activity at time t . The term w_{acc} is the IceCube acceptance as a function of zenith angle (normalized over all zenith angles, θ_s), assuming a neutrino signal spectral index $\gamma = -2.13$. This factor accounts for the zenith-dependent sensitivity of the IceCube detector. The function $w_s(t)$ derived from the *Fermi*-LAT light curve, describes the model-dependent relation between the γ -ray emission and the expected neutrino flux from source s as a function of time.

The leading factor inside the summation is the spatial weight accounting for the distance of a source at position, \vec{x}_s , to the reconstructed neutrino direction, \vec{x} , in terms of the reconstruction uncertainty σ of the neutrino direction, which is found on a per-event basis (3). The uncertainty of the γ -ray source position is negligible compared to the neutrino angular uncertainty. Sources at large angular distances from the neutrino are assigned a negligible weight by the spatial factor, which models the IceCube point-spread function (PSF). The ‘‘signalness’’ of a neutrino event, as mentioned in the main text, is a quantity constructed by the realtime system from the energy and zenith angle estimates, to rapidly allow an assessment of whether an event is a worthy target of opportunity. It does not enter into the likelihood.

The background PDF is described by the zenith acceptance, $\mathcal{P}_{BG}(\sin \theta)$, which is a probability density function describing the zenith distribution of the alert events that are due to background.

$$\mathcal{B}(\vec{x}) = \frac{\mathcal{P}_{BG}(\sin \theta)}{2\pi}, \quad (\text{S4})$$

where θ is the zenith angle of the reconstructed neutrino direction \vec{x} . To construct a background TS distribution we randomly draw neutrino events from an IceCube all-sky Monte Carlo sample containing muon-neutrinos and misidentified muons from air-showers and astrophysical neutrinos with energies according to the spectral shape presented in (2).

The final p-value is then determined by calculating the fraction of background TS values larger than the measured one for IceCube-170922A. Note that the overall normalization of \mathcal{S} and \mathcal{B} does not influence the final p-value, but only shifts the TS distribution.

As the production mechanisms of neutrinos and γ -rays in astrophysical environments are poorly understood, three models connecting the γ -ray and the neutrino flux are considered for $w_s(t)$. All models are based on the assumption that at least part of the γ -ray emission is of hadronic origin. In all cases the extragalactic sources from the *Fermi*-LAT catalog are used.

Model 1: The neutrino energy flux is proportional to the γ -ray energy flux of the source in the time bin where the neutrino arrives (4). This is motivated by the fact that a similar amount of energy is expected to be channeled into the neutrino and γ -ray emission, if pion decays from pp or p γ interactions dominate at high energies. Alternatively, it can be relevant even if emission from electrons dominate, as long as protons and electrons are accelerated at a fixed power ratio.

In this case the weight is equal to the γ -ray energy flux defined as:

$$w_s(t) = \phi_E(t) = \int_{1 \text{ GeV}}^{100 \text{ GeV}} E_\gamma \frac{d\phi_\gamma(t)}{dE_\gamma} dE_\gamma, \quad (\text{S5})$$

where $\phi_\gamma(t)$ is the photon flux from the γ -ray light curves, at time t . The resulting pre-trial p-value is $2.1 \cdot 10^{-5}$, corresponding to a Gaussian equivalent one-sided probability of 4.1σ .

Model 2: The neutrino production and detection probability depend only on the relative flux change of the γ -ray source emission around the neutrino event time, t . This prevents missing a correlation with γ -dim sources that may be much brighter in neutrinos than γ -rays, at the cost of some sensitivity to bright sources.

Here,

$$w_s(t) = \phi_\gamma(t) / \langle \phi_\gamma \rangle, \quad (\text{S6})$$

where $\langle \phi_\gamma \rangle$ is the time averaged γ -ray flux from the source. The resulting pre-trial p-value is $2.5 \cdot 10^{-5}$ (4.1σ).

Model 3: The neutrino energy flux is proportional to the γ -ray energy flux predicted in the very-high-energy (VHE) γ -ray regime (100 GeV – 1 TeV). This approach is triggered by the detection of VHE γ -ray emission by MAGIC.

If a similar amount of energy is channeled into neutrinos and γ -rays in the sources (as in Model 1) the energy flux is expected to be correlated with the neutrino energy flux. The VHE γ -ray emission is closer in energy to the observed neutrino and might therefore be a better indicator for high-energy particle acceleration.

As no unbiased survey of the sky exists at energies above 100 GeV, the 2257 extragalactic *Fermi*-LAT sources were considered. The VHE spectral functional form was obtained through extrapolations of the spectrum measured by *Fermi*-LAT in the energy range from 1 GeV – 100 GeV over the entire 9.5-year *Fermi*-LAT exposure. The VHE spectral normalization was scaled to match each monthly bin of the *Fermi*-LAT light-curve. Since any additional softening of the spectrum in the VHE energy band due to limitations in the acceleration capabilities of the source, limitations in the radiative efficiency, absorption within the source or in the extragalactic background light (EBL) would yield a lower flux, these extrapolations represent a conservative assumption.

The pre-trial p-value in this case is $4.9 \cdot 10^{-5}$ (3.9σ). Including absorption by the extragalactic background light for the extrapolations does not change the p-value significantly. Extrapolations to VHE energies are potentially uncertain for weaker, hard-spectrum sources with a spectral shape not well constrained in the high-energy band. For the sources within the Fermi 3FHL catalog, the results obtained with the best fit from 9.5 years of *Fermi*-LAT data (*e.g.* power-law or log-parabola or power-law with exponential cutoff) were compared to extrapolations based on the power-law fit. Minimal impact was found on the weights in the energy band considered.

A test was applied to assess the impact of the flux weight on the chance coincidence probability, and to quantify the probability of a simple spatial coincidence between a neutrino alert and a cataloged source. To achieve that, the flux weight was set to one for all cataloged sources ($w_s(t) = 1$). This choice implies that the intensities of the neutrino and γ -ray emission are not correlated for LAT catalog sources. In this case, the pre-trial p-value is reduced to 0.0017 (2.9σ). Another set of tests was applied to check the impact of the spatial factor in the likelihood description above, given that IceCube-170922A was found very close to the source (at a distance of 0.1 deg, much smaller than the 90% angular error typical for IceCube through-going track events). The Gaussian PSF factor is replaced by 1 in this test for neutrino events within 0.5 deg of the source and by 0 otherwise. If the full PSF information is not used, the significance values drop by $0.4\sigma - 0.5\sigma$ for the three models described above.

Prior to 22 September 2017, IceCube had publicly issued 9 alerts. In addition 41 archival events (before April 2016) were inspected, which would have triggered alerts if the realtime system had been operational. Since no *Fermi*-LAT source comparable in energy flux to TXS 0506+056 was found within the 90% error region of any of the potential previous alerts, the global p-value, corrected for all trials, can be obtained from the pre-trial local p-value $p_{\text{global}} = 1 - (1 - p_{\text{local}})^N$, where $N = 51$ is the number of trials. For $p_{\text{local}} \ll 1$ this simplifies to $p_{\text{global}} \approx p_{\text{local}}N$. For Model 1 and 2, the trial factor correction yields a global p-value of 3.0σ . Five of the 10 IceCube alerts were followed-up by VHE observations. With the exception of IceCube-170922A,

no alert has been observed by an IACT more than 3.2 hours. Considering 5 alerts only, the global p-value for Model 3 based on the formula above becomes 3.5σ . For 10 (51) alerts the corresponding p-values are 3.3σ (2.8σ). Since IACTs do not follow up all IceCube alerts, it is not clear if these values are relevant in this case.

Correlation analysis sensitivity To demonstrate that the test described above is sensitive to our signal hypothesis, an ensemble of simulated IceCube observations was generated assuming a proportionality between the instantaneous γ -ray and neutrino emission, corresponding to Model 1 above.

In these simulations, the signal normalization is set such that the expected number of IceCube real-time alerts originating from cataloged extragalactic *Fermi*-LAT sources is equal to 1. Here we have assumed that the purity of the IceCube real-time stream is $\sim 40\%$ and that blazars produce $\sim 5\%$ of the diffuse neutrino flux, which is consistent with the current upper limits in (4). With a total of 51 alerts, we expect roughly one coincidence. In each realization of these signal simulations, one IceCube event is injected on a cataloged extragalactic *Fermi*-LAT source. The probability to select each individual source is set proportional to its energy flux.

For each injected IceCube event, we calculate the TS as described above using the observed γ -ray light curves.

The resulting signal and background TS distributions are compared in Figure S7. Defining sensitivity as the fraction of the signal realizations correctly identified as such, the figure shows that for a reasonable cut at e.g. $TS = 9$, a sensitivity $> 50\%$ is obtained for a p-value less than 1%. The pre-trial p-value shown for IceCube-170922A is $2.1 \cdot 10^{-5}$, corresponding to Model 1. This test has been applied for the assumption of one signal event and can therefore be directly compared with the pre-trial p-values of the energy flux weighting scenario described above.

Furthermore the energy flux distribution of γ -ray sources with simulated neutrino coincidences was inspected assuming that all sources produce neutrinos proportional to their γ -ray energy flux. It is found that 14% of all sources have an equal to or larger γ -ray energy flux than TXS 0506+056 during the time of IceCube-170922A (see Fig. S7). This shows that if the neutrino flux is in fact highly correlated with the γ -ray flux it is not surprising that we detect a neutrino in coincidence with this particular source and flaring incident. This test neglects dim γ -ray sources below the detection threshold of the *Fermi*-LAT, which would also contribute to the neutrino flux.

Previous high-energy IceCube events Prior to IceCube-170922A, the IceCube real-time system sent 9 public high-energy neutrino alerts. IceCube data recorded prior to the start of the real-time system in April 2016, starting from 2010, has been inspected for events that would have passed the selection criteria of the real-time stream. An additional 41 events were identified. The 90% error contours of all 51 events were searched for γ -ray sources in spatial coincidence. The angular resolution for those events varies strongly with the topology and energy of the event. Only events with an angular uncertainty of less than 5 deg^2 are considered, excluding 4 events from the pre-alert time period. Events with larger uncertainty would get

a small spatial weight assigned in the likelihood analysis and would not yield a significant p-value. One neutrino (9 December 2014) is found with a 90% location uncertainty region of 1.76 deg^2 in spatial coincidence with the γ -ray source 3FGL J1040.4+0615. The best-fitting neutrino position is 0.27 deg from the position of the γ -ray source. In the monthly time bin around the neutrino arrival time, the source was detected with an energy flux of $1.3 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ between 1 GeV and 100 GeV, more than an order of magnitude lower than the energy flux at TXS 0506+056 during the time of IceCube-170922A of $1.9 \times 10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$, and about a factor of 2 below the brightest emission period ($2.7 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$) observed for this particular source. Therefore, this event would have produced substantially lower test statistic values in the statistical tests for chance coincidence described above, where a correlation between the gamma-ray and neutrino emission is assumed.

Table S9: **VLA Radio Frequency Flux Densities of TXS 0506+056.** A $\sim 5\%$ systematic uncertainty in the absolute flux scale should be included when comparing these to flux densities measured with other facilities.

The Radar Echo Telescope for Cosmic Rays (RET-CR) is a recently initiated experiment designed to detect the englacial cascade of a cosmic-ray initiated air shower via in-ice radar, toward the goal of a full-scale, next-generation experiment to detect ultra high energy neutrinos in polar ice. For cosmic rays with a primary energy greater than 10 PeV, roughly 10% of an air-shower's energy reaches the surface of a high elevation ice-sheet ($\gtrsim 2$ km) concentrated into a radius of roughly 10 cm. This penetrating shower core creates an in-ice cascade many orders of magnitude more dense than the preceding in-air cascade. This dense cascade can be detected via the radar echo technique, where transmitted radio is reflected from the ionization deposit left in the wake of the cascade. RET-CR will test the radar echo method in nature, with the in-ice cascade of a cosmic-ray initiated air-shower serving as a test beam. We present the projected event rate and sensitivity based upon a three part simulation using CORSIKA, GEANT4, and RadioScatter. RET-CR expects ~ 1 radar echo event per day.

I. INTRODUCTION

Ultra high energy cosmic rays (UHECR) and neutrinos (UHEN) are important messengers from the most energetic astrophysical sources. Identifying and understanding these sources is a key goal of current multi-messenger astronomy, a burgeoning field with exciting recent breakthroughs and many discoveries to be made [1–3].

The primary challenge to detecting UHECR and particularly UHEN is the low flux at the highest energies. This low flux requires an observatory that can efficiently probe a large target volume, in order to acquire a statistically significant sample of events. There are several current and proposed experimental strategies to achieve this large volume [4–10]. In this paper we discuss the *radar echo* method. This method has promising projected sensitivity to neutrinos in the 10-100 PeV range, providing complementarity with existing and future techniques for measuring UHEN. [11–16]

A high energy particle (e.g. neutrino) interacting in a dense medium (e.g. ice) creates a cascade of relativistic particles that ionize atoms in the target medium. A short-lived cloud of

FIG. 1. The RET-CR concept. A surface detector triggers on the charged in-air cascade particles as they reach the surface. The energy of this in-air cascade is deposited into the ice, where a denser in-ice cascade is produced. Radio is broadcast from the transmitter (TX) and reflected from the in-ice cascade to the embedded receiver (RX).

charge is left behind, which can, if sufficiently dense, reflect incident radio waves. RET proposes to illuminate a volume of ice with a transmitter radio-frequency antenna and monitor that same volume for reflections with a receiving antenna. To improve reconstruction of the geometry of a cascade, and therefore the progenitor source direction, a target volume can

* prohira.1@osu.edu

† Krijn.de.Vries@vub.be

be illuminated with multiple transmitters, and monitored with multiple receivers. Overall, the radar echo method allows for the coverage of a large volume with minimal apparatus and station layout optimized for a given neutrino energy, making it an attractive option for UHEN detection.

The radar echo method has been verified in the lab [11, 12], with first observations of radar echoes from particle cascades recently reported [15, 16]. These lab tests are critical steps in developing an ultimate radar echo neutrino observatory. The final step in validating the technique is to translate the laboratory tests into nature, and test the method *in situ* with a known test beam: the in-ice cascade produced when the extensive air shower (EAS) of an UHECR impacts the ice.

In this paper we describe the Radar Echo Telescope for Cosmic Rays (RET-CR) (Figure 1) which will serve as a testbed for the radar echo method, and a final stepping stone toward the eventual construction of a full-scale radar echo telescope for UHEN.

II. HISTORY, THEORY, AND BACKGROUND.

First efforts on the radar echo method were chronicled by Lovell [17]. With collaborator Blackett, the Jodrell bank observatory was constructed in the UK, anticipating that radar echoes from UHECR might explain “sporadic radio reflexions” from the upper atmosphere. Ultimately, those signals were determined to be from meteors, which ionize similar, far denser trails in the upper atmosphere. After several experimental efforts (including the Telescope Array RADar (TARA)) failed to detect UHECR via radar [18–21], and theoretical work explaining the lack of observed reflections [22, 23], the in-air method was finally deemed not viable due to short ionization lifetimes in the atmosphere at EAS altitudes, and damping from collisions between ionized electrons and neutral air molecules (an issue first raised by Eckersley in 1941 [17], though largely subsequently ignored.)

Neutrino interactions in the ice produce ionization densities many orders of magnitude more dense than those in-air, owing to the $\sim 10^3$ greater density of ice relative to air. Therefore, while the ionization lifetime remains short in ice (roughly 10 ns [24]) and the collision rate is extremely high, so too is the underlying ionization density, allowing for a possible scatter. Several models now exist for the in-ice radar echo [13, 14] and show promising experimental sensitivity. Laboratory tests have shown good agreement with theory, but in order to test the radar echo method in nature, a source of *in-ice* ionization is required; EAS offer such a source.

The EAS of a UHECR expands radially outward from the shower axis, such that an EeV cascade has a $\mathcal{O}(100\text{ m})$ footprint on the ground. However, nearly all of the cascade energy is contained within $\sim 10\text{ cm}$ of the shower axis, as illustrated below [25]. The sought-after signal depends on the total number of particles in the shower core, as well as the geometry of the shower. In Figure 2, we plot the ratio of the number of particles at the air/ground boundary (N_b) to the maximum number in the cascade (N_{max}) for different primary UHECR energies for different ice elevations as a function of zenith an-

FIG. 2. The ratio of the number of cascade particles, N_b , arriving at the air/ground boundary relative to the maximum number in the cascade, N_{max} , for various energies and ground elevations. At 2.4 km elevation and 1 EeV primary energy, shower maximum at normal incidence is in-ice.

gle using the NKG approximation [26]. For a high elevation (such as the interior Antarctic plateau), this ratio is ≥ 0.9 for energies $\geq 10\text{ PeV}$ for a wide zenith angle range, indicating that a significant fraction of the energy of the primary particle will arrive at the air/ice boundary.

The core of a UHECR when it impacts the ice can be used as an in-nature test beam. Though TARA demonstrated that UHECR detection *in air* via radar echo was not feasible, the *in-ice* cascade produced by the remaining EAS particles, as demonstrated by our beam tests, should be detectable via radar echo. For energies above 10 PeV, we expect an ionized column with a density that decreases rapidly with radius, and an in-ice length of about 10 m. The effective radius along this column at which radar will scatter depends on the transmitter frequency (discussed below); for frequencies in the 100s of MHz range, this radius is approximately 10 cm. The profile of this ionization deposit is similar to that which would be produced by a neutrino-induced cascade, the primary difference being that neutrino events are more likely to occur in deep ice rather than near the surface.

The properties of the *in-ice* cascade from EAS have been studied using CORSIKA [27] to simulate the extensive air shower evolution, GEANT-4 [28] to simulate the propagation of these cascades once they enter the ice, and RadioScatter [29] to calculate the reflected signals from the ionization deposits left in the wake of the cascades. We next discuss our planned detector layout and design, and then describe our simulation and projected sensitivity.

III. EXPERIMENTAL CONCEPT

The experimental concept is shown in Figure 1. A transmitter illuminates the region of ice just below the surface, with receivers monitoring this same region. The EAS of a UHECR with a primary energy greater than 10^{16} eV deposits a fraction ($\gtrsim 10\%$) of the primary energy at the surface of a high-elevation ice sheet. This energy is largely centered around the cascade axis, resulting in a dense secondary in-ice cascade roughly 10-20 m long. The charged particles from the EAS are detected by a surface scintillator array, triggering a radio receiver waveform to be recorded in the radar data acquisition system (DAQ). This simple setup closely parallels that already employed for the laboratory test-beam experiment, with the focus of the experiment on post-run, offline analysis of the data. This relative simplicity also allows for testing various radar based trigger routines, which can be optimized for efficacy against the charged particle trigger. Such testing is critical, as an eventual neutrino detector will be triggered by the radar signal itself.

When the cascade leaves the air and enters the ice, the density of the resultant ionization increases dramatically. This results in an ionization deposit in the ice with a plasma frequency $\omega_p = \sqrt{4\pi n_e q^2/m}$ far higher than any point in air. The plasma frequency, with n_e the number density of the ionization, q the electric charge, and m the electron mass, is a measure of the density of an ionization deposit. To first order, incident fields with interrogating frequencies lower than ω_p are reflected efficiently.¹ The profile of ω_p from a primary cosmic ray as it moves through air into the ice is shown in Figure 3, where the in-air and in-ice components of an EAS are indicated, as well as a vertical line indicating 100 MHz. The plasma frequency for the in-ice portion of EAS with primary energies greater than 10^{16} eV exceeds 100 MHz, indicating efficient scattering for interrogating frequencies in this range.

In the following sections, we describe the various subsystems of RET-CR. We provide a detail of the experimental layout in the Appendix.

A. Surface detector

The RET-CR surface detector is designed to detect the air shower incident on the surface of the radar detector, providing both an external trigger to the radar DAQ, and an independent reconstruction of the air shower. Using the surface detector as a trigger for the radar system will ensure that an UHECR has entered the radar detector volume with sufficient energy to be detected through the radar echo technique. The independent reconstruction of shower parameters by the surface detector will provide values for the core position, energy, and arrival

direction of the incident UHECR. These values will then be used to validate the reconstruction parameters obtained by the radar echo system.

The primary component of the surface detector is a scintillator plate array. The plates will be grouped in pairs following the design of the Cosmic-Ray Energy Cross-Calibration Array [30]. The plates in each pair of scintillators will be separated by 20 m and will be accompanied by a radio antenna operating in the frequency band 30-300 MHz, to form a station. Each station will have its own DAQ and power system. The combination of a radio and scintillator signal at each station will be beneficial in providing event reconstruction and energy estimates. The current deployment layout is shown in Appendix A, where the stations are grouped into two sets of three stations, separated by the central radar system. Additionally, a system diagram is provided in Appendix B. The station layout has been optimized for trigger efficiency, discussed below.

For the current prototyping and development of the RET-CR surface detector, and the current simulation work, the scintillators used are those from the KASCADE experiment [31]. The radio antennas have been donated by the CODALEMA/EXTASIS experiment [32, 33]. As such, for modelling the polyvinyl-toluene scintillator in GEANT4 we use a carbon:hydrogen ratio of 9:10 [34]. The panels deployed to the field will be similar in size and composition, and we do not expect any difference in performance from the panels simulated here.

The scintillator trigger threshold is tuned to maximize the radar echo detections. Simulations indicate that air showers with energy less than $10^{15.5}$ eV are inadequate to produce an in-ice cascade detectable via radar echo (and the rate of such showers would overwhelm the DAQ storage and may cause interesting events at higher energies to be lost). Additionally,

FIG. 3. The peak plasma frequency (ω_p) of the cascade as it develops in-air and then in-ice, at normal incidence. The in-ice cascade is far more dense than the in-air cascade, making it detectable via radar for primary energies greater than 10^{16} eV. The red line indicates the point at which $\omega_p > 100$ MHz.

¹ In a collisionless plasma, ω_p is a hard cutoff between the 'overdense' and 'underdense' regimes, which indicate fully coherent and incoherent scattering respectively. When taking collisions into account, this boundary is smeared, but ω_p is still a useful discriminator for the underlying ionization density.

simulations of the air shower radio footprint show that radio reconstruction of the air shower is not possible for showers with an energy less than approximately $10^{16.0}$ eV. Therefore we target 100% efficiency at $10^{16.5}$ eV, with efficiency defined as the percentage of cosmic ray air showers traversing the instrumented area that trigger the surface detector. We aim for a trigger rate of order 10^5 events per month, leading to approximately 300 surface triggered events a day. This is a manageable rate for both the surface and radar DAQ systems.

Simulation studies have been conducted to determine an appropriate triggering scheme for the surface detector. Events have been simulated with energies in the range $10^{15.0}$ eV to $10^{19.0}$ eV and zenith angles in the range 0-30 degrees. We limit ourselves to this zenith range because in-ice energy deposition decreases dramatically beyond 30 degrees zenith. The simulations were made using the CORSIKA and CoREAS [35] software for air shower simulation with a ground elevation set to 2400 m, that of an optimal deployment site, Taylor Dome, Antarctica. A change in this altitude will affect the point within the shower development at which the air shower passes through the detector. Showers at sea level are generally developed beyond shower maximum before reaching the ground. At the altitude of Taylor Dome, whether the shower has developed to a point before or after the shower maximum is strongly dependent on the energy and zenith angle of the air shower (Figure 2).

The stations of the surface detector will trigger independently. Each scintillator will be required to contain a deposit of 6 MeV (1 minimally ionizing particle) or greater per event and both scintillators in a station must trigger coincidentally within an event (an L0 trigger). The final trigger requirement is that all stations within one cluster must have coincident (restricting our zenith angle to $< 30^\circ$ zenith), above threshold energy deposits in all scintillators (an L1 trigger). A timing diagram is provided in Appendix C. The resulting trigger efficiency is shown in Figure 4. In this figure, we show that we achieve 100% efficiency at $10^{16.5}$ eV, as desired. Decreasing a half-decade in energy, at $10^{16.0}$ eV the efficiency decreases to $\sim 90\%$. In the lowest energy bin simulated, the efficiency is approximately 5%. This rapid turn-on in our trigger threshold allows us to target our desired event rate.

B. Radar echo detector

1. Data Acquisition System

The primary element of the radar echo detector DAQ is a Xilinx RFSoc [36]. This device serves as both our transmitter and our receiver. The transmit portion comprises 8 channels, each with a 6 GS/s digital-to-analog converter (DAC) capable of producing a phased, modulated output to an array of transmitters. The receive portion has 8 channels, each channel with a 4 GS/s analog-to-digital converter (ADC). A Virtex-7 FPGA provides transmit and receive functions and trigger logic, and an on-board ARM processor facilitates information transfer between the FPGA and the communication subsystems, also described below. This array is centrally located, and will be

FIG. 4. Trigger efficiency curve for the surface system as a function of primary UHECR energy.

described below.

The DAQ will have local storage for buffering data and a prioritizer system for telemetry, with a design expectation that our data transfer rate will be the primary bottleneck in getting data from the station. The most promising events are sent via communication link as well as being stored locally on disk. The criteria for this can include i) measured primary energy from the surface detectors or ii) the proximity of the in-ice vertex to a receive antenna, or a combination of the two. The disks will be retrieved at the end of the season.

The FPGA will host a number of radar “triggers” with potentially varying topologies, even though these triggers do not actually signal an event snapshot. These triggers will be trained against the surface detector trigger to determine their efficacy for eventual use in the successor neutrino detector, where the radar signal itself must trigger the DAQ. One such trigger under investigation is a heterodyne trigger (also called a “chirp trigger”) based upon a method developed for the TARA remote stations [37, 38] that exploits the frequency shift of the return signal. The geometry of RET-CR is such that all of the received radar echoes will exhibit this frequency shifting behavior. Other triggers based on the unique radar signature are also being explored. The sensitivity studies in this article employ a simple threshold trigger for the radar component.

2. Transmit array and transmitter modulation

The transmitter for RET-CR will be a vertical phased array of 8 vertically polarized antennas buried 2-20 m below the ice surface. This phased array serves 2 critical functions. The first is directionality—a phased array governed by an FPGA can form high gain beams in a defined direction, achieved via adjusting the relative phases of the transmit signal being delivered to each of the antennas in the array. A vertical phased

array has azimuthal symmetry with a high gain beam at a defined zenith angle, defined by the relative phase delays of each antenna. Since our reflectors are confined to the top ~ 10 m of the ice just below the surface, we can steer the beam slightly upward and waste virtually no power to the region below, where we do not expect to receive UHECR core reflections. Recent studies in Antarctica have shown that in-ice phased arrays are highly efficient receivers [39], and phased transmitter arrays are common in use throughout the world, including the TARA experiment. The second critical function of a phased array is to lower the single-amplifier gain for the transmit power amplifier. In lieu of a single 160 W power amplifier, each antenna will have its own 20 W power amplifier. This distributes the ohmic heating losses over 8 antennas instead of 1 and provides some redundancy: in the event that a power amplifier malfunctions, the experiment loses some efficiency, but does not shut down entirely.

The antennas will be based upon the simple bicones or biconical dipoles used by the RICE, ARA, and ARIANNA experiments in Antarctica. These antennas are small enough to fit down a borehole but are sufficiently broadband as to allow for a range of transmit frequencies and modulations. Studies are underway to determine if antennas with an asymmetric zenith angle gain can increase transmitter efficiency in the direction the beam is ‘steered’.

The modulation scheme is currently being defined. We plan to frequency hop or frequency shift around a central carrier of 100-300 MHz, with a transmitter bandwidth of 50-100 MHz. The central frequency is determined by maximizing the signal to noise ratio of a radar signal to the background noise. The signal has an optimal frequency dependent on the cascade dimensions and density, and the noise decreases with increasing frequency as thermal noise begins to dominate over galactic noise above ~ 150 MHz.

This frequency and the ultimate modulation strategy will be determined via simulations that are already underway. Modulation, as opposed to pulsing, increases detector livetime, as long as the carrier signal can be removed from the receivers. We discuss this below in section III B 4.

3. Receive array

The receiver array will be laid out in the configuration shown in Appendix A. Two different TX-RX baselines allow for a wide range of primary particle energies to be detected. Similar to the transmitter array, the receiver antennas will be buried 2-20 m below the surface of the ice. Each receive antenna will be a vertical phased array, similar to the transmit array, in order to maximize near-surface gain with full azimuthal coverage.

The receivers will not trigger the DAQ, but will form triggers as a testbed for eventual use in a neutrino array.

4. Amplification and active filtration

We will have a limiter and high-gain, low-noise amplifier on each receive channel, providing protection during transmitter turn-on and approximately 70 dB of gain, respectively. This amount of gain is sufficient to attain the galactic noise floor at our frequency, location, and receiver bandwidth of ~ 100 MHz.

Because radar receivers will be illuminated by the transmitter, it is essential to filter the transmitter or gate the receivers such that amplifier saturation does not occur. We plan to adopt an adaptive filtration scheme, whereby we will record an amplifier-bypassed snapshot of the transmitted signal over a horizon-distance window in time at each receiver, and then inject it time-delayed and phase-inverted into the receiver stream before the amplifier chain. The delay and output amplitude are tuneable, allowing for an iterative reduction of the input amplitude until the carrier is fully eliminated. This procedure will be updated at intervals throughout the day to account for environmental changes such as snow accumulation, which have been shown to introduce measurable changes in reflection times on \sim day timescales [40].

5. Power, system health, calibration, and communications

The detector will be fully autonomous and powered by three 1.2 kW solar arrays arranged in a triangle, such that at any time of (a sunny) day the station is provided with approximately 1 kW of power, with the majority of this power being used by the transmit power amplifiers. A bank of batteries will buffer power to assist in running the stations during adverse weather conditions. Each surface station will be powered by an individual photovoltaic. RET-CR will run only during the austral summer.

The system health, including power consumption, DAQ enclosure temperature, power amplification health, and local weather will all be monitored remotely, in real-time.

We will deploy a small, autonomous calibration unit that sends out a broadband pulse at regular intervals. This unit will serve as a regular baseline for thresholds and ensure global time synchronization, as well as for active monitoring of the above mentioned environmental changes, such as snow accumulation.

The communication system will be a 2-way satellite-based internet link. Through this link we will telemeter the prioritized data and system health information back to the lab, and, from the Northern Hemisphere, new trigger schemes and other station software and commanding to RET-CR. Alternative communications links via point-to-point Ethernet may be possible if there are line-of-sight repeater stations between a major base and the remote RET-CR.

IV. PROJECTED SENSITIVITY

The approximate sensitive surface area instrumented by RET-CR is 50×10^3 m². Through this area we can expect

FIG. 5. A one centimeter wide, two-dimensional slice of the in-ice energy density distribution along the cascade axis for a primary proton with $E = 10^{17}$ eV. The solid white line outlines the region for which the plasma frequency exceeds 100 MHz.

a flux of roughly 1 event at 100 PeV per day. The surface system will trigger on every cosmic ray with a primary energy above this, with decreasing efficiency at lower energies, as described in section III A. To simulate our radar echo detection efficiency, we performed a detailed multi-step Monte Carlo which we describe here using (in order) CORSIKA, GEANT4, and RadioScatter.

A. CORSIKA cascades and the surface stations

A CORSIKA-based Monte Carlo simulation for optimizing the surface array location was described in section III A. This same distribution of events (core positions, zenith angles, and energies) was used to simulate the radar sensitivity of RET-CR. A separate set of CORSIKA simulations was prepared specifically for producing the GEANT4 output used in subsequent simulation steps. These CORSIKA showers were produced at 0, 15, and 30 degrees zenith for each half-decade energy, with a ground elevation of 2400 m, as before. For 10^{16} eV and $10^{16.5}$ eV, no thinning was employed. For higher energies, thinning is set to 10^{-7} of the primary particle energy. For 10^{17} eV and $10^{17.5}$ eV the CORSIKA ‘weight’ of a single particle will never be larger than 10, for 10^{18} eV it will never be larger than 100. Thinning retains the overall energy of a cascade, such that the total in-ice ionization number will be the same for any thinning, but it changes the distribution of low-energy particles in the final footprint (which is then used as the input to GEANT4). We therefore minimized thinning as much as possible, subject to computing constraints.

B. GEANT4 simulations from CORSIKA output

The CORSIKA particle output at the surface of the ice was subsequently used as input for the GEANT4 simulation code configured to propagate particles into the ice. For this a realistic density profile similar to that found at South Pole was used, $\rho(z) = 0.460 + 0.468 \cdot (1 - e^{-0.02z})$ with ρ the density in g/cm^3 and z the depth in m. In each step of the simulation, the ionization energy loss is recorded; taking a typical ionization energy of 50 eV allowed us to obtain the free charge density profile in the ice [41]. An example of this profile is shown in Figure 5 for an air shower induced by a 10^{17} eV proton primary incident on an ice sheet at 2400 m elevation. The plasma frequency is a good indicator of the reflective properties of the induced plasma, as discussed previously. The solid white line in Figure 5 outlines the region for which the plasma frequency has a value larger than 100 MHz, where fully coherent scattering is expected.

C. RadioScatter simulations of GEANT4 output

To simulate the overall sensitivity, we use the RadioScatter [29] code. RadioScatter is a particle-level c++ code to simulate radio scattering from ionization deposits. It calculates the received radio signal reflected from an ionization deposit (from e.g. a particle cascade) for an arbitrary geometry of transmitter(s) and receiver(s).

The energy deposition calculated by GEANT4 was used as the input to RadioScatter. An example of a triggered event from a $10^{16.5}$ eV primary at normal incidence is shown in Figure 6. Clearly visible is the characteristic frequency shift expected for the RET-CR geometry, which can be exploited in trigger routines. At each cascade position in the surface scintillator simulation set, we simulated two different GEANT4 cascades: 1) the cascade with the closest half-decade energy *below* the primary energy of the surface simulation and 2) the cascade with the closest half-decade energy *above* the primary energy of the surface simulation. This is done because generating the GEANT4 cascades from the CORSIKA output is computationally expensive, so each discrete energy and zenith angle cannot be simulated individually. This method bounds the amount of energy that could arrive at the surface and accounts for shower-to-shower fluctuations. Both energies were simulated at each cascade position at one of three zenith angles, 0, 15, and 30 degrees selected according to their proximity to the ‘true’ zenith angle of the cascade from the surface simulation. These cascades were generated with a uniform distribution in $\cos \theta$ because cosmic rays arrive isotropically at earth, and a uniform distribution in $\cos \theta$ ensures that any zenith angle dependencies of the trigger are reflected in the sensitivity. The horizon distance for an in-ice transmitter is finite owing to the changing index of refraction in the firm (the top ~ 100 m of an ice sheet where snow is being compacted into ice) [42–45]. We therefore put a hard cut on a horizon distance of 150 m, which is commensurate with the point at which the in-ice shower maximum is out of view for a transmitter depth of ~ 20 m. The simulations in this paper eschew

FIG. 6. An example event simulated using CORSIKA+GEANT4+RadioScatter, as described in the text. This is a $10^{16.5}$ eV primary at normal incidence with a 10 ns plasma lifetime, simulated with a 160 W transmitter at 100 MHz.

the typical ray-tracing approach for studying propagation in the firm since this has recently been shown to be incomplete without in-situ studies of the ice density profile [46, 47]. The hard horizon cutoff for the results presented here are a proxy for the loss in efficiency due to propagation effects. These effects will be explored in detail in a future work.

D. Calculation of the event rate for RET-CR

The two components of the event rate are the effective area of the detector and the cosmic ray flux. We define both of these over an energy bin E_i with index i and width dE . The effective area $\mathcal{A}_i^{eff}(E_i)[m^2]$ for energy bin i is a function of the cross sectional area \mathcal{A}_\perp over which the sensitivity is calculated and a dimensionless trigger efficiency for the same bin, $\mathcal{T}_i(E_i)$.

To detail the effective area we first introduce the boxcar function, \mathbf{B} , which bounds a number $x_1 < x < x_2$:

$$\mathbf{B}(x, x_1, x_2) = \Theta(x - x_1)\Theta(x_2 - x), \quad (1)$$

where Θ is the Heavyside step function. Then we define our trigger conditions δ^S (for surface) and δ^R (for radar) which are 1 if the trigger condition is satisfied, and 0 if not. For example,

$$\delta^R = \Theta(v^{peak} - v^{thresh}) \quad (2)$$

for a peak waveform voltage v^{peak} and threshold voltage v^{thresh} , and δ^S is 1 when the surface system trigger logic is satisfied (a coincidence between surface stations with a certain per-station energy threshold, as described in Section III A). We then define the number of detected events, for event index k , energy bin with index i and θ bin with index j , as a matrix n_{ij} . These events are weighted by $\cos\theta_k$ to account for the

correction to the perpendicular cross-sectional area \mathcal{A}_\perp seen by a cosmic ray at zenith angles greater than zero.

$$n_{ij}(E_i, \theta_j) = \sum_k \delta_k^S \delta_k^R \cos(\theta_k) \mathbf{B}(E_k, E_i, E_{i+1}) \mathbf{B}(\theta_k, \theta_j, \theta_{j+1}) \quad (3)$$

n_{ij} will be zero for bins in zenith outside of the aperture of the instrument. For RET-CR, this aperture is 0-30 degrees as discussed in section III A. The total number of simulated events N_{ij} , also as a matrix in E and θ is

$$N_{ij}(E_i, \theta_j) = \sum_k \mathbf{B}(E_k, E_i, E_{i+1}) \mathbf{B}(\theta_k, \theta_j, \theta_{j+1}). \quad (4)$$

The trigger efficiency \mathcal{T}_{ij} in energy and zenith bins is represented as the ratio of these two,

$$\mathcal{T}_{ij}(E_i, \theta_j) = \frac{n_{ij}}{N_{ij}} \quad (5)$$

and we can then sum over all θ to get this expression as a function of energy only,

$$\mathcal{T}_i(E_i) = \sum_j \frac{n_{ij}}{N_{ij}}, \quad (6)$$

meaning that the effective area for energy bin E_i is

$$\mathcal{A}_i^{eff}(E_i) = \mathcal{T}_i \mathcal{A}_\perp \quad (7)$$

The flux as a function of energy $\mathcal{F}(E)[m^{-2}s^{-1}sr^{-1}eV^{-1}]$ is a broken power-law fit to the measured CR flux by many experiments [41, 48, 49]. To get a number of events per square meter, per second, per steradian, in energy bin E_i , we integrate $\mathcal{F}(E)$ over the energy range of bin i ,

FIG. 7. (Left) Event rates per day as a function of energy for the RET-CR detector. Colors correspond to different signal-to-noise relative to thermal noise of $8\mu\text{V}$ for a 100 MHz bandwidth. Width of the bands are explained in the text. (Right) Integrated event rates per 150 days as a function of energy for the RET-CR detector. Each bin represents the total integrated number of events per 150 days at and above that energy. Colors correspond to different signal-to-noise relative to thermal noise.

$$\mathcal{F}_i(E_i) = \int_{E_i}^{E_{i+1}} \mathcal{F}(E) dE. \quad (8)$$

Finally, the expression we use to calculate the event rate as a function of energy, for energy bin index i , $\mathcal{R}_i(E_i)$ is given in Eq. 9,

$$\mathcal{R}_i(E_i) = \mathcal{A}_i^{eff} \mathcal{F}_i \int dt \int d\Omega, \quad (9)$$

where the integral over time is the detector live time, and $\int d\Omega = \int d\phi d(\cos\theta) = \int d\phi \sin\theta d\theta$ is the integral over the aperture of the instrument. For an experiment sensitive to cosmic rays from the full sky, $\int d\Omega = 2\pi$ sr; the aperture for RET-CR is from 0-30 degrees zenith, $\int d\Omega \approx 0.26\pi$ sr.

We note that the measured flux of cosmic rays differs per experiment. A global study seeking to quantify this fluctuation between experiments [50] shows roughly 20% spread in measured energies between various experiments in our range of interest, leading to an uncertainty in the true flux. Therefore, to account for this uncertainty, we use the cosmic ray flux normalization in line with the mean of the global fit. A goal of the forthcoming Cross-Calibration Array [30] is to mitigate this uncertainty between experiments.

Figure 7, left, presents our expected event rate per day as a function of energy for various signal-to-noise levels relative to a thermal noise RMS of $8\mu\text{V}$. This is for a 160 W transmitter at 100 MHz with a 10 ns plasma lifetime, a likely plasma lifetime for polar ice near the surface [24]. The upper and lower bounds of the bands correspond to the over and underestimated energy simulation respectively. The mean of the 0 dB SNR curve integrates to roughly 1 event per day.

Figure 7, right, shows the integrated event rate for one austral running season, approximately 150 days. To produce this

figure, we have integrated the daily event rate histograms in Figure 7 at all energies. An entry here represents the integrated number of events detected per 150 days at and above that energy, at that SNR. We expect e.g. ~ 50 events at and above 10^{17} eV per season at the 0 dB threshold level.

For comparison to RET-N, the in-ice cascade energy for a 10^{17} eV primary detected by RET-CR is roughly 10^{16} eV. This cascade energy would correspond to that of a charged-current neutrino-nucleon interaction of 10^{16} eV, or a neutral current neutrino-nucleon interaction at $\sim 5 \times 10^{16}$ eV for inelasticity $y \sim 0.2$. Thus, the primary cosmic ray energies probed with RET-CR are similar to those of neutrinos to be targeted with RET-N.

V. CONCLUSION

We have presented the Radar Echo Telescope for Cosmic Rays, a pathfinder *in-situ* detector to test the radar echo method. Using the dense in-ice shower core of a cosmic ray air shower as a test beam, RET-CR will train trigger routines, energy and direction reconstruction methods, and analysis techniques to be employed by an eventual full-scale next-generation neutrino detector.

SOFTWARE

CORSIKA version 7.7400 (with QGSJETII-04 and URQMD 1.3cr), CORSIKA 7.7100 (with QGSJETII-04 and GHEISHA 2002d), CoREAS version 1.4 with a typical Taylor Dome, Antarctica atmosphere, GEANT4 versions 10.5 and 9.6, and RadioScatter version 1.1.0 were used to produce results for this paper.

ACKNOWLEDGEMENTS

RET-CR is supported by the National Science Foundation under award numbers NSF/PHY-2012980 and NSF/PHY-2012989. This work is also supported by the Flemish Foundation for Scientific Research FWO-12ZD920N, the European Research Council under the EU-ropean Unions Horizon 2020 research and innovation programme (grant agreement No 805486), and the Belgian Funds for Scientific Research

(FRS-FNRS). A. Connolly acknowledges support from NSF Award #1806923. S. Wissel was supported by NSF CAREER Awards #1752922 and #2033500. DZB is grateful for support from the U.S. National Science Foundation-EPSCoR (RII Track-2 FEC, award ID 2019597). We express our gratitude to R. Dallier, L. Martin, J-L. Beney and the CODALEMA experiment for providing electronics and hardware to be used in the surface radio stations of RET-CR. Computing resources were provided by the Ohio Supercomputer Center.

Appendix A: Station Layout

The station layout for RET-CR is shown in Figure 8. A phased transmitter is centrally located along with a data acquisition system and an amplifier enclosure for the transmitter. Three 1 kW solar power arrays are oriented in a triangle to maximize power over the full austral summer day. Satellite communications are shown near the solar power array. Each receive antenna is a vertical phased dipole array to maximize gain in an azimuthally symmetric region near the surface. The

cosmic ray detector system is shown in blue, where each of the six, two-panel stations is shown in blue. The receive antennas are arranged in two sets, near at 20 m from the TX and far at 100 m from the TX. The drawing is not to scale.

Appendix B: System diagram

A schematic of the RET-CR system, including the surface system, is shown in Figure 9.

Appendix C: Timing diagram

A schematic of the RET-CR trigger timing is shown in Figure 10. Each of three surface stations outputs an L0 trigger. If all three of these happen within the coincident window, here set to 170 ns, then an L1 trigger is satisfied, and the data is read out.

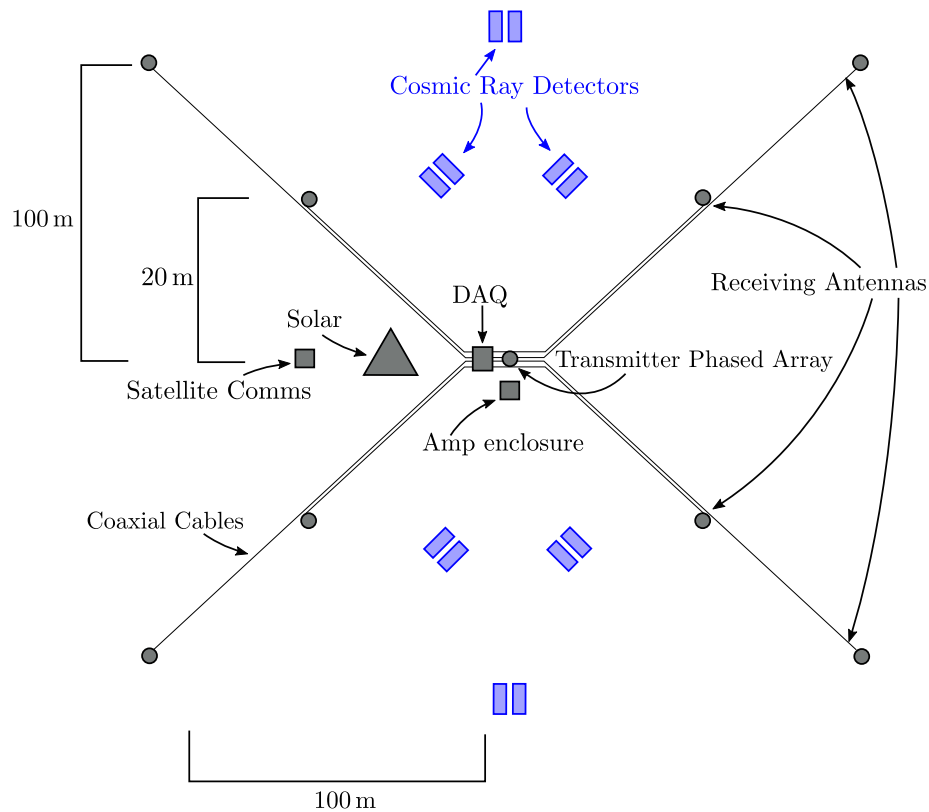

FIG. 8. The station layout for RET-CR. A phased transmitter array is centrally located along with a data acquisition system (DAQ) and an amplifier enclosure for the transmitter power amplifier(s). Three 1 kW solar power arrays oriented in a triangle are indicated along with satellite communications. The cosmic ray detector system is shown in blue. These serve to trigger the DAQ. The dimensions of the station are also indicated.

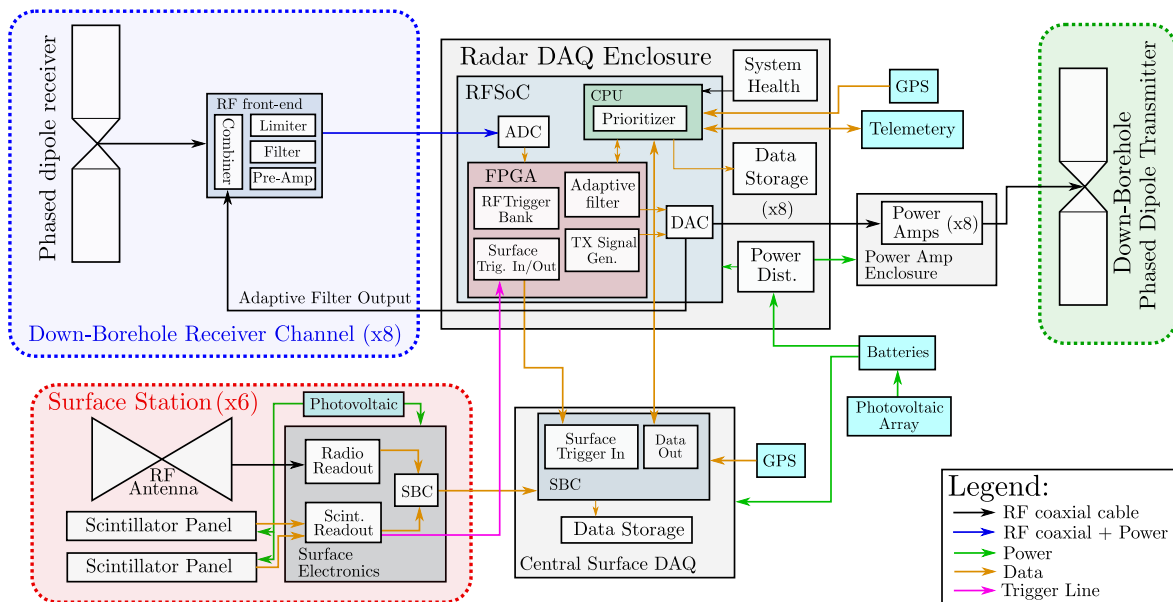

FIG. 9. The system diagram for RET-CR. The down-borehole receiver system is indicated on the left. There are 8 identical receivers placed according to the layout shown in Figure 8. The line indicating RF cable + power going to the receiver channel is powered via the bias-tee. The down-borehole transmitter is an 8-channel phased array, each antenna having its own DAC channel and power amplifier. The surface system, shown on the bottom, has 6 identical individual stations (bottom left).

FIG. 10. The timing diagram for the RET-CR trigger. Top: all 3 surface stations in one quadrant provide an L0 trigger within the coincident window, forming a global L1 trigger, which triggers an event record. Bottom: all 3 surface stations provide an L0 trigger, but not within the coincident window, meaning this event is unlikely to have a radar echo and therefore not recorded.

The cosmic-ray air-shower signal in Askaryan radio detectors

Abstract

We discuss the radio emission from high-energy cosmic-ray induced air showers hitting Earth's surface before the cascade has died out in the atmosphere. The induced emission gives rise to a radio signal which should be detectable in the currently operating Askaryan radio detectors built to search for the GZK neutrino flux in ice. The in-air emission, the in-ice emission, as well as a new component, the coherent transition radiation when the particle bunch crosses the air-ice boundary, are included in the calculations.

Key words: Cosmic rays, Neutrinos, Radio detection, Coherent Transition Radiation, Askaryan radiation

1. Introduction

We calculate the radio emission from cosmic-ray-induced air showers as a possible (background) signal for the Askaryan radio-detection experiments currently operating at Antarctica [1, 2, 3]. A high-energy neutrino interacting in a medium like (moon)-rock, ice, or air will induce a high-energy particle cascade. In 1962 Askaryan predicted that during the development of such a cascade a net negative charge excess arises mainly due to Compton scattering [4]. This net excess charge by itself will induce a radio signal that can be used to measure the original neutrino. This Askaryan radio emission [4, 5, 6] has been confirmed experimentally at SLAC [7], and more recently the Askaryan effect was also confirmed in nature by the radio emission from cosmic-ray induced air showers [8, 9, 10].

For high-energy cosmic-ray air showers, along with the Askaryan emission, there is another emission mechanism due to a net transverse current that is induced in the shower front by Earth's magnetic field [11-14]. Recently the radio emission from cosmic-ray air showers has been measured in great detail by the LOFAR collaboration [10, 15, 16], confirming the predictions from several independent radio emission models [17-20].

Most Askaryan radio detectors [1-3, 21-23] search for so-called GZK neutrinos that are expected from the interaction of ultra-high-energy cosmic-ray protons with the cosmic microwave background [24, 25]. The expected GZK neutrinos are extremely energetic with energies in the EeV range, while the flux at these energies is expected to fall below one neutrino interaction per cubic kilometer of ice per year. Therefore, to detect these neutrinos an extremely large detection volume, even larger than the cubic kilometer currently covered by the IceCube experiment, is

needed. Due to its long attenuation length, the induced radio signal is an excellent means to detect these GZK neutrinos. This has led to the development of several radio-detection experiments [1-6, 26-30]. Nevertheless, the highest-energy neutrinos detected so-far are those observed recently by the IceCube collaboration [31] and have energies up to several PeV, just below the energies expected from the GZK neutrino flux.

In this article we calculate the radio emission from cosmic-ray-induced air showers as a possible (background) signal for the Askaryan radio-detection experiments currently operating at Antarctica [1, 2, 3]. Besides the emission during the cascade development also transition radiation should be expected when the cosmic ray air shower hits Earth's surface [32, 33]. It follows that the induced emission is very hard to distinguish from the direct Askaryan emission from a high-energy neutrino induced cascade in a dense medium such as ice.

2. Radio emission from a particle cascade

We start from the Liénard-Wiechert potentials for a point-like four current from classical electrodynamics and closely follow the macroscopic MGMR [34] and EVA [20] models. Both models were developed to describe the radio emission from cosmic-ray-induced air showers. The Liénard-Wiechert potentials for a point charge, $A_{PL}^\mu(t, \vec{x})$, as seen by an observer positioned at \vec{x} at an observer time t are obtained directly from Maxwell's equations after fixing the Lorenz gauge [35],

$$A_{PL}^\mu(t, \vec{x}) = \frac{1}{4\pi\epsilon_0} \left. \frac{J^\mu}{|\mathcal{D}|} \right|_{ret}. \quad (1)$$

The point-like current is defined by $J^\mu = eV^\mu$, where e is the charge, and V^μ is the four-velocity for a particle at

Email address: krijndeVries@gmail.com (Krijn D. de Vries)

$\vec{\xi}(t_r)$ where the retarded emission time is denoted by t_r . The denominator of the vector potential, \mathcal{D} , is the retarded four-distance. For an extended current with longitudinal dimension h and lateral dimensions \vec{r} , the vector potential has to be convolved with the charge distribution given by the weight function $w(\vec{r}, h)$,

$$A^\mu(t, \vec{x}) = \frac{1}{4\pi\epsilon_0} \int dh d^2r \frac{J^\mu w(\vec{r}, h)}{|\mathcal{D}|} \Big|_{ret}, \quad (2)$$

where the vector potential has to be evaluated at the retarded emission time t_r . The corresponding geometry is

Figure 1: The geometry used to calculate the radiation emitted from a charge cloud crossing a boundary at $z = z_b$. The observer is positioned at an impact parameter $d = \sqrt{(x - r_x)^2 + (y - r_y)^2}$.

denoted in Fig. 1. We consider an observer positioned at an impact parameter $d = \sqrt{(x - r_x)^2 + (y - r_y)^2}$ perpendicular to the charge track, where r_x , and r_y denote the lateral position of the considered charge within the charge cloud. Defining the element in the plane of the observer perpendicular to the charge-track as $z = 0$, we can define the time at which the front of the charge cloud crosses this plane to be $t = 0$. Using these definitions the position of the charge along the track is now given by $z = -ct_r + h$.

Fixing the geometry, the vector potential can now be evaluated. The retarded emission time is obtained from the light-cone condition with respect to the optical path length L ,

$$c(t - t_r) = L, \quad (3)$$

from which the relation between the observer time and the emission time, $t_r(t)$, can be obtained. It should be noted that t_r is a negative quantity. For a medium consisting out of m layers with different index of refraction n_i , the optical path length can be defined by

$$L = \sum_{i=1}^m n_i d_i, \quad (4)$$

where the distance d_i , the distance covered by the emission in layer i , is obtained by using a ray-tracing procedure based on Snell's law. Following [36], the retarded distance for a signal traveling through different media is given by,

$$\mathcal{D} = L \frac{dt}{dt_r}. \quad (5)$$

In this work the index of refraction is assumed to be independent of frequency within the radio frequency range starting from a few MHz, up to several GHz. In the simplified situation where the signal travels through a medium with constant index of refraction n , the retarded distance can be written in the more common form,

$$\mathcal{D} = nR(1 - n\beta \cos(\theta)), \quad (6)$$

where θ denotes the opening angle between the line of sight from the emission point to the observer and the direction of movement of the emitting charge.

2.1. Cherenkov effects for a single electron

For a single electron moving at a highly relativistic velocity $\vec{\beta} = \vec{v}/c \approx 1$ along the z -axis (by definition), the current is given by $J^\mu = e(1, 0, 0, -\beta)$. The electric field is now obtained directly from the Liénard-Wiechert potentials through,

$$E^i(t, \vec{x}) = -\frac{dA^0}{dx^i} - \frac{dA^i}{dct}, \quad (7)$$

where $i = x, y$ gives the polarization of the field in the transverse direction, and x^i denotes the observer position in the transverse plane ($x^1 = x, x^2 = y$). For the moment we will ignore the electric field in the longitudinal direction and, since $A^i \propto J^i = 0$ for $i = 1, 2$ (there is no transverse current), we only have to consider the spatial derivative of the scalar potential. The electric field in the longitudinal direction will in general be small and can easily be calculated following the gauge condition $\vec{k} \cdot \vec{\epsilon} = 0$, where \vec{k} is the momentum vector of the photon and $\vec{\epsilon}$ the polarization. Hence the photon cannot be polarized along its direction of motion. Starting at the zeroth component of the vector potential, the spatial derivative can be evaluated by,

$$\frac{dA^0}{dx^i} = \frac{\partial}{\partial x^i} A^0, \quad (8)$$

which corresponds to the radiation from a net charge moving through the medium. For a relativistic electron ($\beta \approx 1$) moving in a medium with a refractive index $n > 1$ this term becomes,

$$\begin{aligned} E_{st}^i(t, \vec{x}) &= -\frac{\partial}{\partial x^i} A^0 \\ &= \frac{-e}{4\pi\epsilon_0} \frac{(1 - n^2)x^i}{|\mathcal{D}|^3}. \end{aligned} \quad (9)$$

Where the label 'st', denotes that the field is due to a highly relativistic non time-varying steady charge. The emission shows a radial polarization direction and vanishes

linearly with the distance of the observer to the shower core. This component of the electric field is suppressed by the factor $1 - n^2$, which vanishes in vacuum. In a medium with an index of refraction larger than unity however, this factor does not vanish and Cherenkov radiation is observed at the point where the retarded distance vanishes, $\mathcal{D} = \sqrt{t^2 + (1 - n^2\beta^2)(x^2 + y^2)} = 0$.

The retarded distance vanishes at the finite Cherenkov angle $\cos(\theta_{CH}) = \frac{1}{n\beta}$ (see Eq. (6)) where the electric field diverges. One intuitive way to understand the Cherenkov effect follows from the more general definition of \mathcal{D} given in Eq. (5). For a vanishing retarded distance, the derivative dt/dt_r has to vanish. It follows that the function $t(t_r)$ is flat at this point. Hence at an observer time t , signals emitted at different emission times t_r will be observed at once, leading to a boosted electric field. The vanishing of the retarded distance leads to a divergence in the electric field expressions. These divergences are integrable and therefore disappear for coherent emission by performing an integration over the finite charge and current distributions in the shower front [20].

2.2. Transition radiation for a single electron

So far we calculated the component of the electric field due to a relativistically moving net charge in a medium with a refractive index equal to n . How does this compare to the transition radiation for a relativistic charge crossing from a medium with refractive index n_1 to a medium with refractive index n_2 ? The vector potential for a single electron now becomes,

$$A^0(t, \vec{x}) = \frac{e}{4\pi\epsilon_0} \left(\frac{x^i}{|\mathcal{D}|} \theta(z - z_b) + \frac{x^i}{|\mathcal{D}|} \theta(z_b - z) \right), \quad (10)$$

where the discontinuity at a distance $z_b = -ct_b$, corresponding to the retarded emission time t_b when the electron crosses the boundary, is reflected by the step function $\theta(x)$ which is defined by,

$$\theta(x) = \begin{cases} 0 & \text{if } x < 0 \\ 1 & \text{if } x > 0 \end{cases}. \quad (11)$$

Since the step function is a function of the retarded emission time,

$$\theta(z - z_b) = \theta(-c(t_r - t_b)), \quad (12)$$

an additional term has to be added to Eq. (8). The full electric field is now given by,

$$\frac{dA^0}{dx^i} = \frac{\partial}{\partial x^i} A^0 + \frac{\partial t_r}{\partial x^i} \frac{\partial}{\partial t_r} A^0, \quad (13)$$

where in case of a single electron the second term on the right hand side of Eq. (13) will correspond to the transition radiation. The transition radiation can therefore be

evaluated as,

$$E_{tr}^i(t, \vec{x}) = \frac{\partial t_r}{\partial x^i} \frac{\partial}{\partial t_r} A^0 = \frac{e\delta(c(t_r - t_b))}{4\pi\epsilon_0 c} \lim_{\epsilon \rightarrow 0} \left(\frac{x^i}{|\mathcal{D}|_{t_r+\epsilon}^2} - \frac{x^i}{|\mathcal{D}|_{t_r-\epsilon}^2} \right). \quad (14)$$

It follows that when there is no boundary, hence $n_1 = n_2$, the transition radiation vanishes as it should. Looking more closely at the obtained expression in Eq. (14), it can be described as the superposition of the emission just before the particle crosses the boundary and the field just after the particle crossed the boundary. The two terms interfere destructively. This corresponds well to the mirror-charge approach for determining the transition radiation as applied by Ginzburg et al. [37] and the expressions obtained in [23, 38] and references therein.

Figure 2: The angular intensity of the transition radiation seen from a charge moving from vacuum, $n_1 = 1$, to a dense medium $n_2 > 1$.

In Fig. 2 the intensity of the transition radiation is shown as function of angle. Since in vacuum the retarded distance vanishes at forward angles the first term dominates in the forward direction. At very small angles the intensity is suppressed due to the factor x in Eq. (14). With increasing angle $1/|\mathcal{D}|_{t_r+\epsilon}^2$ drops in magnitude while the contribution from below the surface, proportional to $1/|\mathcal{D}|_{t_r-\epsilon}^2$ increases in magnitude. Since the two interfere destructively there is a cancellation at a certain angle after which the second term dominates. At the Cherenkov angle in the medium, θ_2 , the second term diverges.

2.2.1. The sudden appearance signal

Another effect which is similar to transition radiation is the sudden appearance signal. One example of such a signal is found in accelerator experiments [39, 40]. Here the charged particle beam is accelerated, but during the acceleration process the charge is (partly) blocked from an

observer. The consequence is that when the beam leaves the accelerator, the observer suddenly observes a charge. This effect can be described in a similar way as transition radiation. The vector potential simply becomes,

$$A^0(t, \vec{x}) = \frac{e}{4\pi\epsilon_0} \frac{1}{|\mathcal{D}|} \theta(z_b - z), \quad (15)$$

for a beam traveling in a medium with refractive index n . Following the transition radiation calculation, the electric field is now directly obtained by,

$$\begin{aligned} E_{sa}^i(t, \vec{x}) &= \frac{\partial t_r}{\partial x^i} \frac{\partial}{\partial t_r} A^0 \\ &= \lim_{\epsilon \rightarrow 0} \frac{e\delta(c(t_r - t_b))}{4\pi\epsilon_0 c} \frac{x^i}{|\mathcal{D}|_{t_r+\epsilon}^2}. \end{aligned} \quad (16)$$

It should be noted that the delta-function is a function of the retarded emission time, t_r . The functional dependence can be shifted to the observer time, t , after which the field is given by the more common expression,

$$E_{sa}^i(t, \vec{x}) = \frac{e\delta(ct + z_b - L_b)}{4\pi\epsilon_0 c} \frac{x^i}{LD}, \quad (17)$$

where L_b denotes the optical path length for the signal emitted at the boundary point toward the observer.

2.3. Time varying current emission

So far we considered radiation from a single electron. In case of an electron bunch, there will be another radiation component due to the time variation of the total number of charges. In general this time variation can be linked to the net contribution of coherent bremsstrahlung emission of charges dropping out of the high-energy charge cloud and the emission of Compton electrons which are suddenly accelerated to relativistic speed. More generally, we can define the total number of particles at the retarded emission time t_r by the distribution $N_e(t_r)$. Defining the four-current as,

$$J^\mu(t_r) = eN_e(t_r)V^\mu, \quad (18)$$

the vector potential becomes,

$$A^\mu(t, \vec{x}) = \frac{1}{4\pi\epsilon_0} \frac{J^\mu(t_r)}{|\mathcal{D}|} \Big|_{ret}, \quad (19)$$

which gives the point-like vector potential for a non extended current. For a cosmic-ray air shower, the two main emission mechanisms are due to a time-varying transverse current which is induced by Earth's magnetic field, and the Askaryan emission due to the time-variation of the net negative charge-excess in the cascade. Nevertheless, for the geometry considered in this article, describing the emission for a perpendicular incoming shower hitting the ice surface at the South-Pole, the cascade will be aligned with Earth's magnetic field and the transverse current vanishes. Therefore, in this section we focus on the emission from a time varying charge. For more information about

the radio emission arising from the transverse current the reader is referred to [20, 34].

In case of a point-like time varying charge $Q(t_r) = eN_e(t_r)$, the partial derivative with respect to the retarded time of the second term on the right hand side of Eq. (13) will now also get a contribution where the derivative acts on this current. This leads to the varying charge emission,

$$E_{vc}^i(t, \vec{x}) = \frac{-1}{4\pi\epsilon_0 c} \frac{nx^i}{|\mathcal{D}|^2} \frac{dQ}{dt_r}, \quad (20)$$

which is the far-field radiation component. It should be noted that also here the signal scales like $1/|\mathcal{D}|^2$ and hence Cherenkov or equivalently relativistic time-compression effects apply equally well for this component of the radiation. Furthermore, a similar polarization behavior as for the emission from a highly relativistic steady charge as well as the transition radiation is obtained.

3. Coherent emission

To obtain the coherent emission we need to consider the spatial extent of the particle cascade. This is done by inclusion of the weight function $w(\vec{r}, h)$. The weight function is normalized such that $\int dh d^2r w(\vec{r}, h) = 1$. In a realistic situation, there will also be emission from the charged trail which is left behind after the cascade has passed. A detailed calculation including this can be found in [34]. The expressions given below for the coherent emission are obtained including this positive trail.

The electric field is now obtained by convolving the point-like current with the particle distributions in the shower front which can be evaluated numerically,

$$\begin{aligned} \vec{E}_{st}(t, \vec{x}) &= \frac{-e d}{4\pi\epsilon_0} \int dh d^2r \frac{(1-n^2)}{|\mathcal{D}|^3} \\ &\times N_e(t_r) w(\vec{r}, h) \hat{p} \end{aligned} \quad (21)$$

$$\begin{aligned} \vec{E}_{vc}(t, \vec{x}) &= \frac{-e d}{4\pi\epsilon_0 c} \int dh d^2r \frac{n}{|\mathcal{D}|^2} \\ &\times w(\vec{r}, h) \frac{dN_e(t_r)}{dt_r} \hat{p}. \end{aligned} \quad (22)$$

Here $\hat{p} = \vec{e}_r \times (\vec{e}_r \times \vec{e}_\beta)$ is the polarization of the signal, \vec{e}_r is the unit vector pointing from the emission point to the observer, and \vec{e}_β is the unit vector denoting the direction of the cascade. For the transition radiation the delta-function in Eq. (14) can be rewritten as,

$$\delta(z - z_b) = \delta(h - c(t_r - t_b)). \quad (23)$$

The electric field can now be solved analytically by integrating the delta-function and is given by,

$$\begin{aligned} \vec{E}_{tr}(t, \vec{x}) &= \lim_{\epsilon \rightarrow 0} \int dh d^2r \left[\frac{e d N_e(t_r) w(\vec{r}, h)}{4\pi\epsilon_0 c} \right. \\ &\times \left. \left(\frac{1}{|\mathcal{D}|_{t_r-\epsilon}^2} - \frac{1}{|\mathcal{D}|_{t_r+\epsilon}^2} \right) \right] \\ &\times \delta(h - c(t_r - t_b)) \hat{p} \end{aligned}$$

$$\begin{aligned}
&= \lim_{\epsilon \rightarrow 0} \int d^2r \frac{e dN_e(t_r) w(\vec{r}, h)}{4\pi\epsilon_0 c} \\
&\times \left(\frac{1}{|\mathcal{D}|_{t_r-\epsilon}^2} - \frac{1}{|\mathcal{D}|_{t_r+\epsilon}^2} \right) \hat{p} \Big|_{h=c(t_r-t_b)} \quad (24)
\end{aligned}$$

Following the same procedure the sudden appearance signal is given by,

$$\vec{E}_{sa}(t, \vec{x}) = \lim_{\epsilon \rightarrow 0} \int d^2r \frac{e dN_e(t_r) w(\vec{r}, h)}{4\pi\epsilon_0 c |\mathcal{D}|_{t_r+\epsilon}^2} \hat{p} \Big|_{h=c(t_r-t_b)} \quad (25)$$

4. The cosmic-ray air shower signal in Askaryan radio detectors

(a)

(b)

Figure 3: The number of charges N_e as a function of height z above the antenna as simulated for a cosmic-ray air shower with primary particle energy of 10^{17} eV. The antenna is positioned at an observer level 2900 m above sea level in ice. The ice-air boundary is at 3000 m above sea level.

In the previous section, we obtained the electric field expressions for the transition radiation from a particle cascade traversing the boundary between two different media. We also considered the steady charge emission as well as the varying current emission. We now have all ingredients to solve for the the emission from a high-energy cosmic-ray air shower which penetrates a surface.

4.1. The particle cascade

As an example we consider a shower which is induced by a 10^{17} eV primary cosmic ray, where the shower will hit an ice surface. The shower profile can be expressed as a function of the penetration depth $X(\text{g/cm}^2) = \int \rho(z) dz$, given by the line integral over the density which the shower has passed through. This allows us to naturally take into account for the air-ice boundary by simply writing the density as,

$$\rho(z) = \rho_{air} \theta(z - z_b) + \rho_{ice} \theta(z_b - z), \quad (26)$$

again using the step function $\theta(x)$. We will assume a density profile $\rho_{air}(z) = \rho_0 \exp[-C(z + z_0)]$ for an observer positioned at a height $z = z_0$ above sea level. Here $C = 1.160 \times 10^{-4} \text{ m}^{-1}$, and $\rho_0 = 1.168 \times 10^{-3} \text{ g cm}^{-3}$ [34]. The ice density is assumed to be constant over the few meters in which the cascade will die out and taken as $\rho_{ice} = 0.92 \text{ g cm}^{-3}$.

Since the radiation length $X_0 = 36 \text{ g/cm}^2$, as well as the critical energy $E_{crit} = 80 \text{ MeV}$ for electrons is approximately equal in air and ice, we can now take a NKG approximation [41, 42] given by,

$$N(X) = \frac{0.31 \exp[(X/X_0)(1 - 1.5 \ln s)]}{\sqrt{\ln(E/E_{crit})}} \quad (27)$$

for the total number of particles as a function of depth. The shower age s is given by [43],

$$s(X) = \frac{3X/X_0}{(X/X_0) + 2 \ln(E/E_{crit})}. \quad (28)$$

The excess charge as function of shower depth can be approximated by $N_{ch}(X) \approx 0.23 N(X)$ [34]. The total number of excess electrons as function of depth is shown in Fig. 3. Taking a geometry with the observer positioned at 2900 m above sea level with the air-ice boundary at 3000 m, the boundary at $z_b = 100$ m is clearly visible.

The particle distribution in the shower front is given by the weight function $w(r, h) = \delta(r) f(h)$, where $\int dh f(h) = 1$. The radial extension of the particles in the shower front is taken to be a delta function at the shower axis. To compensate for the loss of the lateral coherence scale, we use an effective width h_1 for the longitudinal particle distribution in the shower front. This width therefore reflects the coherence scale due to the full extension of the shower front. The longitudinal distribution of particles in the shower front is parametrized by [43, 44],

$$f(h) = (4/h_1^2) h e^{-2h/h_1}. \quad (29)$$

The effective width h_1 is chosen to be $h_1^{air} = 0.5$ m following [45] for the in-air development, while for the in-ice part of the cascade a width $h_1^{ice} = 0.1$ m is chosen.

4.2. The refractive index

In [45] it was shown that in determining the radio signal from cosmic-ray air showers it is crucial to take into account a realistic index of refraction. Therefore, in the following we model the index of refraction in air by the Gladstone-Dale law,

$$n_{air}(z) = 1 + 0.226 \frac{\text{g}}{\text{cm}^3} \rho_{air}(z). \quad (30)$$

Furthermore, in [36] it was shown that the bending of the emission in air can safely be neglected. The index of refraction in ice is taken as a constant equal to

$$n_{ice} = 1.78. \quad (31)$$

4.3. Results

Since we now have our electric field expressions, as well as the particle distributions, we can calculate the electric field at different observer positions in ice. We consider two different boundary levels at 500 m and 3000 m above sea level. The shower profile is given in Fig. 3 for a geometry where the air-ice boundary is 3000 m above sea level. In Fig. 3a the full shower profile is given. It follows that the shower hits the ice surface before it reaches its maximum. This is more clear from Fig. 3b where we zoom in on the boundary. In the ice the shower quickly reaches its maximum and dies out within 10 meters.

We consider the emission as seen by an observer positioned at several distances, $d = 40$ m, $d = 80$ m, and $d = 240$ m, from the shower axis, 100 m below the air-ice boundary. The obtained electric fields are shown in Fig. 4 a, c, and e. The full red line gives the electric field generated by the in-air development of the cascade, the striped purple line gives the transition radiation, and the dotted blue line gives the emission from the in-ice development of the cascade. Next to the obtained electric fields, in Fig. 4 b, d, and f we also show the total number of particles as function of height. Furthermore, in these figures we show the observer time for a signal emitted from a certain height. The full green line gives the total number of particles as function of height. It should be noted that the vertical axis is shifted by 90 m for plotting purposes. The full red line gives the emission height as function of the observer time for the in-air emission, where the striped purple line gives the same quantity for the in-ice emission.

The emission observed at $d = 40$ m is shown in Fig. 4a. As follows from Fig. 4b, the in-air emission from large heights is observed before the emission from lower heights. For the in-ice emission, this picture is completely reversed. In-ice signals emitted from large heights are delayed by the medium, while the cascade continues to propagate with the speed of light. Hence signals emitted at later times (lower heights) arrive before signals emitted early and the

observer is positioned inside the Cherenkov cone for the full in-ice emission.

For the transition radiation, it is important to notice that the electric field as given in Eq. (14) can be seen as a superposition of the emission just above, and just below the boundary which interferes destructively. The emission scales with $1/|\mathcal{D}| \sim |dt_r/dt| \sim |dz/dt|$, which is reflected in Fig. 4b by the slopes of the full red and striped purple lines at the boundary. At the boundary, there will be a sudden change of the particle distributions in the shower front. To take this into account in our modeling, the emission just above the boundary is evaluated using the particle distributions for the in-air shower, where the component just below the boundary is modeled using the particle distribution for the in-ice cascade. From this point of view one might also consider the transition radiation from just above the boundary as the sudden-death signal from the emission in air, where the transition radiation from just below the boundary can be seen as the sudden appearance signal for the in-ice emission.

For an observer positioned at $d = 80$ m, see Fig. 4c and d, a similar picture is obtained. The in-air emission is observed over a longer time-scale since we move further away from the Cherenkov cone for the emission emitted in air. For the in-ice emission, however, we shift closer to the Cherenkov angle. It follows that the in-ice emission is observed within a much shorter time-span and becomes much stronger. The transition radiation is now dominated by the emission from just below the boundary.

Finally we consider an observer positioned at $d = 240$ m. From Fig. 4e and f it follows that both the in-air emission as well as the in-ice emission are observed outside the Cherenkov cone. The emission is observed over a rather long time-scale, although the in-air component starts to be rather weak. One interesting feature is that the emission just above the boundary does not arrive at the same time as the emission just below the boundary. The transition radiation component just above the boundary is highly suppressed, and arrives just before $t = 1000$ ns, where the component emitted just below the boundary is much stronger and arrives at a much later time around $t = 1200$ ns. The time difference arises due to the fact that the signal emitted just above the air-ice boundary will first travel a significant part of its path almost horizontally before breaking into the ice under the critical angle, which in this case is equal to the in-ice Cherenkov angle. The signal emitted just below the air-ice boundary will travel its full path through the ice and hence obtain a large delay with respect to the signal emitted just above the boundary. It should be noted that this effect occurs in the situation of a perfectly flat and smooth surface. In a realistic experiment, the emission from just above the boundary however will not be able to travel almost perfectly horizontally along the surface and hence will lose coherence and become suppressed (already in the present case it is almost negligible in magnitude). The signal emitted just below the surface will not be affected and keep its

Figure 4: The electric field at different observer distances equal to, a) $d = 40$ m, b) $d = 80$ m, c) $d = 240$ m. The figures on the right show the emission height, plotted as function of the observer time. The full red line gives the emission in air, the dotted purple line gives the transition radiation, and the dashed blue line gives the in-ice emission. For the figures on the right, the total number of particles is given by the full green line.

coherence.

The emission will be coherent up to relatively high frequencies. This is also seen in Fig. 5a where we plot the frequency spectrum of the different components of the emission when the observer is positioned at a distance of $d = 240$ m. In Fig. 5b, we plot the frequency spectrum for the same geometry shifting the ice-air boundary to 500 m above sea level. Coherence of the in-ice emission as well

Figure 5: The frequency spectrum of the different components to the electric field as seen by an observer positioned 100 m below the ice-air boundary and $d = 250$ m from the shower axis. The simulation is performed for a 10^{17} eV primary energy cosmic-ray air shower.

as the in-air emission away from the Cherenkov angle is typically determined by the length of the shower trajectory leading to a suppression at the highest frequencies. The transition radiation, however, is emitted from a single point at the boundary, and hence its coherence is fully determined by the particle distributions in the shower front

which gives a cut-off at relatively high-frequencies in the GHz range. Each of the several different components has a finite response at zero frequency. One should note however that the combined response of all different components vanishes at zero frequency.

In Fig. 4, and Fig. 5, the detailed properties of the emission in time and frequency space were shown. This allows us to understand the angular distribution of the different components of the emission shown in Fig. 6. Here we plot the integrated absolute value of electric field $I = \int |E| dt$. It follows that the in-air emission given by the full red

Figure 6: The angular distribution of the integrated field for a radial observer distance of $R = \sqrt{z^2 + d^2} = 300$ m. The full red line gives the angular distribution for the in-air emission, the dotted purple line gives the transition radiation, and the dashed blue line shows the in-ice emission.

line in Fig. 6, as expected, peaks toward a highly forward angle ($\theta = 0^\circ$), after which the emission drops rapidly to

ward larger angles. The transition radiation, shown by the dotted purple line in Fig. 6, shows a similar behavior as observed in Fig. 2. There is a strong forward peak, after which the transition radiation gets suppressed due to the destructive interference between the emission just above the air-ice boundary and the emission just below the air-ice boundary. When the destructive interference is maximal, contrary to Fig. 2, the field does not vanish completely. This is due to the different particle distributions for the in-air emission and the in-ice emission which is taken into account for in the evaluation of the transition radiation. The in-ice emission, as expected, peaks at the in-ice Cherenkov angle. Nevertheless, the emission pattern is rather broad toward smaller angles due to the longitudinal extent of the cascade.

4.4. Zenith angle dependence

Up to now we only considered a perpendicular incoming cosmic-ray induced air shower. Since a shower coming in under a finite zenith angle can be treated by a direct rotation of the geometry, we do not expect the emission to change significantly. One effect that is to be expected for an inclined shower, or in case of a non-perpendicular boundary, is that the transition radiation from different radial parts of the shower is emitted at different times. In case of an observer positioned underneath the shower axis this will lead to a small additional spread in the arrival time of signals emitted from different positions in the shower front, and hence a slight decrease of pulse-strength can be expected. For an observer positioned away from the shower axis however, this effect is reversed, leading to a slightly enhanced pulse-strength in the detector. Furthermore, it should also be noted that for more inclined geometries, a larger part of the signal created in air will be reflected off of the surface suppressing the in-air emission over the in-ice emission even more.

The most important effect, however, will be due to the change of the total number of charges hitting the air-ice boundary. Since for larger zenith angles the shower traverses a longer distance through air, the total number of particles actually hitting the air-ice boundary changes. Other effects influencing the total number of particles hitting the air-ice surface are the chemical composition and the energy of the primary cosmic ray. An iron induced shower typically develops earlier in the atmosphere than a proton induced shower, where cosmic rays of higher energy typically peak deeper in the atmosphere. In Fig. 7 we show the total number of particles hitting the air-ice surface for boundary layers at $z_b = 3000$ m (full lines) and $z_b = 500$ m (dotted lines) for a typical proton shower with a primary energy of $E_p = 10^{17}$ eV (red lines) and $E_p = 10^{18}$ eV (blue lines).

For an air-ice boundary at $z_b = 3000$ m, the air shower is still below shower maximum for both considered energies. It follows that the total number of particles peaks at a zenith angle of approximately $\theta \approx 40 - 50$ degrees, where the air shower is fully developed at the boundary. For

larger zenith angles, the total number of particles hitting the air-ice boundary becomes smaller, and for zenith angles larger than $\theta \gtrsim 60$ degrees the shower dies out before hitting the air-ice boundary. Hence no transition radiation and in-ice emission will be observed for showers at zenith angles larger than approximately $\theta \approx 60$ degrees.

Figure 7: The total number of particles hitting the air-ice surface for boundary layers at $z_b = 3000$ m (full lines) and $z_b = 500$ m (dotted lines) for a typical proton shower with a primary energy of $E_p = 10^{17}$ eV (red lines) and $E_p = 10^{18}$ eV (blue lines).

4.5. Cosmic-ray air shower or neutrino induced cascade?

One important question to consider is how the cosmic-ray air shower signal compares to the emission from a neutrino induced cascade in ice. This is shown in Fig. 8. For the cosmic-ray air shower signal, we consider both the in-ice emission as well as the transition radiation component just below the boundary. As follows from Fig. 4, the in-air emission is very small and will therefore be ignored for this comparison.

The neutrino induced cascade is modeled by taking a 10^{17} eV primary neutrino interacting at the surface of the air-ice boundary, after which the cascade develops in ice. The observer is positioned 100 m below the ice surface at a distance $d = 240$ m perpendicular to the shower axis. The effective width of the particle distribution is taken as $h_1 = 0.1$ m, approximately corresponding to the dimensions of the cascade front in ice.

It follows that the emission from a typical proton induced high-energy cosmic ray air shower hitting the ice surface is of similar magnitude compared to the Askaryan signal from a neutrino induced particle cascade in ice of the same energy. Since the total number of particles hitting the air-ice interface is slightly larger at $z_b = 500$ m for the considered geometry of a vertical cosmic-ray air shower (see Fig. 7), the transition radiation gets slightly enhanced with respect to the emission seen at $z_b = 3000$ m.

Figure 8: The electric field from a neutrino induced particle cascade in ice (full red line), compared to the transition radiation just below the boundary layer and the in-ice emission from a vertical, proton induced, cosmic-ray air shower of the same energy. The electric field is shown for ice-air boundaries equal to $z_b = 3000$ m (dashed blue line) and $z_b = 500$ m (dotted purple line). The observer is positioned at a lateral distance $d = 250$ m perpendicular to the shower axis.

The direct consequence is that the radio emission from a high-energy cosmic ray air shower will be very hard to distinguish from the emission of a high-energy neutrino induced particle cascade without directional information about the signal. Another possible method to separate the cosmic-ray air shower from the neutrino induced cascade might be obtained by adding a surface veto to the array.

5. Summary and conclusions

We derived an analytical expression for coherent transition radiation from a particle bunch with a net charge which is traversing from one medium to another. In addition to the transition radiation also the emission due to a highly-relativistic steady charge and a time-varying current are given.

As a first application we calculate the radio emission from a cosmic-ray-induced air shower hitting an ice layer before the shower has died out. It is shown that a relatively strong transition radiation component can be expected from an air shower when taking an air-ice boundary in the range between 500-3000 m above sea level. The emission from such a cosmic-ray air shower is calculated to be of similar strength as the Askaryan signal obtained from an in-ice cascade induced by a GZK-neutrino of similar energy. Furthermore, the polarization of the transition radiation will be similar to the polarization of the Askaryan signal. It follows that without directional information or a surface veto, it will be very hard to distinguish between both signals. Therefore, the emission from

cosmic-ray air showers might induce a significant (background) signal in the currently operating Askaryan neutrino detectors at Antarctica.

Next to the discussed application for cosmic-ray air showers hitting a dense medium, the transition radiation from neutrino induced particle cascades traveling from a dense medium to air or vacuum is also expected to give a strong signal. This signal might be a promising probe to detect high-energy neutrino-induced particle cascades escaping dense media. A more detailed calculation for this component will be given in future work.

ABSTRACT: We develop the notion of “entwinement” to characterize the amount of quantum entanglement between internal, discretely gauged degrees of freedom in a quantum field theory. This concept originated in the program of reconstructing spacetime from entanglement in holographic duality. We define entwinement formally in terms of a novel replica method which uses twist operators charged in a representation of the discrete gauge group. In terms of these twist operators we define a non-local, gauge-invariant object whose expectation value computes entwinement in a standard replica limit. We apply our method to the computation of entwinement in symmetric orbifold conformal field theories in 1+1 dimensions, which have an S_N gauging. Such a theory appears in the weak coupling limit of the D1-D5 string theory which is dual to AdS_3 at strong coupling. In this context, we show how certain kinds of entwinement measure the lengths, in units of the AdS scale, of non-minimal geodesics present in certain excited states of the system which are gravitationally described as conical defects and the $M = 0$ BTZ black hole. The possible types of entwinement that can be computed define a very large new class of quantities characterizing the fine structure of quantum wavefunctions.

1 Introduction

When a quantum system finds itself in a pure state $|\psi\rangle$, the entanglement between a part A of the system and its complement \bar{A} is quantified by the entanglement entropy. In most applications, A and \bar{A} describe the degrees of freedom in complementary spatial regions. In systems with localized degrees of freedom such as spin chain models or local quantum field theory, this corresponds to a natural separation of the total Hilbert space. However, it is also fruitful to consider other ways of separating the Hilbert space.

In [1, 2], the degrees of freedom of a local quantum field theory were separated into high and low spatial momentum modes. It was demonstrated that in a generic interacting field theory, even in the vacuum state, the long wavelength (low energy) degrees of freedom necessarily find themselves in a nontrivial reduced density matrix because of entanglement with the short wavelength (high energy) degrees of freedom. This gives rise to finite entanglement entropy, which was computed explicitly in perturbative scalar field theories. The more traditional way of describing the low energy degrees of freedom is Wilsonian renormalization. In this language, the vacuum state of a Wilsonian low energy theory is necessarily a density matrix with finite entropy [1, 2]. This phenomenon of UV-IR entanglement in quantum field theories could be particularly important in theories of gravity (in which ultraviolet and infrared degrees of freedom are known to couple in nontrivial ways), as well as in the ground states of strongly correlated electronic systems (see, e.g. [3]).

This also raises the question whether it is fruitful to consider other non-spatial ways of dividing the degrees of freedom of quantum field theories. One interesting way to separate energy scales is by imagining a collection of local observers who have a finite duration T over which they can make measurements. This is a natural situation to consider, as it describes the practical constraints of most measurements. Intuitively, given Heisenberg’s energy-time uncertainty relation, such observers will be insensitive to energies smaller than the inverse duration of the experiment, so that those low energy degrees of freedom are effectively traced out, turning the accessible part of the state into a nontrivial density matrix. Thinking in this way, [4–7] proposed a new information theoretic quantity, the *differential entropy*, as a measure of UV-IR entanglement, at least for two-dimensional theories.

These effects should become stronger for theories with an energy gap that is smaller than the inverse spatial size of the system. For example, consider relativistic theories where the local degrees of freedom are matrices, e.g. $SU(N)$ gauge theories. In such systems the energy gap can be much smaller than the inverse spatial size of the system so that even a set of observers with enough time to observe the entire spatial domain will not have access to the lowest energy excitations. Another example which is easier to visualize is a “long string” theory, where strings or spin chains are multiply wound around a spatial circle, allowing for excitation wavelengths that exceed the system size. In both these examples, the key to the physics lies in entanglement between “internal” degrees of freedom (matrix components, or strands of string) that are not spatially organized.

One way to study the entanglement of gauge degrees of freedom in an $SU(N)$ theory is to break the gauge group into $SU(m) \times SU(N - m)$ while allowing for interactions between the two sectors. This could be realized holographically by separating a stack of N branes into a stack of m and one of $N - m$ branes and studying entangling surfaces in the $AdS_d \times S^{10-d}$ geometry which arises in the low energy limit. Such a set-up was first considered in [8] and later refined in [9–11]. The authors of [9, 10] also considered global symmetries and in case of an $SO(11 - d)$ global symmetry they proposed a quantity in the field theory which would holographically be represented by the area of caps on the internal S^{10-d} .

One important complication that we have glossed over so far is that in systems exhibiting gauge symmetry, even the association of degrees of freedom to spatial regions is subtle. For example, some of the fundamental degrees of freedom, such as Wilson loops, are not local in space, making it more complicated to split up the Hilbert space according to spatial regions. Interesting work on how to define entanglement entropy in gauge theories has recently appeared (see e.g. [12–21]), but a complete understanding is still lacking.

These questions about entanglement in quantum field theory are also linked to equally deep questions about the nature of black hole horizons and the holographic emergence of spacetime. It was proposed in [22–24] that the entanglement entropy of a spatial region A in the field theory is proportional to the area of the minimal surface in AdS space that ends on the boundary of A . Furthermore, [4–7] showed that the area of closed surfaces in the bulk of AdS can be related to a measure of UV-IR entanglement, the differential entropy discussed above, at least for two-dimensional boundary theories and higher dimensional cases with translational symmetries — some of the limitations were discussed in [25]. Fi-

nally, in [26–31] it was suggested that spacetime connectedness is related to entanglement of the underlying quantum degrees of freedom, and that the linearized equations of motion of gravity can be derived from the dynamics of entanglement perturbations.

In general, can all of spacetime geometry be reconstructed from spatial entanglement entropy in the AdS/CFT correspondence? At least when we do not consider bulk quantum corrections to the entanglement entropy [32], the answer is no — in some asymptotically AdS spacetimes, the minimal surfaces anchored on the boundary that geometrically reproduce the entanglement entropy will not penetrate a region [33, 34] which has been called the *entanglement shadow* [35, 36]. It is argued in [35] that in such systems entanglement can be dominated by “internal” degrees of freedom (e.g. the matrix components, or strands of string discussed above) that are not spatially organized, and that these entanglements can measure the areas of non-minimal, extremal surfaces that can penetrate part of the entanglement shadows of the gravitational dual. In the examples arising in the AdS/CFT correspondence, such internal degrees of freedom are usually gauged. Thus, reconstructing the emergent space in gauge/gravity duality will involve entanglement between “internal”, gauged degrees of freedom — a notion that was named *entwinement* in [35]. While we will not address the question of which part of a general spacetime can be probed by extremal surfaces (see, for instance, [33, 34, 36]), it is clear that entwinement will often allow the reconstruction of a larger part of spacetime than spatial entanglement entropy. Entwinement also plays a key role in the description of holographic spacetimes using methods of integral geometry based in kinematic space [37–39].

In summary, both in quantum field theory and in quantum gravity, we are driven to consider a new notion of “entwinement” — non-spatial quantum entanglement between gauged degrees of freedom. In this paper we will define entwinement formally in discretely gauged theories, and discuss how it can be explicitly computed. Section 2 develops the general formalism. For two-dimensional theories, we define entwinement in terms of a replica method using twist operators that are charged under the discrete gauge group. We use these operators to construct a new non-local, gauge invariant object whose expectation value is defined to be the entwinement in a standard replica limit. Section 3 applies this formalism to symmetric orbifold conformal field theories in two dimensions. By explicitly applying uniformization maps, obtained by generalizing a construction of [40], to the Riemann surfaces arising from the replica method we directly compute entwinement in generic microstates of these theories. We also comment on how to recover the usual spatial entanglement entropy as a special limit of entwinement.

In section 4, we apply our formalism to the weak coupling limit of the D1-D5 CFT, a theory with a holographic dual. Ordinary spatial entanglement entropy in generic classes of the D1-D5 CFT was considered before in [40–42]. For generic microstates, entanglement entropy was computed approximately using both a short interval expansion [41] and large c methods [42]. In [40], a specific state corresponding to a local quench was considered, and the evolution of the entanglement entropy was computed using a uniformization map — we generalize the construction for use with other microstates. Although this uniformization map will work for computing single interval entwinement in general microstates, in section 4 to compare with holography we focus on two examples of microstates, which are

gravitationally related to conical defects and the $M = 0$ BTZ black hole, respectively. We demonstrate that the lengths of non-minimal geodesics that penetrate entanglement shadows of the spacetime are computed by certain entwinements. In the same way as spatial entanglement entropy corresponds to minimal extremal area surfaces in the bulk, here entwinement provides a direct field theory interpretation for non-minimal extremal surfaces.

The paper concludes with a discussion of possible directions forward to develop the notion of entwinement in more general situations, and comments on the relation with the appearance of non-minimal geodesics in the semiclassical Virasoro conformal blocks discussed in [43]. A number of technical results are collected in appendices.

2 Defining entwinement

In a gauge theory, states are required to be symmetric under identifications by the gauge group. The main complication in discussing entanglement entropy in gauge theories is that the Hilbert space does not factorize. For example, for a $U(1)$ gauge theory there is a Gauss law constraint which requires that the electric flux entering a region should determine the flux leaving it. We will be interested in situations where the gauge symmetry is discrete.

Recently various authors have developed a formalism for dealing with this lack of factorization in gauge theories. One method is to consider an extended Hilbert space in which the gauge constraints are temporarily relaxed [12, 13, 16–18, 20, 21]. A way of achieving this is by introducing “edge modes” on the entangling surface [13]. In this approach, the Hilbert space splits into superselection sectors defined by the fluxes at the entangling surface, making the reduced density matrix block-diagonal. The entanglement entropy then becomes a sum of two contributions, a Shannon entropy associated to the distribution over superselection sections and a distillable piece arising from entanglement within each superselection sector. In the same spirit, the approach to entwinement suggested in [35] was to ungauged the theory, compute, and then symmetrize.

An alternative approach is to define a subalgebra of gauge invariant observables \mathcal{O}_A associated to the region A . Then, given a density matrix ρ for the full theory, the reduced density matrix ρ_A is defined as the element of the subalgebra of region A such that $\text{Tr}(\rho_A \mathcal{O}_A) = \text{Tr}(\rho \mathcal{O}_A)$ for all \mathcal{O}_A [14, 15, 19]. In this formalism, the reduced density matrix splits into blocks according to superselection sectors determined by the center of the subalgebra. An algebraic approach to entwinement was recently proposed in [44], where it was shown that for a spin system the entwinement could be recovered from a state-dependent subalgebra.

A third approach, which works for states that can be constructed by a Euclidean path integral, is the replica trick. In this case, the entanglement entropy is computed by analytically continuing the Rényi entropies. In two dimensions this approach is particularly convenient and the Rényi entropies can be defined in terms of the correlation functions of twist operators that splice together replicated copies of the CFT. At least for the case of 2d Yang-Mills theory in de Sitter space, it was verified in [16] that the replica method gives the same result as the extended Hilbert space method described above. Below we will define entwinement along these lines.

As a working example, consider a CFT with target space M^N/S_N . The CFT contains N sets of fields, where each set can be viewed as coordinates on one copy of the manifold M , together with companion fermions in case of a supersymmetric theory. The S_N indicates that we identify configurations that differ by permutations of these N sets of fields. This is similar to the way one treats indistinguishable particles in quantum mechanics: wavefunctions need to be appropriately symmetrized under permutations. The S_N identification is really a discrete gauge symmetry. We can gauge fix the local symmetry and think of the fields as changing continuously from point to point (i.e., each of the N copies of M has a continuous string embedded in it). The theory has so-called “twisted sectors” in which strings are only periodic up to permutations. A twisted sector is labeled by a conjugacy class, which is characterized by the lengths of its permutation cycles: there will be N_m cycles of length m such that $\sum_m N_m m = N$. Each cycle is referred to as a “long string” because it can be visualized as a string winding m times. We will refer to each winding of the long string as a “strand”.

The conventional spatial entanglement entropy of an angular interval of size α can be thought of as the entanglement entropy of the union of intervals of size α in each of the N strands of the system. Following the proposal of [35], we want to define entwinement as the entanglement of intervals that extend over some strands and not others. For example, one can talk about the entwinement of an interval on a single strand. If one considers the entwinement of a union of identical intervals in each strand, then it reduces to the conventional spatial entanglement. Because there is a gauge symmetry, we cannot invariantly specify which strand we are talking about. But, as we will argue below, we can meaningfully talk about things like “the entanglement of one and a half connected strands”. Likewise, while one cannot invariantly ask for the entanglement of a particular strand, one can ask for the entanglement of a single strand if we do not specify which one it is. This invariance can be made manifest by simply averaging the computation of entanglement of a single strand over all the strands. It is worth emphasizing that this average is *not* the same thing as the entanglement of the union of such intervals. Below, we will give a mathematical definition of such quantities.

2.1 Replica trick — generalities

A useful method for computing entanglement entropy in two-dimensional conformal field theories is the replica trick. In this method, the entanglement entropy of an interval $[0, \alpha]$ is computed from the reduced density matrix for this region ρ_α by taking a limit of the Rényi entropies:

$$S(\alpha) = \lim_{n \rightarrow 1} \frac{1}{1-n} \log \text{Tr}(\rho_\alpha^n). \quad (2.1)$$

Consider a two-dimensional CFT in the plane in Euclidean signature. In radial quantization, circles of fixed radius become equal time slices. An operator σ acting at the origin creates a pure state, and we can find the wavefunction at $t = 0$ by performing the path integral with the operator inserted and fixed boundary conditions at the unit circle. The density matrix $\rho(\phi, \phi')$ corresponding to such a pure state is then computed by inserting operators at the origin and at infinity in the path integral, and imposing boundary condi-

Figure 1. Path integral in radial quantization. The path integral is left open on the cut (indicated in full blue lines) with boundary conditions ϕ on the lower cut and ϕ' on the upper cut. The dashed lines define the complementary interval along which boundary conditions are matched $\phi = \phi'$. The operator σ prepares the state.

tions ϕ and ϕ' on the interior and the exterior of the unit circle, respectively. The reduced density matrix for the interval $[0, \alpha]$ is computed by tracing over the complementary part of the unit circle (i.e., setting $\phi = \phi'$ in the complementary region and then integrating over ϕ there). This leaves us with a path integral over the entire plane, except over the arc corresponding to the interval $[0, \alpha]$, as depicted in figure 1. To compute $\text{Tr}(\rho_\alpha^n)$ we consider n copies of the plane cyclically glued together over the cut $[0, \alpha]$ producing an n -sheeted Riemann surface as in figure 2 (left). This can alternatively be obtained as a correlator of Rényi twist operators $\Sigma^{(n)}$ computed on a single sheet of the n -fold cover of the theory, $\text{CFT}^n/\mathbb{Z}_n$, as represented in figure 2 (right). The n fictitious copies of the CFTs are called “replicas”. Each of the n copies of the CFT is placed in the same state. The Rényi twist cyclically splices together the n CFT copies, such that dragging a field from one CFT around the cut produces a field in the next copy of the CFT.

Below we will illustrate this procedure in symmetric product CFTs with target space M^N/S_N and show how entwinement in these theories can be defined in a similar manner. We will then generalize the definition to apply to more general discretely gauged theories in two dimensions.

Now take the CFT to be a symmetric orbifold with target space M^N/S_N for some M . As discussed above, this CFT can be regarded as having N elementary strands spliced together into series of cycles (“long strings”) determined by the twisted sector. The twist operator can therefore be regarded as a product of elementary twists

$$\Sigma^{(n)} = \Sigma_1^{(n)} \Sigma_2^{(n)} \dots \Sigma_N^{(n)}, \tag{2.2}$$

where each $\Sigma_i^{(n)}$ splices together the n replica copies of the i th strand. Each elementary twist is in the fundamental representation of S_N . Thus we can write for any $g \in S_N$

$$g[\Sigma_i^{(n)}] \equiv g \Sigma_i^{(n)} g^{-1} = \Sigma_{g(i)}^{(n)}, \tag{2.3}$$

where $g(i)$ is the strand produced by permuting i by the action of g . The twist operator appearing in the computation of entanglement entropy (2.2) is a product of all the elementary twists and hence is invariant under the action of S_N . The twists configuration that computes the entanglement entropy is depicted in figure 3 (left).

Figure 2. (Left) The n -sheeted Riemann surface from cyclically gluing n copies of the plane. The dashed arrows denote how to sew fields across the cuts. (Right) Correlator in the plane. The Σ insertions represent Rényi twist operators, while the σ insertions define the replicated state.

Figure 3. Multiwound strings, each consisting of m strands. There are N_m m -wound strings such that the total number of strands is N . Here we depict $N = 7$, $N_2 = 2$, $N_3 = 1$. (Left) The entanglement entropy is computed by inserting Rényi twist operators at the endpoints of the interval on every strand. The entangling region can be visualized in the long string picture as a union of disjoint intervals on all strands. (Right) Configuration of twists corresponding to the bilocal operator of single interval entwinement. The entangling region extends across different strands of the 3-cycle.

We can define entwinement formally in terms of the elementary twists. Take Σ_i to be an elementary twist operator for strand i and consider the bilocal combination

$$\tilde{\Sigma}_i^{(n)}(1) \Sigma_i^{(n)}(e^{i(\alpha+2\pi\ell)}) \tag{2.4}$$

where for compactness we have only written the holomorphic coordinate and $\tilde{\Sigma}_i$ is the conjugate twist. In this bilocal operator the Σ_i is taken around the complex plane relative to $\tilde{\Sigma}_i$ by an amount $\alpha + 2\pi\ell$. In a specific state of the symmetric orbifold the i th strand is

generally spliced with k other strands into a long string. In such a state the twist Σ will be inserted on a different strand, as represented on the right of figure 3. We then consider the bilocal, gauge-invariant quantity

$$\frac{1}{|S_N|} \sum_{g \in S_N} \tilde{\Sigma}_{g(i)}^{(n)}(1) \Sigma_{g(i)}^{(n)}(e^{i(\alpha+2\pi\ell)}), \quad (2.5)$$

where $|S_N|$ is the cardinality of S_N , i is any reference strand of the CFT, and $g(i)$ is the strand to which i is transported when all the strands are permuted by $g \in S_N$. Because we are summing over all permutations in S_N , the final quantity is independent of i . Its expectation value computes the Rényi analog of entwinement of single intervals.

When $\ell > k$ (k being the number of strands of the specific cycle, i.e. long string, in which the strand $g(i)$ lives) we mean the operator in the sum in (2.5) to represent the twisted boundary conditions of the replicated set of fields on the full long string. Intuitively, we can imagine starting from a short interval on a single strand and putting twisted boundary conditions on the fields inside the interval. Enlarging the interval until it eventually covers the full string, i.e. $\alpha + 2\pi\ell = 2\pi k$, represents putting twisted boundary conditions on the fields on the full string. Further increasing the interval to $\alpha + 2\pi\ell > 2\pi k$ does not change this picture and just keeps all fields on the long string twisted, nothing more. Keeping this in mind, we can define the entwinement as

$$E_\ell(\alpha) = \lim_{n \rightarrow 1} \frac{1}{1-n} \log \left[\langle \Psi | \frac{1}{|S_N|} \sum_{g \in S_N} \tilde{\Sigma}_{g(i)}^{(n)}(1) \Sigma_{g(i)}^{(n)}(e^{i(\alpha+2\pi\ell)}) | \Psi \rangle \right]. \quad (2.6)$$

For symmetric product orbifolds this is just a formal way of saying that we are calculating the entanglement entropy of a connected set of partial strands in a long string. This definition of single interval entwinement can be generalized to multi-interval entwinements by taking a product of operators like (2.5) defined at different locations and strands. A particular example of multi-interval entwinement is entanglement, where we take a product of the same interval with $\alpha < 2\pi$ in each of the N strands.

The formalism described above is general. We can consider theories with any discrete gauge symmetry H , and elementary twist operators in any representation R of H that is useful. These can be used to define bilocal, gauge invariant twist operators of the form (2.5) and products of such operators. Entwinements defined as expectation values of these quantities are a very general new class of gauge-invariant objects than can be used to characterize quantum wavefunctions in two-dimensional theories. Conceptually we can also talk about the entanglement of subsets of degrees of freedom in a spatial region even in higher dimensional theories on any manifold, but we need a formalism for calculating such quantities efficiently.

In the next section we will use the replica method to explicitly compute entwinements in symmetric orbifold conformal field theories in two dimensions.

3 Entwinement in symmetric orbifold CFTs

In the following we analyze symmetric orbifold CFTs on a circle of length L . These are obtained starting with a seed CFT with target space M and central charge c . The orbifold theory $\mathcal{C} = \text{CFT}^N/S_N$ has target space M^N/S_N and central charge $c_N = cN$. Because of the S_N identification, states need only be periodic up to the action of a group element. In a sector twisted by $h \in S_N$, the boundary conditions are

$$\phi_i(L) = \phi_{h(i)}(0) \quad i = 1, \dots, N, \quad (3.1)$$

where here ϕ_i collectively indicates the fields in the i -th copy of the CFT. All physical states should be invariant under the action of S_N . Since acting with a group element g maps the sector twisted by h to that twisted by ghg^{-1} , twisted sectors should really be labeled by conjugacy classes $[h]$, as mentioned in the previous section.

Twisted states can be conveniently obtained through the action of *orbifold twist operators* on untwisted states. An orbifold twist operator $\sigma_m(0)$ at the origin of the complex plane causes m copies of the target space M to be linked together by the periodicity condition

$$\sigma_m(0) : \quad \phi_j(ze^{2\pi i}) = \phi_{j'}(z) ; \quad j' = (j + 1) \pmod{m}. \quad (3.2)$$

Here $j = 1, \dots, m$, and the twist operator can be thought of as linking m strands of string, each with period 2π , into a single long string with period $2m\pi$. We will be interested in twisted states of the form

$$|\psi\rangle = \prod_{m=1}^N [\sigma_m(0)]^{N_m} |0\rangle, \quad (3.3)$$

where each σ_m acts on a different subset of the N copies of the target space M . Thus, there will be N_m long strings of period $2m\pi$ and $\sum_m mN_m = N$. In radial quantization this prepares a state on the spatial circle, and the corresponding out state is

$$\langle\psi| = \langle 0| \prod_{m=1}^N [\tilde{\sigma}_m(\infty)]^{N_m} \equiv \langle 0| \prod_{m=1}^N \lim_{z, \bar{z} \rightarrow \infty} \left[z^{2h_m} \bar{z}^{2\bar{h}_m} \tilde{\sigma}_m(z, \bar{z}) \right]^{N_m}, \quad (3.4)$$

where $\tilde{\sigma}_m$ has opposite action to σ_m . The twists transform as primaries with conformal weights

$$h_m = \bar{h}_m = \frac{c}{24} \left(m - \frac{1}{m} \right). \quad (3.5)$$

We wish to define entwinement in such twisted states of the symmetric product CFT.

In radial quantization we can specify a connected entangling region at a fixed time $t = 0$ by an arc on the unit circle. As explained in the previous section, entwinement in twisted states of the form (3.3) can be computed using the replica trick, by inserting *elementary replica twist operators*, Σ_i . Such twists act each on a single strand out of the N strands in the CFT and can be thought of as connecting the n -fold Rényi replicates of that strand. The elementary replica twists, Σ_i , have conformal weights

$$H_n = \bar{H}_n = \frac{c}{24} \left(n - \frac{1}{n} \right). \quad (3.6)$$

We insert the elementary twists at the endpoints of the chosen interval of length $\alpha + 2\pi\ell$ and average over the symmetric group, which moves the left boundary of the interval over all strands while keeping the length of the interval fixed. The state of the replicated theory, $|\Psi\rangle$, is obtained inserting orbifold twist operators for each of the n replica copies of the theory,

$$|\Psi\rangle = \left[\prod_{m=1}^N [\sigma_m(0)]^{N_m} \right]^n |0\rangle, \quad (3.7)$$

i.e., by taking products of (3.3) for each of the n replicated theories. In terms of $|\Psi\rangle$, we can write

$$E_\ell(\alpha) = \lim_{n \rightarrow 1} \frac{1}{1-n} \log \left[\frac{1}{|S_N|} \sum_{g \in S_N} \langle \Psi | \tilde{\Sigma}_{g(i)}^{(n)}(1) \Sigma_{g(i)}^{(n)}(e^{2\pi i \ell} x, e^{-2\pi i \ell} \bar{x}) | \Psi \rangle \right], \quad (3.8)$$

where we have taken the entwinement interval to extend between 1 and x in the complex plane; in the notation of the previous section, $x = e^{i\alpha}$. As before, since we are averaging over S_N , the result is independent of the arbitrary choice of the initial strand i , which can run from 1 to N . This correlator is a four-point function in the cyclic orbifold theory $\mathcal{C}^n/\mathbb{Z}_n$ obtained taking n replicas of the original symmetric orbifold $\mathcal{C} = \text{CFT}^N/S_N$.

At the practical level then, the computation above simplifies drastically. Consider a term in (3.8) where the strand $g(i) = k$ is embedded in a particular long string with m strands, which we relabel here as $1, 2, \dots, m$ for convenience. Let us define a notation

$$\Sigma_k^{(n)}(e^{2\pi i \ell} x, e^{-2\pi i \ell} \bar{x}) \equiv \Sigma_{k+\ell}(x, \bar{x}), \quad (3.9)$$

where the subscripts k and $k + \ell$ are understood modulo m because of the cyclic symmetry of the m -stranded long string. Then we have to compute terms like

$$\langle \Psi | \tilde{\Sigma}_k^{(n)}(1) \Sigma_{k+\ell}^{(n)}(x, \bar{x}) | \Psi \rangle = \langle [\tilde{\sigma}_m(\infty)]^n \tilde{\Sigma}_k^{(n)}(1) \Sigma_{k+\ell}^{(n)}(x, \bar{x}) [\sigma_m(0)]^n \rangle. \quad (3.10)$$

As discussed in the previous section, if the long string is shorter than the interval in question, i.e., $2\pi m < \alpha + 2\pi\ell$, (3.10) is understood as computing how the entire long string is entangled with the rest of the system.

3.1 Single interval entwinement

To evaluate the entwinement of a single interval we must therefore compute the correlator

$$\langle [\tilde{\sigma}_m(\infty)]^n \tilde{\Sigma}_k^{(n)}(1) \Sigma_{k+\ell}^{(n)}(x, \bar{x}) [\sigma_m(0)]^n \rangle. \quad (3.11)$$

The branching structure of the correlator is effectively mn -dimensional as illustrated in figure 4, and we can label the twist fields in terms of these mn sheets involved in the correlator:

$$[\sigma_m]^n = \sigma_{(1\dots m)\sigma_{(m+1\dots 2m)} \cdots \sigma_{(m(n-1)+1\dots mn)}, \quad (3.12)$$

$$\Sigma_k^{(n)} = \sigma_{(k, k+m, \dots, k+(n-1)m)} \quad (3.13)$$

in the cycles notation $\sigma_{(\dots)}$ of S_{mn} .

Figure 4. Representation of the branching structure of a correlator of the form (3.11) in the simple case of a single strand entwinement, $\ell = 0$, on a 3-cycle factor, $m = 3$.

The correlator (3.11) can be evaluated through a uniformization map to a covering space. To compute the map we extend a calculation of [40], which dealt with the case $m = 2$. We first observe that the branched covering has spherical genus, as determined by the Riemann-Hurwitz formula

$$g = \frac{1}{2} \sum_i (r_i - 1) - s + 1 = \frac{1}{2} [2n(m - 1) + 2(n - 1)] - mn + 1 = 0. \quad (3.14)$$

The sum is over the twist insertions in (3.11) of length r_i , and $s = mn$ is the total number of sheets involved in the correlator. An explicit formula for such twist correlation function in terms of the properties of the uniformization map to a genus zero surface is worked out in appendix D of [45] (see also [46, 47]). In appendix A, we review these results and apply them to the computation of single interval entwinement. Our final result is (see eq. (A.26) in the appendix)

$$\langle [\tilde{\sigma}_m(\infty)]^n \tilde{\Sigma}_k^{(n)}(1) \Sigma_{k+\ell}^{(n)}(x, \bar{x}) [\sigma_m(0)]^n \rangle = \left[m^2 |A|^{m-1} |A - 1|^2 \right]^{-\frac{c}{12} \left(n - \frac{1}{n} \right)}, \quad (3.15)$$

with $A = x^{1/m} e^{2\pi i \ell / m}$ and c the central charge of a single copy.

To obtain the entwinement of an interval of opening angle α on the spatial circle $w \sim w + L$, we only need to relate the result (3.15) obtained on the plane to the computation on the cylinder, with elementary replica twists inserted at $w = 0$ and $w = \alpha L / (2\pi)$. Using the map $z = e^{\frac{2\pi i w}{L}}$:

$$\langle \Psi | \tilde{\Sigma}_k^{(n)}(0) \Sigma_{k+\ell}^{(n)} \left(\frac{\alpha L}{2\pi} \right) | \Psi \rangle_{\text{cylinder}} = \left(\frac{2\pi}{L} \right)^{4H_n} \langle \Psi | \tilde{\Sigma}_k^{(n)}(1) \Sigma_{k+\ell}^{(n)}(x, \bar{x}) | \Psi \rangle \quad (3.16)$$

with $x = e^{i\alpha}$, $\bar{x} = e^{-i\alpha}$. If we explicitly insert a UV cutoff ϵ_{UV} to regulate the twist operators and work out the sum over all elements in S_N , we obtain

$$E_\ell(\alpha) = \lim_{n \rightarrow 1} \frac{1}{1 - n} \log \left[\frac{1}{N} \sum_{m=\ell+1}^N m N_m \left| \frac{mL}{\pi \epsilon_{\text{UV}}} \sin \left(\frac{\alpha + 2\pi \ell}{2m} \right) \right|^{-\frac{c}{6} \left(n - \frac{1}{n} \right)} \right] + O(\epsilon_{\text{UV}}^0). \quad (3.17)$$

The sum in the first term extends over long strings with $\ell + 1$ and more strands, because shorter strings are completely covered by intervals of length $\alpha + 2\pi\ell$. The contribution from each of these shorter strings computes the entanglement of the string with the rest of the theory. Since the short string is by construction disconnected from all other strands in this particular twisted sector, its entanglement entropy will not have the dominant UV-divergent contributions that are present for the longer strings with $\ell + 1$ and more strands. In formulas, if one sets $\alpha + 2\pi\ell \approx 2\pi m$ up to a contribution of order ϵ_{UV} , the occurrences of the cutoff will cancel in (3.17) between $1/\epsilon_{UV}$ and the sine, yielding a cutoff-independent result, which is small compared to the cutoff-dependent terms arising from long strings longer than the interval.

3.2 Entanglement entropy of a spatial region

The entanglement entropy of an interval is a specific case of computing entwinement. The gauge invariant twist operators are decomposed into products of twist operators on each strand as in (2.2), and the entanglement entropy of a spatial interval can be expressed as

$$S(\alpha) = \lim_{n \rightarrow 1} \frac{1}{1-n} \log \left[\langle \Psi | \tilde{\Sigma}_1^{(n)}(1) \Sigma_1^{(n)}(x, \bar{x}) \tilde{\Sigma}_2^{(n)}(1) \Sigma_2^{(n)}(x, \bar{x}) \dots \tilde{\Sigma}_N^{(n)}(1) \Sigma_N^{(n)}(x, \bar{x}) | \Psi \rangle \right]. \tag{3.18}$$

In the perspective of entwinement, entanglement entropy coincides with the entwinement of the union over all strands of an interval that fits within a single strand. Clearly, as this quantity is already gauge invariant, the sum over S_N appearing in the entwinement definition exactly cancels the normalization $|S_N|^{-1}$.

In fact the entanglement entropy for a state of the form (3.3) is not known in general. For instance the branching structure of the correlator leads generically to a covering space of non-trivial genus, and thus one cannot straightforwardly apply the same techniques we used for computing entwinement. However, in the limit of a short interval ($x, \bar{x} \rightarrow 1$), using the OPE of the elementary twists $\tilde{\Sigma}_i^{(n)}(1) \Sigma_i^{(n)}(x, \bar{x}) \sim \mathbb{1}/|1-x|^{2H_n}$ the correlator factorizes. Via the conformal map to the cylinder, the result reproduces the short interval expansion of the entanglement entropy for a CFT on a circle of length L with central charge $c_N = cN$,

$$S(\alpha) \approx \frac{c_N}{3} \log \frac{\alpha L}{\pi \epsilon_{UV}}. \tag{3.19}$$

This is N times the single strand ($\ell = 0$) short interval expansion ($\alpha \rightarrow 0$) of the entwinement result given in (3.17). This reflects the fact that $\ell = 0$ entwinement computes the entanglement for a single factor in the symmetric product orbifold theory, while entanglement entropy simultaneously involves fields in all N factors.

4 D1-D5 CFT

A well-known example of a symmetric orbifold CFT is the D1-D5 CFT. This is realized in type IIB string theory compactified on $S^1 \times T^4$ (or $S^1 \times K3$), with N_1 D1-branes wrapping the circle and N_5 D5-branes wrapping the entire compact product space. The near horizon geometry of the D1-D5 brane system is $AdS_3 \times S^3 \times T^4$, and one can formulate

a two-dimensional CFT at the conformal boundary of the AdS₃. This is an $\mathcal{N} = (4, 4)$ supersymmetric sigma model with $SU(2) \times SU(2)$ R-symmetry, corresponding to the isometry group of the S^3 , another $SU(2) \times SU(2)$ global symmetry and central charge equal to $6N_1N_5$ (see for instance [45] for a review). The moduli space of the CFT contains an orbifold point where the theory consists of $N \equiv N_1N_5$ copies of a $c = 6$ free CFT of 4 real bosons and their fermionic superpartners with target space $(T^4)^N/S_N$.

We will work at the orbifold point of the D1-D5 CFT and focus on the Ramond ground states. These can be constructed by multiplying together bosonic and fermionic twist operators to achieve a total twist of N . The theory contains eight bosonic and eight fermionic twists labeled in terms of the global symmetries. Since we are only interested in computing correlators of bosonic quantities that do not carry R-charge, we can simplify the discussion and generically consider the normalized symmetric orbifold microstates (3.3). In this section we will consider two examples of such states, which in the large N limit are dual to conical defects and zero mass BTZ black holes in the bulk (see [48] for discussion of the map between Ramond ground states of the D1-D5 system and AdS₃ gravity).¹ Points in the moduli space with a geometric supergravity description are actually far from the orbifold point where we perform our computations, and agreement with semiclassical gravity is not to be expected a priori. However protected BPS quantities can be computed exactly at the orbifold point and it has been proposed that agreement should extend also to observables computed in terms of covering space constructions [49].

4.1 Conical defects

Simple Ramond ground states of the D1-D5 CFT are of the form [46, 47, 50]

$$|\psi\rangle = [\sigma_{\tilde{m}}(0)]^{N/\tilde{m}} |0\rangle, \tag{4.1}$$

where N/\tilde{m} is an integer. The holographically dual bulk geometries are conical defects

$$ds^2 = -\left(\frac{1}{\tilde{m}^2} + \frac{r^2}{R_{\text{AdS}}^2}\right) dt^2 + \left(\frac{1}{\tilde{m}^2} + \frac{r^2}{R_{\text{AdS}}^2}\right)^{-1} dr^2 + r^2 d\theta^2, \tag{4.2}$$

where θ is a periodic coordinate and the AdS radius is related to the length of the spatial circle introduced in the previous section via $R_{\text{AdS}} = L/(2\pi)$. These geometries can be obtained from empty AdS₃ in global coordinates via $\mathbb{Z}_{\tilde{m}}$ identifications. For a single interval of opening angle α on the boundary, there exist multiple geodesics connecting the endpoints of the interval. These have regulated lengths [35]

$$\mathcal{L}_\ell(\alpha) = 2R_{\text{AdS}} \log \left[\frac{2\tilde{m}r_\infty}{R_{\text{AdS}}} \sin \left(\frac{\alpha + 2\pi\ell}{2\tilde{m}} \right) \right]. \tag{4.3}$$

The index $\ell = 0, \dots, \tilde{m} - 1$ counts the number of times the geodesics winds around the conical defect at $r = 0$. Here r_∞ is an IR gravitational cutoff. Identifying it with the field

¹The BTZ black hole is actually dual to an ensemble of states; we will comment on this point and on the notion of typical states in section 4.2.

theory cutoff ϵ_{UV} via $r_\infty = \frac{L}{2\pi} \frac{R_{AdS}}{\epsilon_{UV}}$ and substituting $c = 6$ in (3.17), we find the relation between entwinement in the state (4.1) and geodesic lengths

$$E_\ell(\alpha) = \frac{\mathcal{L}_\ell(\alpha)}{R_{AdS}}. \tag{4.4}$$

Therefore in this case, the field theory notion of entwinement computes the length of geodesics in AdS, in agreement with the idea advanced in [35] that non-minimal geodesics in the bulk capture the entanglement of internal degrees of freedom. Ordinary entanglement entropy on the other hand is related to the length of minimal geodesics, in agreement with the Ryu-Takayanagi formula [22]

$$S(\alpha) = \frac{\mathcal{L}_0(\alpha)}{4G_N}. \tag{4.5}$$

Since the D1-D5 central charge is $cN = 3R_{AdS}/(2G_N)$, the entanglement entropy of an interval coincides with N times the $\ell = 0$ single interval entwinement E_0 .

4.2 Zero mass BTZ black hole

One could wonder whether the length of long geodesics also captures entwinement in a black hole background. We will show this is indeed the case in the zero mass BTZ black hole

$$ds^2 = -\frac{r^2}{R_{AdS}^2} dt^2 + \frac{R_{AdS}^2}{r^2} dr^2 + r^2 d\theta^2, \tag{4.6}$$

which arises in the $\tilde{m} \rightarrow \infty$ limit of the conical defect geometry (4.2). The $M = 0$ black hole has a horizon of zero size which coincides with the singularity.

The $M = 0$ black hole geometry is not dual to a particular CFT microstate, but rather to an ensemble of states of the D1-D5 CFT with fixed N . Following [50], instead of working with the microcanonical ensemble, it is more convenient to work in the canonical description where N_m as well as the total number of strands fluctuate, but the ensemble average is fixed to N . The average number of m -cycles is [50]

$$\langle N_m \rangle = \frac{8}{\sinh \beta m}, \tag{4.7}$$

where the inverse fictitious temperature β is determined in terms of the average N of the total number of strands, as

$$N = \left\langle \sum_{m=1}^{\infty} m N_m \right\rangle \simeq \frac{2\pi^2}{\beta^2}. \tag{4.8}$$

In the large N limit, typical states in the ensemble have individual twist distributions that lie very close to (4.7) and expectation values of observables in a typical state deviate by only a small amount from those computed in the ensemble. In the following, we therefore compute entwinement in a typical state with representative distribution (4.7), rather than in the ensemble.

The single interval entwinement in a typical microstate is again given by (3.17). As we prove in appendix B, for fixed α and ℓ , the sum over m is dominated by the terms with $m \sim O(\sqrt{N})$. For $\ell \ll \sqrt{N}$, we obtain

$$E_\ell(\alpha) \approx \frac{c}{3} \log \left[\frac{L}{2\pi\epsilon_{\text{UV}}} (\alpha + 2\pi\ell) \right]. \tag{4.9}$$

Black holes admit a region outside the horizon which is not penetrated by minimal geodesics, which we can call the entanglement shadow of the black hole. Just as in the case of the conical defect, non-minimal geodesics penetrate the entanglement shadow. The non-minimal geodesics wind around the horizon and the bigger their winding number, the closer they wrap the horizon. The $M = 0$ BTZ black hole has a horizon that shrinks to zero size, but nevertheless it has a finite entanglement shadow. The lengths of non-minimal geodesics in the $M = 0$ BTZ black hole background are given by

$$\mathcal{L}_\ell(\alpha) = 2R_{\text{AdS}} \log \left[\frac{r_\infty}{R_{\text{AdS}}} (\alpha + 2\pi\ell) \right]. \tag{4.10}$$

Using again that $c = 6$ and $r_\infty = \frac{L}{2\pi} \frac{R_{\text{AdS}}}{\epsilon_{\text{UV}}}$, we recover that entwinement and geodesic length are related by

$$E_\ell(\alpha) = \frac{\mathcal{L}_\ell(\alpha)}{R_{\text{AdS}}}. \tag{4.11}$$

As $\ell \rightarrow \sqrt{N}$, the relation between entwinement and geodesic length breaks down. But the corresponding long geodesics, which wind very many times around the black hole, approach the horizon to within a Planck length. It is not clear that they are well defined in the quantum theory where we expect classical geometry to be ill-defined at the Planck scale. Hence it is not surprising that the lengths of these geodesics do not match the corresponding entwinements.

5 Discussion and outlook

We have verified the correspondence between single-interval entwinement and lengths of non-minimal geodesics in conical defects and $M = 0$ BTZ black holes, which correspond to specific states of the D1-D5 system. We studied these configurations because there are explicit constructions of the corresponding states in the literature [50]. Furthermore, these states are BPS-protected ground states in the Ramond sector of the theory [48, 49], so that we can expect non-renormalization of some quantities as we deform the theory away from its orbifold point. Of course this does not mean that all correlation functions extrapolate from weak to strong coupling, but we were essentially computing partition sums after a conformal map, which might help explain the agreements we found between field theory and gravity. It has also been seen that certain graviton correlators computed at the orbifold point do match the gravitational results which are related to the strongly coupled theory [50]. Possible general reasons for such matching are discussed in [49]. It should be possible to extend our computations in at least two interesting directions. First, we can consider the general R-charged Ramond ground states of the D1-D5 CFT. The $M = 0$

BTZ black hole and the conical defects considered here were two specific examples of such states, but a more general class is discussed in [50], including candidate states describing “black ring” geometries. Another interesting extension is to consider rotating, but extremal, AdS_3 black holes. These are represented in the D1-D5 CFT by adding energy to the left moving sector alone. One approach would be to add a small left-moving temperature; another would be to perturb the theory with a holomorphic stress tensor. Both of these are settings where it would be very interesting to compute both spatial entanglement and entwinement.

While in this paper we have mostly focused on 2d symmetric orbifold CFTs, our definition (2.6) of entwinement can be extended to more general discretely gauged theories. Consider, for instance, the discrete rotation orbifold $\mathbb{R}^2/\mathbb{Z}_N$ with $N > 2$. In the sector twisted by the generator of \mathbb{Z}_N , the target space coordinates satisfy

$$X(\tau, 2\pi) = \cos\left(\frac{2\pi}{N}\right) X(\tau, 0) - \sin\left(\frac{2\pi}{N}\right) Y(\tau, 0), \quad (5.1)$$

$$Y(\tau, 2\pi) = \sin\left(\frac{2\pi}{N}\right) X(\tau, 0) + \cos\left(\frac{2\pi}{N}\right) Y(\tau, 0). \quad (5.2)$$

We can extend the range of the σ coordinate in $X(\tau, \sigma)$ to $0 \leq \sigma < 4\pi$ by defining

$$X(\tau, \sigma) \equiv \cos\left(\frac{2\pi}{N}\right) X(\tau, \sigma - 2\pi) - \sin\left(\frac{2\pi}{N}\right) Y(\tau, \sigma - 2\pi), \quad 2\pi \leq \sigma < 4\pi. \quad (5.3)$$

A twisted sector string is then determined by the “long string” profile $X(\tau, \sigma)$ with $0 \leq \sigma < 4\pi$, which satisfies the boundary condition

$$X(\tau, 4\pi) = -X(\tau, 0) + 2 \cos\left(\frac{2\pi}{N}\right) X(\tau, 2\pi). \quad (5.4)$$

Entwinement defined in analogy with (2.6) then quantifies how one part of this long string is entangled with its complement. There does seem to be an important difference, however, with symmetric orbifold theories. For the above rotation orbifold, we could equally well have defined entwinement by considering target space coordinates X', Y' related to X, Y by rotation in field space over an arbitrary angle. Entwinement defined using long string profiles $X'(\sigma)$ would generically be different from that defined using $X(\sigma)$, reflecting the basis dependence of measures of quantum entanglement in general. In contrast, for symmetric orbifolds the requirements that the target space coordinates should be mapped into each other by permutations and should have diagonal kinetic terms does select a preferred notion of entwinement. It is interesting to ask for which gauge theories our definition of entwinement leads to “natural” quantities, including quantities with a clear geometrical meaning in a holographic dual. Other generalizations worth studying are continuous gauge theories, higher dimensional theories and matrix models.

Note that entwinement, as we defined it, measured the lengths of geodesics in units of the AdS scale, rather than in units of the Planck length (which is related to the three dimensional Newton constant G_N). In the original formulation of holographic entanglement entropy [22, 23], it seemed natural that G_N should appear in the formulas, in analogy

with black hole entropy which is measured by horizon area in units of G_N . Of course field theories with a holographic dual having a classical description generally have a large number of local degrees of freedom arising from e.g. dynamical variables that are large matrices. The entwinement that we are defining seeks to piece apart the entanglement of some of these local degrees of freedom (e.g. parts of the local matrices) with other elements of the Hilbert space. As such, we are extracting the elementary parts out of which spatial entanglement arises in such quantum field theories. These elementary entanglements are correspondingly smaller, and are thus related to geodesic lengths measured relative to a length scale that is much larger than the Planck length. One might ask if single interval entwinement can ever be of the same order of magnitude as the spatial entanglement as we make the interval size larger. At least in the 2d CFT states we considered, this cannot happen because entanglement between different long strings is negligible and within a single long string entanglement only depends logarithmically on the interval size. This could be different in excited or thermal states where there could be extensive contributions to entanglement, or in theories with less local interactions such as matrix models. It is also interesting that the fundamental object (2.6) from which we construct entwinement is non-local. This recalls the discussion in [51] of the relevance of non-local observables in field theory for reconstructing local physics in AdS space in a gauge-invariant manner.

One of our goals in this paper has been to define the field theoretic dual of extremal, non-minimal geodesics in AdS_3 . These geodesics also appear in the semiclassical CFT computation of Rényi entropies in terms of the conformal block expansion of heavy-heavy-light-light correlators [43]. There it was shown that the single interval entanglement entropy in a state created by heavy operator insertions, and dual to an AdS_3 conical defect or BTZ, is well approximated by the semiclassical identity block and reproduces the Ryu-Takayanagi minimal geodesic result. This leading answer for the four-point function however has monodromies as the Rényi twists are moved around the heavy operators in the CFT. These monodromies transform the minimal geodesic result into quantities related to the length of non-minimal geodesics. Therefore in this context non-minimal geodesics are also related in the dual CFT to analytic properties of semiclassical Virasoro blocks.

Acknowledgments

We thank Alexandre Belin, Netta Engelhardt, Jutho Haegeman, Volkher Scholz, Norbert Schuch, Karel Van Acoleyen, Henri Verschelde, and Frank Verstraete for very helpful discussions. We are also particularly grateful to Bartek Czech, Lampros Lamprou, Sam McCandlish, and Jamie Sully for discussing details of their ongoing work on related questions with us. B.C. thanks the organizers of the Nordita program “Black Holes and Emergent Spacetime” for hospitality while this work was in progress.

A Twist correlator

In this appendix we briefly review the result described in [45] for general bare twists correlators with covering space of spherical genus, and apply them explicitly to the computation of the correlator in eq. (3.11),

$$\langle [\tilde{\sigma}_m(\infty)]^n \tilde{\Sigma}_1^{(n)}(1) \Sigma_{1+\ell}^{(n)}(x, \bar{x}) [\sigma_m(0)]^n \rangle, \tag{A.1}$$

where, since the strands are indistinguishable, we have set without loss of generality $k = 1$.

Consider a general correlator of $P + Q$ normalized twists,

$$\langle \sigma_{p_1}(z_1) \sigma_{p_2}(z_2) \dots \sigma_{p_P}(z_P) \sigma_{q_1}(\infty) \sigma_{q_2}(\infty) \dots \sigma_{q_Q}(\infty) \rangle, \tag{A.2}$$

where p_i, q_j denote the lengths of the symmetric group cycles of the corresponding operators, inserted in the finite z -plane and at infinity, respectively. We restrict attention to correlators of genus zero,

$$g = \frac{1}{2} \sum_{i=1}^P (p_i - 1) + \frac{1}{2} \sum_{j=1}^Q (q_j - 1) - s + 1 = 0, \tag{A.3}$$

where, as in the main text, s denotes the total number of copies.

The map to the covering space $z = z(t)$ should be meromorphic and reproduce the correct monodromies corresponding to the twist insertions

$$\begin{aligned} z - z_i &\approx a_i (t - t_i)^{p_i} && \text{for } z \approx z_i, \quad t \approx t_i && \forall i = 1, \dots, P \\ z &\approx b_1 t^q && \text{for } z \rightarrow \infty, \quad t \rightarrow \infty \\ z &\approx b_j (t - t_j^\infty)^{-q_j} && \text{for } z \rightarrow \infty, \quad t \approx t_j^\infty && \forall j = 2, \dots, Q \end{aligned} \tag{A.4}$$

to leading order near each branch point. The correlator (A.2) can then be shown to depend only on the coefficients a_i, b_j and parameters p_i, q_j and to be given by [45]

$$\begin{aligned} &\langle \sigma_{p_1}(z_1) \sigma_{p_2}(z_2) \dots \sigma_{p_P}(z_P) \sigma_{q_1}(\infty) \sigma_{q_2}(\infty) \dots \sigma_{q_Q}(\infty) \rangle = && \tag{A.5} \\ &= \left(\prod_{i=1}^P p_i^{-\frac{c}{12}(p_i+1)} \right) \left(\prod_{j=1}^Q q_j^{\frac{c}{12}(q_j-1)} \right) \left(\prod_{i=1}^P |a_i|^{-\frac{c}{12} \frac{p_i-1}{p_i}} \right) \left(\prod_{j=1}^Q |b_j|^{-\frac{c}{12} \frac{q_j+1}{q_j}} \right) |b_1|^{\frac{c}{6}} q_1^{\frac{c}{6}}, \end{aligned}$$

where

$$F = s + Q - \sum_{j=1}^Q q_j \quad (\text{A.6})$$

is the number of distinct images of infinity and c denotes the central charge of the seed CFT.

Specializing to the correlator (A.1), we have

$$\begin{aligned} z &\approx a_i(t - t_i)^m && \text{for } z \approx 0, && t \approx t_i && \forall i = 1, \dots, n \\ z - 1 &\approx a_{n+1}t^n && \text{for } z \approx 1, && t \approx 0 \\ z - x &\approx a_{n+2}(t - 1)^n && \text{for } z \approx x, && t \approx 1 \\ z &\approx b_1t^m && \text{for } z \rightarrow \infty, && t \rightarrow t_1^\infty = \infty \\ z &\approx b_j(t - t_j^\infty)^{-m} && \text{for } z \rightarrow \infty, && t \approx t_j^\infty && \forall j = 2, \dots, n \end{aligned} \quad (\text{A.7})$$

and a map that satisfies these properties is

$$z = \left[\frac{At^n - (t - 1)^n}{t^n - (t - 1)^n} \right]^m \quad (\text{A.8})$$

with

$$x = A^m. \quad (\text{A.9})$$

In order to completely fix the map that computes the correlator (3.11), we choose the branch requiring that for two elementary replica twists in (A.1) acting on the same strand, i.e. for $\ell = 0$, $A \rightarrow 1$ as the interval size goes to zero. We then impose continuity as we increase the interval size and take x ℓ times around the unit circle in the complex plane, that is

$$A = e^{\frac{2\pi i \ell}{m}} x^{\frac{1}{m}}. \quad (\text{A.10})$$

In the t -plane, the insertions map to

$$t_k = \frac{1}{1 - A^{\frac{1}{n}} e^{\frac{2\pi i k}{n}}}, \quad t_j^\infty = \frac{1}{1 - e^{\frac{2\pi i (j-1)}{n}}}, \quad (\text{A.11})$$

and

$$At^n - (t - 1)^n = (A - 1) \prod_{i=1}^n (t - t_i), \quad t^n - (t - 1)^n = n \prod_{j=2}^n (t - t_j^\infty), \quad (\text{A.12})$$

so that the conformal map can also be written as

$$z = \frac{(A - 1)^m \prod_{i=1}^n (t - t_i)^m}{n^m \prod_{j=2}^n (t - t_j^\infty)^m}. \quad (\text{A.13})$$

From this expression we can directly determine the coefficients

$$b_1 = \left(\frac{A - 1}{n} \right)^m, \quad b_j = \left[\frac{A - 1}{n} \frac{\prod_{k=1}^n (t_j^\infty - t_k)}{\prod_{k=2, k \neq j}^n (t_j^\infty - t_k^\infty)} \right]^m. \quad (\text{A.14})$$

To work out the remaining coefficients a_i , we consider the first derivative

$$\frac{dz}{dt} = \frac{mn(A-1)^m}{[t^n - (t-1)^n]^{m+1}} t^{n-1} (t-1)^{n-1} \prod_{i=1}^n (t-t_i)^{m-1}. \quad (\text{A.15})$$

Near $t \approx 0, 1, t_i$ the first derivative vanishes. In fact, the first $m-1$ derivatives vanish near $t = t_i$, and the first $n-1$ near $t = 0, 1$. This implies that in a Taylor expansion near these points we have

$$\begin{aligned} z &= \frac{1}{m!} \left. \frac{d^m z}{dt^m} \right|_{t=t_i} (t-t_i)^m + \dots, \\ z &= 1 + \frac{1}{n!} \left. \frac{d^n z}{dt^n} \right|_{t=0} t^n + \dots, \\ z &= x + \frac{1}{n!} \left. \frac{d^n z}{dt^n} \right|_{t=1} (t-1)^n + \dots, \end{aligned} \quad (\text{A.16})$$

from which we read

$$\begin{aligned} a_i &= \frac{n(A-1)^m}{[t_i^n - (t_i-1)^n]^{m+1}} t_i^{n-1} (t_i-1)^{n-1} \prod_{k=1, k \neq i}^n (t_i - t_k)^{m-1}, \\ a_{n+1} &= m(-1)^{-(n+1)}(A-1), \\ a_{n+2} &= mA^{m-1}(A-1). \end{aligned} \quad (\text{A.17})$$

Substituting in (A.5), we obtain

$$\begin{aligned} &\langle [\tilde{\sigma}_m(\infty)]^n \tilde{\Sigma}_1^{(n)}(1) \Sigma_{1+\ell}^{(n)}(x, \bar{x}) [\sigma_m(0)]^n \rangle \\ &= m^{\frac{c}{6}(1-n)} n^{-\frac{c}{6}(n+1)} \left(\prod_{i=1}^n |a_i|^{-\frac{c}{12} \frac{m-1}{m}} \right) |a_{n+1}|^{-\frac{c}{12} \frac{n-1}{n}} |a_{n+2}|^{-\frac{c}{12} \frac{n-1}{n}} \left(\prod_{j=1}^n |b_j|^{-\frac{c}{12} \frac{m+1}{m}} \right) |b_1|^{\frac{c}{6}}. \end{aligned} \quad (\text{A.18})$$

To evaluate explicitly the products, observe that from (A.11), (A.12), (A.15) we can derive the following identities

$$\prod_{k=1}^n |t_k^n - (t_k-1)^n| = \prod_{k=1}^n \frac{|1-A|}{\left| 1 - A^{\frac{1}{n}} e^{\frac{2\pi i k}{n}} \right|^n} = |1-A|^n \prod_{k=1}^n |t_k|^n = 1, \quad (\text{A.19})$$

$$\prod_{k=1}^n |t_k - 1| = |A| \prod_{k=1}^n |t_k| = \frac{|A|}{|A-1|}, \quad (\text{A.20})$$

$$\begin{aligned} \prod_{k=1}^n \prod_{j=1, j \neq k}^n |t_k - t_j| &= \prod_{k=1}^n \frac{1}{|A-1|} \left| \frac{d}{dt} (At^n - (t-1)^n) \right|_{t=t_k} \\ &= \prod_{k=1}^n \frac{n}{|A-1|} |At_k^{n-1} - (t_k-1)^{n-1}| \\ &= \prod_{k=1}^n \frac{n}{|A-1|} \left| \frac{A^{1-\frac{1}{n}}}{\left(1 - A^{\frac{1}{n}} e^{\frac{2\pi i k}{n}} \right)^{n-2}} \right| \\ &= \frac{n^n |A|^{n-1}}{|A-1|^n} \prod_{k=1}^n |t_k|^{n-2} = n^n |A|^{n-1} |A-1|^{2(1-n)}, \end{aligned} \quad (\text{A.21})$$

$$\begin{aligned} \prod_{j=2}^n \prod_{k=1}^n |t_j^\infty - t_k| &= \prod_{k=1}^n \frac{1}{n} |t_k^n - (t_k - 1)^n| = n^{-n} \prod_{k=1}^n \frac{|1 - A|}{\left|1 - A^{\frac{1}{n}} e^{\frac{2\pi i k}{n}}\right|^n} \\ &= n^{-n} |1 - A|^n \prod_{k=1}^n |t_k|^n = n^{-n}, \end{aligned} \tag{A.22}$$

$$\begin{aligned} \prod_{j=2}^n \prod_{k=2, k \neq j}^n |t_j^\infty - t_k^\infty| &= \prod_{j=2}^n \frac{1}{n} \left| \frac{d}{dt} (t^n - (t-1)^n) \right|_{t=t_j^\infty} \\ &= \prod_{j=2}^n \left| (t_j^\infty)^{n-1} - (t_j^\infty - 1)^{n-1} \right| \\ &= \prod_{j=2}^n \left| 1 - e^{\frac{2\pi i(j-1)}{n}} \right|^{2-n} = \prod_{j=2}^n |t_j^\infty|^{n-2} = n^{2-n}. \end{aligned} \tag{A.23}$$

Using these identities we can write the expressions (A.14) and (A.17) as

$$\prod_{i=1}^n |a_i| = n^{mn} |A|^{m(n-1)} |A - 1|^{m(2-n)}, \tag{A.24}$$

$$\prod_{j=1}^n |b_j| = n^{-m(n+2)} |A - 1|^{nm}, \tag{A.25}$$

and substituting in the correlator gives

$$\langle [\tilde{\sigma}_m(\infty)]^n \tilde{\Sigma}_1^{(n)}(1) \Sigma_{1+\ell}^{(n)}(x, \bar{x}) [\sigma_m(0)]^n \rangle = \left[m^2 |A|^{m-1} |A - 1|^2 \right]^{-\frac{c}{12} \left(n - \frac{1}{n} \right)}. \tag{A.26}$$

B Dominant contributions to the entanglement of $M = 0$ BTZ

In this appendix, we show that in a typical state of the zero mass BTZ black hole the sum

$$\sum_m m N_m \left| 2m \sin \left(\frac{\alpha + 2\pi\ell}{2m} \right) \right|^{-\frac{c}{6} \left(n - \frac{1}{n} \right)} \tag{B.1}$$

appearing in the correlator (3.17) is dominated by strings with $m \sim O(\sqrt{N})$.

We assume we are working at large enough N , such that deviations from typicality are small. The total number of strings of length m in a typical state is

$$N_m = \frac{8}{\sinh \beta m} \tag{B.2}$$

with $\beta \simeq \sqrt{2}\pi/\sqrt{N}$ [50]. Since m is an integer, we can write the total number of strands as

$$N = \sum_m m N_m \Delta m, \tag{B.3}$$

with $\Delta m = 1$, and by redefining $m \equiv xN$, $\Delta m \equiv \Delta xN$:

$$1 = N \sum_x x N_x \Delta x. \tag{B.4}$$

In the limit $N \rightarrow \infty$ this becomes the integral

$$1 = N \int_0^\infty dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})}, \quad (\text{B.5})$$

which can be split as

$$1 = N \int_0^{N^{\gamma-1}} dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})} + N \int_{N^{\gamma-1}}^{N^{\gamma'-1}} dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})} + N \int_{N^{\gamma'-1}}^\infty dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})} \quad (\text{B.6})$$

with $\gamma < 1/2$ and $\gamma' > 1/2$. We now observe that the first and last integral vanish in the large N limit.

- For $x \in [0, N^{\gamma-1})$, or $m \in [0, N^\gamma)$, and $\gamma < 1/2$:

$$N \int_0^{N^{\gamma-1}} dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})} \sim \int_0^{N^{\gamma-1}} dx \frac{8\sqrt{N}}{\sqrt{2\pi}} = \frac{8N^{\gamma-1/2}}{\sqrt{2\pi}} \rightarrow 0, \text{ as } N \rightarrow \infty. \quad (\text{B.7})$$

- For $x \in [N^{\gamma'-1}, \infty)$, or $m \in [N^{\gamma'}, \infty)$, and $\gamma' > 1/2$:

$$N \int_{N^{\gamma'-1}}^\infty dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})} \sim N \int_{N^{\gamma'-1}}^\infty dx \frac{16x}{e^{\sqrt{2\pi x\sqrt{N}}}} \quad (\text{B.8})$$

$$\sim \frac{8\sqrt{2}}{\pi} N^{\gamma'-1/2} e^{-\sqrt{2\pi} N^{\gamma'-1/2}} \rightarrow 0, \text{ as } N \rightarrow \infty. \quad (\text{B.9})$$

It follows that

$$1 \approx N \int_{N^{\gamma-1}}^{N^{\gamma'-1}} dx \frac{8x}{\sinh(\sqrt{2\pi x\sqrt{N}})} = \frac{1}{N} \sum_{m \sim N^\gamma}^{N^{\gamma'}} \frac{8m}{\sinh \beta m} \quad (\text{B.10})$$

and

$$N \approx \sum_{m \sim N^\gamma}^{N^{\gamma'}} m N_m \quad (\text{B.11})$$

for any $\gamma < 1/2$ and $\gamma' > 1/2$, and especially for γ, γ' arbitrarily close to $1/2$ proving that indeed strings with $m \sim O(\sqrt{N})$ dominate the sum (B.3).

To complete the proof, we observe that for fixed α and l

$$2m \sin\left(\frac{\alpha + 2\pi\ell}{2m}\right) \sim O(1) \quad (\text{B.12})$$

is of the same order regardless of m . Therefore

$$\sum_m m N_m \left| 2m \sin\left(\frac{\alpha + 2\pi\ell}{2m}\right) \right|^{-\frac{\epsilon}{6}(n-\frac{1}{n})} \sim N \left| 2\sqrt{N} \sin\left(\frac{\alpha + 2\pi\ell}{2\sqrt{N}}\right) \right|^{-\frac{\epsilon}{6}(n-\frac{1}{n})} \quad (\text{B.13})$$

for all finite ℓ not scaling with N .

ABSTRACT: The strongly coupled D1-D5 conformal field theory is a microscopic model of black holes which is expected to have chaotic dynamics. Here, we study the weak coupling limit of the theory where it is integrable rather than chaotic. In this limit, the operators creating microstates of the lowest mass black hole are known exactly. We consider the time-ordered two-point function of light probes in these microstates, normalized by the same two-point function in vacuum. These correlators display a universal early-time decay followed by late-time sporadic behavior. To find a prescription for temporal coarse-graining of these late fluctuations we appeal to random matrix theory, where we show that a progressive time-average smooths the spectral form factor (a proxy for the 2-point function) in a typical draw of a random matrix. This coarse-grained quantity reproduces the matrix ensemble average to a good approximation. Employing this coarse-graining in the D1-D5 system, we find that the early-time decay is followed by a dip, a ramp and a plateau, in remarkable qualitative agreement with recent studies of the Sachdev-Ye-Kitaev (SYK) model. We study the timescales involved, comment on similarities and differences between our integrable model and the chaotic SYK model, and suggest ways to extend our results away from the integrable limit.

1 Introduction

Black holes are the most entropic objects in the universe. Their entropy $S_{\text{BH}} = \frac{A_{\text{BH}}}{4G_N\hbar}$ is proportional to the horizon area and implies that the energy spectrum of microstates has a miniscule gap ($\delta E \sim e^{-A_{\text{BH}}/4G_N\hbar}$), which becomes infinitesimal in the classical $\hbar \rightarrow 0$ limit. Various lines of evidence also suggest that the dynamics of the Hamiltonian acting on these microstates is chaotic [1–3], implying that the spectrum of excitations must be irregular [4]. Around a typical state of such a bounded system, general arguments from quantum mechanics suggest that the gapped, irregular spectrum will lead to temporal correlations showing a universal initial decay which gives way at very late times to rapid, small fluctuations whose precise structure is determined by the actual microstate.

Random matrix theory (RMT), where the Hamiltonian is drawn from a fixed ensemble, has been proposed as a universal description of this sort of behavior. In this theory it has been shown that the ensemble average of the spectral form factor, a proxy for the two-point function related to the ‘easy’ version of the information paradox [5–7], exhibits a characteristic initial decay, followed by an increasing ramp, and then a plateau. Recently, it was shown that the Sachdev-Ye-Kitaev (SYK) model [8–10], which is a strongly coupled

model of quenched disorder inspired by black hole physics,¹ also displays the decay, ramp and plateau phenomena [16].² Like random matrix theory, the SYK model contains an average over Hamiltonians — the coupling of the theory is drawn from a distribution and the smooth ramp and plateau arise after averaging over this ensemble. We would like to understand whether this behavior occurs generally in black hole physics.

String theory contains many examples of black holes whose microscopic descriptions are well understood. The simplest setting is Type IIB string theory compactified on a torus with five asymptotically flat dimensions. This theory contains charged black holes whose extremal limit still has a large entropy. The low-energy excitations of such a black hole are described by a two-dimensional conformal field theory [18], the “D1-D5 CFT”, which is a marginal deformation of a sigma model on the symmetric product target space $(T^4)^N/S_N$. Here S_N is the permutation group acting on N copies of T^4 . The marginal deformation parameter acts as the coupling in the theory. When it is large the theory is expected to be chaotic as it describes a macroscopic black hole. When it goes to zero, the theory approaches the symmetric product limit where it is integrable.

These five dimensional black holes can be reduced through a sequence of near-horizon, low-energy limits to extremal black holes in three and two dimensional Anti-de Sitter space. Indeed, through these limits, the D1-D5 CFT is known to be exactly dual to type IIB string theory on $\text{AdS}_3 \times S^3 \times T^4$ [19, 20]. The SYK model was inspired by AdS_2 black holes, and hence it may be that the D1-D5 CFT at finite coupling has a reduction to an SYK-like model [13, 15]. Here, we instead study the weak coupling limit of the theory. In this limit, the theory is integrable rather than chaotic but, remarkably, we show that many of the qualitative features of the chaotic RMT and SYK dynamics are already present.

Specifically, we consider dynamics around Ramond ground states of the D1-D5 theory which are typical microstates of the lightest black hole. These black holes have a large microscopic entropy, although it is not large enough to produce a classical black hole horizon. The temporal correlation function of graviton operators in these states shows an initial universal decay followed by sporadic fluctuations [21]. A similar structure occurs in observables computed with a *single* draw of a Hamiltonian in a random matrix theory. We argue, and numerically demonstrate, that the ensemble average in RMT can be mimicked by a progressive time-average in a single draw from the theory, over windows that scale proportionally to time. Applying this progressive time average to correlators in a typical ground state of the D1-D5 theory reveals an initial decay, followed by a long ramp and a plateau, qualitatively resembling both the RMT and SYK theories. The initial decay exactly reproduces the expected results in a black hole background [21]. We present analytic calculations of the plateau height and the shape of the ramp, and comment on the reasons for the quantitative differences between our results and those in fully chaotic theories like RMT and SYK. An interesting challenge for the future is to perturbatively turn on the marginal deformation that takes the integrable limit of the D1-D5 theory into a chaotic regime.

The paper is organized as follows. In section 2 we give a short review of the D1-D5 system at the orbifold point and the two point functions in the Ramond ground states

¹This model exhibits a tractably broken Virasoro symmetry [11] and its effective action takes a form which also arises in two-dimensional dilaton gravity [12–15].

²In fact, the level statistics in SYK is well approximated by RMT around the mean level spacing [16, 17].

based on [21]. In section 3 we introduce progressive time averaging in the context of random matrix theory and present evidence that it is capable of capturing both qualitative and quantitative features of the ensemble average. In section 4 we apply this time average to the D1-D5 graviton two point function and present the main results of the paper, including analytic estimates for the ramp and the plateau. In section 5 we conclude the paper. We include two appendices with some additional details of the discussion in section 4.

2 Correlators in the D1-D5 CFT at the orbifold point

We will consider Type IIB string theory compactified to five dimension on $S^1 \times T^4$ with N_1 D1-branes wrapped on the S^1 and N_5 D5-branes wrapped on the entire compact space. At low energies, the effective theory describing the dynamics of excitations is a certain marginal deformation of an $\mathcal{N} = (4, 4)$ supersymmetric sigma model on the symmetric product target space $\mathcal{M}_0 = (T^4)^N/S_N$, where $N = N_1N_5$ and S_N is the permutation group acting on the N copies of T^4 [18]. The sigma model on \mathcal{M}_0 describes N “strands” of string propagating on T^4 . While this is a free orbifold theory, it has an interesting spectrum and correlation functions, as we will see. The marginal deformation corresponds to turning on an interaction that allows splitting and joining of strings.

Taking an appropriate limit isolates the part of the spacetime that is exactly described by the CFT. In this low-energy limit we say that the D1-D5 CFT is holographically dual to Type IIB string theory on $\text{AdS}_3 \times S^3 \times T^4$. To have a large, weakly coupled AdS_3 space, N must be large and, in addition, the CFT must be strongly coupled, i.e. deformed far from the orbifold point. We are going to study the theory in the opposite, weakly coupled limit, but still at large N .

The extremal, supersymmetric black holes in the five dimensional asymptotically flat theory descend in this construction to the BTZ black holes of AdS_3 with periodic boundary conditions for fermions around the asymptotic circle in the AdS_3 geometry, i.e., they are in the Ramond sector of the theory. The lightest black hole, which is massless, has the quantum numbers of a ground state in this sector.

The construction of Ramond ground states of the D1-D5 CFT at the orbifold point is reviewed in detail in appendix A of [21]; here we provide a brief summary. We think of the CFT as describing N distinct “strands” of string, each of which propagates on T^4 . The ground states of the theory are formed by joining strands into various closed strings, which may be “short” (consisting of one strand) or “long” (consisting of multiple strands). The strands are attached together by applying elementary bosonic (σ) and fermionic (τ) twist operators which create n -wound string sectors. Each twist operator has 8 polarizations associated with the global symmetries of the theory. A general Ramond sector ground state is created by multiplying together bosonic and fermionic twist operators to achieve a total twist of $N = N_1N_5$:

$$\sigma = \prod_{n,\mu} (\sigma_n^\mu)^{N_{n\mu}} (\tau_n^\mu)^{N'_{n\mu}}, \tag{2.1}$$

$$\sum_{n\mu} n(N_{n\mu} + N'_{n\mu}) = N, \quad N_{n\mu} = 0, 1, 2, \dots, \quad N'_{n\mu} = 0, 1, \tag{2.2}$$

where $\mu = 1, \dots, 8$ labels the polarizations, and $n = 1, 2, \dots, N$ labels the possible lengths of strings (i.e. the number of strands a string is made of). For our purposes, the integers $N_{n\mu}$ and $N'_{n\mu}$, which count the various twist operators, uniquely specify a Ramond ground state of the theory.

Note that while Ramond ground states all have the same energy, the spectrum of excitations around each of them is different. For example, consider a case with $N = 4$ strands. Three possible states are four strings of length 1 ($N_1 = 4$), two long strings of length 2 ($N_2 = 2$), and one string of length 3 with another of length 1 ($N_3 = 1, N_1 = 1$). If we take the CFT to be on a circle of circumference L , the momentum spectrum of excitations is very different in these sectors — the first has modes gapped by $1/L$ with four-fold degeneracy, the second has modes gapped by $1/2L$ with 2-fold degeneracy and the third spectrum is a union of modes gapped by $1/L$ and $1/3L$ each with unit degeneracy. Thus correlation functions computed in each of the microstates will be different and will depend on the twist distributions $\{N_{n\mu}, N'_{n\mu}\}$.

Now observe that the number of Ramond ground states is given by counting (colored) partitions of the integer N . When $N \gg 1$, there are $O(e^{2\sqrt{2\pi N}})$ such partitions, leading to an enormous ground state degeneracy in the theory, corresponding to an entropy $S = 2\sqrt{2\pi N}$. Nearly all partitions of a large integer lie very close to a certain “typical partition” [21]. This means that most Ramond states will in fact have twist distributions $\{N_{n\mu}, N'_{n\mu}\}$ that lie close to a certain typical distribution. Thus, although correlation functions measured in individual microstates will depend on the precise form of the state, for almost all microstates the generic correlation functions will take a typical form, which we seek to investigate. Microcanonically, we should study all partitions of integers that lead to a total twist of N . The easiest way, however, to derive the form of the typical state is to use the grand canonical ensemble with a “chemical potential” η to fix the total “charge” N for eight types ($\mu = 1 \dots 8$) of bosons (σ_n^μ) and fermions (τ_n^μ) with integral charges n . When N is large, the grand canonical average populations for $\{N_{n\mu}, N'_{n\mu}\}$ will also be typical, in the sense that most configurations will be very close to the average (the standard deviation over the mean will tend to zero). Thus we can derive that most of the Ramond ground states have twist distributions close to the Bose-Einstein and Fermi-Dirac forms:

$$N_{n\mu} = \frac{1}{e^{\eta n} - 1}, \quad N'_{n\mu} = \frac{1}{e^{\eta n} + 1}, \quad N_n = \sum_{\mu} (N_{n\mu} + N'_{n\mu}) = \frac{8}{\sinh \eta n}, \quad (2.3)$$

with η set by

$$N = \sum_n n N_n \approx \frac{2\pi^2}{\eta^2}. \quad (2.4)$$

For further reference, we note that the entropy scales as $S \sim 1/\eta$.

Now that we know the form of the typical Ramond ground state in the D1-D5 system it remains to calculate the correlation function. Again following [21], we will consider bosonic non-twist operators, which do not cut and join the N strands of the CFT. (An operator describing a fluctuation of the metric in the T^4 directions is an example.) We focus on S_N

invariant operators obtained as sums of copies acting on each strand,

$$\mathcal{O} = \frac{1}{\sqrt{N}} \sum_{a=1}^N \mathcal{O}_a. \tag{2.5}$$

We are interested in two-point functions of the form

$$\langle \sigma^\dagger \mathcal{O}^\dagger \mathcal{O} \sigma \rangle. \tag{2.6}$$

Since the state as a whole splits into a product of strings of lengths n , the correlator splits into a sum of terms, each of which reduces to a two point function in a CFT on a spatial circle that is n times as long. After some algebra (see [21] for details), the correlation function becomes

$$\langle \sigma^\dagger \mathcal{O}^\dagger \mathcal{O} \sigma \rangle = G(w, \bar{w}) = \frac{1}{N} \sum_{n=1}^N n N_n \sum_{k=0}^{n-1} \frac{C}{[2n \sin(\frac{w-2\pi k}{2n})]^{2h} [2n \sin(\frac{\bar{w}-2\pi k}{2n})]^{2\bar{h}}}. \tag{2.7}$$

Here h and \bar{h} are the left and right conformal dimensions, C is a constant, the sum on n accounts for the contribution from strings of length n , and the sum on k accounts for the placement of operators on different strands of a long string. Also, $w = w_1 - w_2$ and $\bar{w} = \bar{w}_1 - \bar{w}_2$ are differences in the lightcone positions of the probe operators. In Lorentzian signature we will set

$$w = \phi - t, \quad \bar{w} = \phi + t, \tag{2.8}$$

where ϕ and t are dimensionless angular and time coordinates in the CFT, normalized by setting the length of the spatial circle to be equal to 2π .

The correlator $G(w, \bar{w})$ exhibits physical lightcone divergences on the cylinder. We can regularize these divergences by dividing by the vacuum correlation function, which is fixed by conformal invariance. Focusing, for definiteness, on operators with conformal dimensions $h = \bar{h} = 1$ this results in [21]

$$\hat{G}(w, \bar{w}) = \frac{1}{N} \sum_{n=1}^N n N_n \sum_{k=0}^{n-1} \left(\frac{4 \sin \frac{w}{2} \sin \frac{\bar{w}}{2}}{2n \sin(\frac{w-2\pi k}{2n}) 2n \sin(\frac{\bar{w}-2\pi k}{2n})} \right)^2. \tag{2.9}$$

Setting $\phi = 0$, we can evaluate the temporal correlation function numerically — the result is plotted in figure 1. We see a smooth initial decay followed by sporadic behavior, which is qualitatively similar to the behavior of observables in a single draw from a random matrix theory or in the SYK model before the average over disorder.

What is the origin of this sporadic behavior? As shown in appendix A, the two-point function (2.9) for $\phi = 0$ receives contributions from frequencies of the form m/n , with n an integer labeling the length of a component string (so $1 \leq n \leq N$). This is a dense spectrum consisting of all rational numbers with denominators smaller than $N + 1$. The mixing of this large number of incommensurate frequencies produces the rapid late time oscillations. A feature of the theory is that excitations on different long strings do not interact at the orbifold point. This means that the smallest frequencies that occur in the

Figure 1. The regularized two-point function (2.9).

two-point function are much larger than implied by the dense spectrum because no terms depend on the energy *differences* between excitations of strings of different lengths. (Hence, while the spectrum contains excitations with energies $1/(N - 1)$ and $1/N$ the two point function does not contain the difference $1/(N - 1) - 1/N$.) If we were dealing with a fully chaotic system, we would expect all the degeneracies in the spectrum to be broken, leading to exponentially small energy spacings. When we later analyze smooth, time-averaged versions of our two-point function, we will see that the relatively large frequency gap will cause the late-time plateau value to be reached earlier than would have been the case for smaller gaps.

One might wonder why the averaging over states we have performed by going to the grand canonical ensemble has not led to a smoothing of the sporadic behavior, in the way that ensemble averaging does for random matrix theory and SYK. The reason is that every state in the ensemble has exactly the same spectrum, albeit with different degeneracies. Our ensemble average therefore does not have the same effect as the averaging over different spectra that produces smoothing in random matrix theory and SYK. Thus, to obtain smooth late-time behavior, we will need another way of coarse graining, to which we turn next.

3 Random matrices and progressive time-averaging

The sporadic late-time fluctuations of the two-point correlation function (2.9) are reminiscent of similar behavior found in [16] for the SYK model. There, smooth curves were obtained by averaging over random couplings. The main object of study in [16] was the spectral form factor

$$F_\beta(t) = \sum_{m,n} e^{-\beta(E_m + E_n)} e^{-i(E_m - E_n)t}, \tag{3.1}$$

where the sum runs over all the eigenvalues E_n of a Hamiltonian drawn from an ensemble. The spectral form factor displays sporadic late-time behavior, which can be smoothed by averaging over the ensemble of Hamiltonians. The main result of [16] is that the result agrees very well with the spectral form factor in random matrix theory, again after averaging over the random Hamiltonians. One motivation for studying the spectral form factor is

found in the spectral decomposition of the thermal two point function,

$$\langle O(t)O(0) \rangle \sim \sum_{m,n} |\langle m|O(0)|n \rangle|^2 e^{-\beta E_m + i(E_m - E_n)t}. \quad (3.2)$$

It is believed that the late-time behavior is controlled by the phases $e^{i(E_m - E_n)t}$, so that some features of the two point function in this regime are captured by the spectral form factor (3.1). Another motivation is that the spectral form factor is a more primitive quantity than two-point functions, in that it can be obtained directly from the partition function and does not require the introduction of operators. As a result, it can be straightforwardly studied in random matrix theory.

Our D1-D5 CFT has a definite Hamiltonian, so we cannot resort to disorder averaging for smoothing the sporadic late-time behavior of two-point functions. Is there any other meaningful way in which the late-time oscillations can be smoothed? A natural idea is to coarse-grain the correlator over time. One quickly notices, however, that averaging with any fixed time window either fails to remove the late-time oscillations or significantly distorts the early-time decay. This leads to the idea of using a time-window that grows with time, which we refer to as progressive time-averaging. In order to motivate a specific prescription we turn to random matrix theory. We will ask whether the well-known result of ensemble averaging could be alternatively obtained by progressive time-averaging applied to a single Hamiltonian drawn from the ensemble. We will find that this is the case for a time window that grows linearly with time, which will motivate our use of this procedure in the context of the D1-D5 CFT.

3.1 Ergodicity in random matrix theory

We consider Hamiltonians that are $L \times L$ matrices drawn from a random matrix ensemble. An important phenomenon in random matrix theory is self-averaging of certain quantities, i.e. the agreement of a quantity evaluated on a typical instance of the ensemble with the ensemble average of the same quantity. An interesting generalization of self-averaging quantities are ergodic quantities. For ergodic quantities the result of averaging over random Hamiltonians can be approximately reproduced by using a single Hamiltonian drawn from the ensemble and coarse-graining in time.

It is known in random matrix theory that the spectral form factor is self-averaging for sufficiently short times but not for longer times [22]. On the other hand, we can study the ergodicity of the form factor by considering suitable time averages

$$\bar{F}_\beta(t, \Delta t) = \int_{-\infty}^{\infty} dt' g(t - t', \Delta t) F_\beta(t'), \quad (3.3)$$

where $g(t, \Delta t)$ is some smearing function with peak at $t = 0$, width Δt and $\int dt g(t, \Delta t) = 1$. We could imagine it to be a Gaussian

$$g(t, \Delta t) = \frac{1}{\sqrt{2\pi}\Delta t} e^{-\frac{t^2}{2(\Delta t)^2}}, \quad (3.4)$$

or a step function, but its details should not matter too much. The spectral form factor for a Gaussian random matrix ensemble, which is related to the late time behavior of the SYK model, is not ergodic for any fixed time window Δt [22].³

3.2 Progressive time-averaging

We will now provide evidence suggesting that a progressive time average with $\Delta t \sim t$ gives a good approximation to the ensemble average for Gaussian random matrices. This is equivalent to averaging over fixed windows in $\log t$. We first present a heuristic motivation, followed by numerical evidence.

In Gaussian random matrix ensembles, the probability distribution for the difference of two neighboring energy levels $s = E_{n+1} - E_n$ with $s > 0$ is given by [24]

$$p(s) = \frac{A}{s_0} \left(\frac{s}{s_0}\right)^\beta e^{-\alpha\left(\frac{s}{s_0}\right)^2}, \tag{3.5}$$

where s_0 is the average value of s , A is the normalization, and the constants α and β depend on the specific ensemble. In the spectral form factor (3.1), the phases $\exp(\pm ist)$ appear with the same weight and so add to give a term proportional to $\cos(st)$. Let us ask what happens to this cosine upon ensemble averaging:

$$\int_0^\infty ds p(s) \cos(st) \sim \partial_t^\beta e^{-\frac{s_0^2 t^2}{4\alpha}}. \tag{3.6}$$

We see a cancellation of the random phases in the average, resulting in Gaussian decay. Can we reproduce this with a time average? Consider for example a Gaussian smearing function applied to a typical phase $e^{is_0 t}$ and its conjugate:

$$\int_{-\infty}^\infty dt' \frac{1}{\sigma} e^{-\frac{(t-t')^2}{2\sigma^2}} \cos(s_0 t') \sim \cos(s_0 t) e^{-\frac{s_0^2 \sigma^2}{2}}. \tag{3.7}$$

We see that we need to set $\sigma = \frac{t}{\sqrt{2\alpha}}$ in order to reproduce the decay of the ensemble average. At the qualitative level the argument depends relatively little on the smearing function. For instance, for a step function we find

$$\frac{1}{\sigma} \int_{t-\sigma/2}^{t+\sigma/2} dt \cos(s_0 t) = 2 \cos(s_0 t) \frac{\sin\left(\frac{s_0 \sigma}{2}\right)}{s_0 \sigma}, \tag{3.8}$$

which for $\sigma \sim t$ is again a decaying function with width of order $\frac{1}{s_0}$.

The argument above focuses on time dependences associated to differences of *neighboring* energy levels rather than generic energy differences, so that we may really trust it only at very late times. While it would be interesting to find a more precise analytic argument, in the present paper we will simply use the heuristic argument as motivation, verify numerically that the resulting prescription produces good results in random matrix theory, and then apply it to our system of interest.

³Note that for sufficiently large, fixed values of Δt and L the spectral form factor is ergodic for circular ensembles [23].

Figure 2. Log-log plot of the spectral form factor (3.1) with $\beta = 1$ for a single 1024×1024 matrix drawn from the Gaussian Unitary Ensemble (GUE). The early part is self-averaging but the late part is superseded by noise.

Now we present numerical evidence suggesting that the progressive time-average with window $\Delta t \sim t$ of the spectral form factor (3.1) is ergodic. We work with 1024×1024 matrices and — for numerical speed up — discretized time averages

$$\bar{F}_\beta(t, \Delta t) = \frac{1}{100} \sum_{k=-50}^{49} F_\beta \left(t + \frac{k}{100} \Delta t \right). \quad (3.9)$$

We draw a single pseudorandom Hermitian matrix H from the Gaussian Unitary Ensemble (GUE), $p(H) = \frac{1}{2^{L/2} \pi^{L^2/2}} e^{-\frac{L}{2} \text{Tr} H^2}$ with $L = 2^{10}$. The spectral form factor for such a single matrix is plotted in figure 2. We see self-averaging for early times which is quickly overtaken by noise for late times.

The ensemble average of the spectral form factor for Gaussian ensembles is a well studied quantity. In particular, it behaves universally for large L , exhibiting an early slope from an initial value $\sim L^2$, followed by a dip, a linear rise over time scale $\sim L$, and finally a plateau which is the infinite-time average and is of order L [25]. We plot this ensemble average for 500 random matrices in figure 3 and figure 4, with the results of time-averaging for a single matrix drawn from GUE superposed, with various fixed windows and a progressive window $\Delta t = 0.8t$, respectively.⁴ It is clear that the progressive time window provides a much better approximation to the ensemble average than the fixed time windows.

⁴The order one coefficient in front of t should be smaller than 2 because otherwise, in (3.9), we are calculating the total integral of the function. Other than this constraint, the late part of the ramp and the plateau are rather insensitive to this coefficient, as follows from the argument presented around (3.6). On the other hand, the location of the dip depends slightly on the choice of the coefficient. The coefficient could be tuned to minimize deviations from the early self-averaging part of the curve in order extract the dip time.

Figure 3. Log-log plot of the average spectral form factor with $\beta = 1$ for five hundred 1024×1024 matrices drawn from the Gaussian unitary ensemble (GUE) (black), and the sliding window average (3.9) with fixed time windows $\Delta t = 10, 60, 110, 160$ (color) for a single instance of a random matrix. Notice that for averaging with a fixed time window there is tension between preserving the dip and having a sufficiently smooth ramp and plateau.

Figure 4. Log-log plot of the average spectral form factor with $\beta = 1$ for five hundred 1024×1024 matrices drawn from the Gaussian unitary ensemble (GUE) (purple), and the sliding window average (3.9) for a progressive time window $\Delta t = 0.8t$ (blue) for a single instance of a random matrix. The progressive window captures the behavior of the ensemble average, in particular the dip, the ramp and the plateau.

4 Echoes of chaos in D1-D5 two-point functions

Our examination of the D1-D5 theory at the orbifold point will focus on the regularized Lorentzian two-point function (2.9) evaluated at temporal distance t and equal location in space:

$$\hat{G}(t) = \frac{1}{N} \sum_{n=1}^N n N_n \sum_{k=0}^{n-1} \frac{\sin^4 \frac{t}{2}}{n^4 \sin^2 \left(\frac{t+2\pi k}{2n} \right) \sin^2 \left(\frac{t-2\pi k}{2n} \right)} \equiv \frac{1}{N} \sum_{n=1}^N N_n C_n(t). \quad (4.1)$$

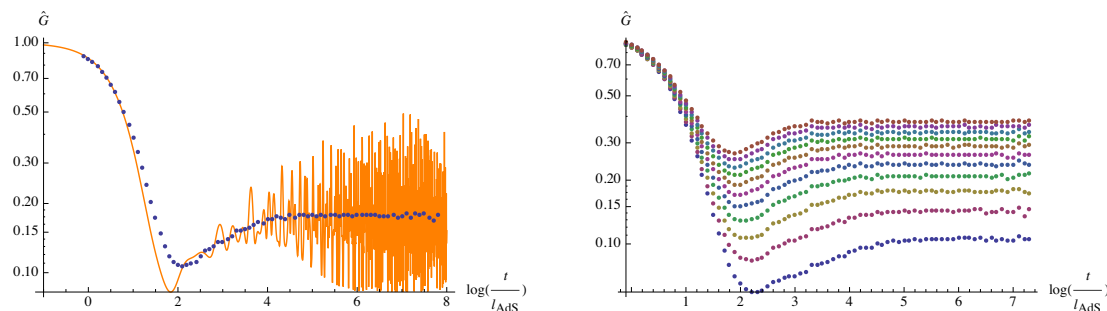

Figure 5. Left: the continuous orange line represents the regularized two-point function (4.1). The blue dotted line is its progressive time-average. Right: the progressive time-average of (4.1) for $\eta = 0.05 + 0.025j$, $j = 0, \dots, 10$. Smaller values of η correspond to larger N and smaller plateau height.

We start by applying the progressive time average of the previous section to this two point function. For numerical simplicity, we will use the pointwise averaging⁵ of (3.9) with $\Delta t = t$. The results are presented in figure 5. The smoothed curve has a dip that is lower than the late time average (plateau), which it reaches after climbing a ramp whose length increases with N . This is in qualitative agreement with random matrix theory and the SYK model. The remainder of this section is devoted to an analytic study of the late time ramp and plateau, highlighting the quantitative differences from random matrix theory.

In the following, we will find two ways of rewriting $C_n(t)$ useful. The first was obtained in [21] by explicitly evaluating the sum over k :

$$C_n(t) = 2n \left(\frac{\sin \frac{t}{2}}{n \sin \frac{t}{n}} \right)^2 \left(1 + \frac{\sin t}{n \tan \frac{t}{n}} \right). \quad (4.2)$$

The second rewriting (worked out in appendix A) will be handy for deriving analytically the late-time behavior of the correlator (4.1). In addition, it emphasizes the similarity between the D1-D5 two-point function and the spectral form factor:

$$C_n(t) = \frac{1}{n^3} \sum_{m_1=0}^{2n-2} \sum_{m_2=0}^{2n-2} \rho_n(m_1) \rho_n(m_2) e^{it \frac{(m_1 - m_2)}{n}} \mathcal{G}_n(m_1 + m_2 + 2). \quad (4.3)$$

Here the ‘spectral weights’ follow a ‘triangle law’ (see figure 6)

$$\rho_n(m) = \begin{cases} m + 1 & m < n \\ 2n - 1 - m & m \geq n \end{cases} \quad (4.4)$$

and

$$\mathcal{G}_n(x) = \begin{cases} n & n \text{ divides } x \\ 0 & \text{otherwise.} \end{cases} \quad (4.5)$$

Below, we analyze the behavior of (4.1) after progressive time-averaging.

⁵One might expect a Gaussian kernel to produce smoother curves but it is numerically more challenging.

Figure 6. The spectral weights (4.4) follow a ‘triangle law’.

4.1 Plateau

At very late times, the progressive time averages of the quantities $C_n(t)$ tend to limiting values:

$$\bar{C}_n = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T dt C_n(t) = \frac{1}{n^3} \sum_{m=0}^{2n-2} \rho_n(m)^2 \mathcal{G}_n(2m+2). \quad (4.6)$$

The function $\mathcal{G}_n(2m+2)$ vanishes unless $2m+2$ is a multiple of n . This requires that

$$m = \frac{n}{2} - 1, n-1, \frac{3n}{2} - 1 \quad (4.7)$$

for even n and $m = n-1$ for odd n . This leads to

$$\bar{C}_{n(\text{even})} = \frac{3}{2} \quad \text{and} \quad \bar{C}_{n(\text{odd})} = 1, \quad (4.8)$$

from which we obtain:

$$\bar{G} \equiv \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T dt \hat{G}(t) = \frac{1}{N} \left(\frac{3}{2} \sum_{n \text{ even}}^N N_n + \sum_{n \text{ odd}}^N N_n \right) = \frac{1}{N} \left(\sum_{\text{all } n}^N N_n + \frac{1}{2} \sum_{n \text{ even}}^N N_n \right). \quad (4.9)$$

We may approximate \bar{G} for the typical state using the grand canonical ensemble in which the total twist N is fixed with a chemical potential η according to equations (2.3) and (2.4). In this approximation, we may let the sums in (4.9) run to infinity,

$$\bar{G} \approx \frac{1}{N} \left(\sum_{s=1}^{\infty} \frac{8}{\sinh(\eta s)} + \frac{1}{2} \sum_{s=1}^{\infty} \frac{8}{\sinh(2\eta s)} \right), \quad (4.10)$$

and then, when N is large, approximate them with integrals:

$$\bar{G} \approx \frac{1}{N} \cdot \frac{8}{\eta} \int_{\delta\eta}^{\infty} \frac{du}{\sinh u} + \frac{1}{N} \cdot \frac{1}{2} \cdot \frac{8}{2\eta} \int_{2\delta\eta}^{\infty} \frac{du}{\sinh u}. \quad (4.11)$$

Here δ is an $O(1)$ number that parameterizes the discretization error at the lower limit. Evaluating the integrals gives:

$$\bar{G} \approx \frac{8\eta}{2\pi^2} \left[\log \coth \left(\frac{\eta\delta}{2} \right) + \frac{1}{4} \log \coth(\eta\delta) \right]. \quad (4.12)$$

Remembering that $\delta = O(1)$ and $\eta = O(1/\sqrt{N})$, we further approximate and get:

$$\bar{G} \approx \frac{5\eta}{\pi^2} \log\left(\frac{1}{\eta}\right) + O(1). \tag{4.13}$$

Thus, at late times, the coarse-grained temporal 2-point function approaches a constant plateau that scales as $\log(\sqrt{N})/\sqrt{N} \sim \log(S)/S$, where S is the entropy of the black hole.

4.2 Ramp

To exhibit the ramp behavior of the correlator (4.1), we again employ progressive time averaging. For numerical convenience, we use a simple step-function averaging reminiscent of eq. (3.9):

$$\tilde{G}(t) = \frac{1}{t} \int_{t/2}^{3t/2} dt' \hat{G}(t'). \tag{4.14}$$

The progressively time-averaged $\tilde{G}(t)$ decomposes into progressively time-averaged contributions from individual modes,

$$\tilde{G}(t) = \frac{1}{N} \sum_n N_n \tilde{C}_n(t), \tag{4.15}$$

each of which takes the form:

$$\tilde{C}_n(t) = \frac{1}{t} \cdot \frac{2}{n} \int_{t/2}^{3t/2} \left(\frac{\sin t'/2}{\sin t'/n}\right)^2 \left(1 + \frac{\sin t'}{n \tan t'/n}\right) dt'. \tag{4.16}$$

This rewriting follows from eq. (4.2).

An intuitive approach to estimate the ramp is to recognize that for each individual n , the contribution of $\tilde{C}_n(t)$ to the correlator jumps fairly quickly from the low point in the dip to the plateau. This is because there is only one timescale, as the gap (which sets the plateau time as $\gamma \times 1/\text{gap}$ for some constant γ) and the level spacing are the same.⁶ We also know from the above that for odd n the contribution to the plateau is 1 and for even n it is 3/2. This suggests that we can write the ramp part of the correlator as:

$$\tilde{G}(t) \approx \frac{1}{N} \left(\frac{3}{2} \sum_{n \text{ even}}^{t/\gamma} N_n + \sum_{n \text{ odd}}^{t/\gamma} N_n \right) = \frac{1}{N} \left(\sum_{\text{all } n}^{t/\gamma} N_n + \frac{1}{2} \sum_{n \text{ even}}^{t/\gamma} N_n \right). \tag{4.17}$$

In this equation we have taken into account that by a time t the contribution of any n with $n < t/\gamma$ will have hit its plateau, and we approximate the other modes as being 0. Here γ is some $O(1)$ number that relates the scale of the gap to the precise timescale of the plateau. This may depend on the spectrum and on the operator. The sum includes a unit contribution from the plateau for any n and the second sum includes the additional 1/2 that is present for even n . Putting in the occupation numbers, we get

$$\tilde{G}(t) = \frac{1}{N} \sum_{n=1}^{t/\gamma} \frac{8}{\sinh(\eta n)} + \frac{1}{N} \sum_{n=1}^{t/(2\gamma)} \frac{1}{2} \frac{8}{\sinh(2\eta n)}. \tag{4.18}$$

We plot this function on top of the time averaged two point function on figure 7 with⁷

⁶For further justification of this intuition and a slight improvement of the simple estimate below, see appendix B.

⁷To see better why this value works so well, see appendix B.

Figure 7. The estimate (4.18) for the ramp and the plateau with $\gamma = 2$ (solid lines) versus the numerically evaluated progressive time averaged regularized two point function (dots) for $\eta = 0.05, 0.075, 0.1, 0.125, 0.15, 0.175$ (from bottom to top).

$\gamma = 2$. For large N we again approximate the sum as an integral,

$$\sum_{n=1}^{\tau} \frac{8}{\sinh(\eta n)} \approx \frac{8}{\eta} \log \left[\frac{\tanh\left(\frac{\tau\eta}{2}\right)}{\tanh\left(\frac{\delta\eta}{2}\right)} \right]. \quad (4.19)$$

For the first sum $\tau = t/\gamma$ and for the second sum $\tau = t/(2\gamma)$. Also, note that η in second sum is multiplied by a factor of 2. Putting this all together and doing some elementary algebra gives

$$\tilde{G}(t) = \frac{5\eta}{\pi^2} \log \left[\frac{1}{\eta\delta} \tanh\left(\frac{t\eta}{2\gamma}\right) \right] + \frac{8\eta}{2\pi^2} \log 2, \quad (4.20)$$

where we can ignore the last term for our purposes. The characteristic time scale is the plateau time $t_p \sim 1/\eta \sim \sqrt{N}$.

Let us understand the time dependence. First, note that t cannot be taken to zero since the integral approximation is invalid in that case. Thus, t is at least $\mathcal{O}(1)$ and $\tilde{G}(t) \geq 0$. We can consider two useful limits. First

$$1 < t \ll \sqrt{N} : \quad \tilde{G}(t) = \frac{5\eta}{\pi^2} \log \frac{t}{\gamma\delta}, \quad (4.21)$$

so the ramp rises logarithmically, in contrast to the linear rise for random matrices. In this range,

$$1 < t \ll \sqrt{N} : \quad \frac{d\tilde{G}}{dt} \sim \frac{\eta}{t} \sim \frac{1}{t\sqrt{N}}. \quad (4.22)$$

As a check also note that at late times

$$t \gg \sqrt{N} : \quad \tilde{G}(t) = \frac{5\eta}{\pi^2} \log \frac{2}{\eta\delta}, \quad (4.23)$$

which reproduces the plateau value from eq. (4.13).

From (4.22), we see that when $t \sim O(1)$, then $d\tilde{G}/dt \sim O(1/\sqrt{N})$, while when $t \sim O(\sqrt{N})$ at central times in the ramp, $d\tilde{G}/dt \sim 1/N$. So the plateau height will be parametrically controlled by $d\tilde{G}/dt$ at central times in the ramp, multiplied by the duration of the ramp (which is determined by the inverse of the typical gap size, which is $1/\sqrt{N}$). This gives the estimate $1/N \times \sqrt{N} \sim 1/\sqrt{N}$ for the plateau height. The more rapid growth with slope of $O(1/\sqrt{N})$ in the early part of the ramp gives a logarithmic correction, resulting in a plateau height of $\log N/\sqrt{N} \sim \eta \log(1/\eta)$.

4.3 Dip

In this subsection, we consider the temporal coarse graining of (4.1) with generic progressive time window of width $\Delta t = at$ (generalizing (4.14)), which we will denote by

$$\tilde{G}_a(t) = \frac{1}{at} \int_{t-at/2}^{t+at/2} dt' \hat{G}(t'). \quad (4.24)$$

Such a generalization does not modify the conclusions about the late part of the ramp and the plateau time. However, we do expect the precise location of the dip to be sensitive to the parameter a and therefore the specific coarse graining that we pick. As we will see, the scaling with the entropy is independent of a .

The strategy we use is to approximate (4.24) as the sum of the contribution coming from the regularized $M = 0$ BTZ two point function [21]⁸

$$\hat{G}_{\text{BTZ}}(t) = 2 \sin^2\left(\frac{t}{2}\right) \frac{t + \sin t}{t^3}, \quad (4.25)$$

and our ramp estimate (4.20), i.e.

$$\tilde{G}_a(t) \approx \frac{1}{at} \int_{t-at/2}^{t+at/2} dt' \hat{G}_{\text{BTZ}}(t') + \frac{5\eta}{\pi^2} \log\left[\frac{1}{\eta\delta} \tanh\left(\frac{t\eta}{2\gamma}\right)\right] + \frac{8\eta}{2\pi^2} \log 2. \quad (4.26)$$

We illustrate on the left of figure 8 how remarkably well this naive estimate works. The very precise match indicates that there is no extra physics going on at intermediate time scales.

In order to extract the dip time, we want to find the minimum of this curve. Let us assume that the dip happens at $1 \ll t_d \ll \sqrt{N}$. In this case, we can approximate the ramp part with the logarithmic rise of (4.21). On the other hand, the BTZ part asymptotes to⁹

$$\frac{1}{at} \int_{t-at/2}^{t+at/2} dt' \hat{G}_{\text{BTZ}}(t') \approx \frac{4}{4-a^2} \frac{1}{t^2}, \quad t \gg 1, \quad a < 2, \quad (4.27)$$

so that for times $1 \ll t \ll \sqrt{N}$ we have

$$\tilde{G}_a(t) \approx \frac{4}{4-a^2} \frac{1}{t^2} + \frac{5\eta}{\pi^2} \log \frac{t}{\gamma\delta}, \quad (4.28)$$

⁸To arrive at this expression, take (2.14) of [21], set $w = -\bar{w} = -t$ and divide by the two point function in the NS vacuum.

⁹For $a \geq 2$ the asymptote crosses over to $1/t$. In this case, the lower end of the integral moves to the left, so we no longer have a good temporal coarse graining.

Figure 8. Left: the black dots represent the progressive time-average of the regularized two point function (4.1), the blue line is the progressive time-average of the BTZ two point function (4.25), the yellow line is the ramp estimate (4.18), while the green line is the sum of the latter two, i.e. the function (4.26). Right: same as the left, with the addition of: purple line is the BTZ asymptote (4.27); the dark orange line is the curve (4.28). Both figures are for $\eta = 0.005$ and use $\gamma = 2$, $\delta = 0.55$ and $a = 1$.

see the right panel of figure 8 for an illustration. The minimum of this curve is at

$$t_d = \sqrt{\frac{8\pi^2}{5(4-a^2)\eta}}, \tag{4.29}$$

which scales as $t_d \sim \sqrt{S}$ with the entropy. Note that we indeed have $1 \ll t_d \ll \sqrt{N}$. This establishes a parametrically long ramp. Notice that we have $t_d \sim \sqrt{t_p}$ which is also valid for random matrices.

4.4 Variances

Eqs. (4.13) and (4.18) apply to the typical Ramond ground state of the D1-D5 system. We may ask by how much other Ramond ground states differ from these typical values.

We start by considering eigenstates of the occupation numbers N_n . The middle expression in eq. (4.17) casts $\tilde{G}(t)$ as a linear combination of distinct occupation numbers N_n , which in the grand canonical ensemble are independent random variables. Thus, the variance in the ramp part of progressively time-averaged correlator, $\tilde{G}(t)$, can be approximated in terms of variances in N_n :

$$\text{var } \tilde{G}(t) \approx \frac{1}{N^2} \left(\frac{9}{4} \sum_{n \text{ even}}^{t/\gamma} \text{var } N_n + \sum_{n \text{ odd}}^{t/\gamma} \text{var } N_n \right). \tag{4.30}$$

Using

$$\text{var } N_{n\mu} = \frac{e^{\eta n}}{(e^{\eta n} - 1)^2} \quad \text{and} \quad \text{var } N'_{n\mu} = \frac{e^{\eta n}}{(e^{\eta n} + 1)^2}, \tag{4.31}$$

we get:

$$\text{var } N_n = \frac{8 \cosh \eta n}{\sinh^2 \eta n}. \tag{4.32}$$

Substituting, we obtain:

$$\begin{aligned} \text{var } \tilde{G}(t) &\approx \frac{8}{N^2} \left(\frac{1}{\eta} \int_{\eta\delta}^{\eta t/\gamma} \frac{du \cosh u}{\sinh^2 u} + \frac{5}{4} \cdot \frac{1}{2\eta} \int_{2\eta\delta}^{\eta t/\gamma} \frac{du \cosh u}{\sinh^2 u} \right) \\ &= \frac{8}{N^2\eta} \left(\frac{1}{\sinh \eta\delta} + \frac{5}{8 \sinh 2\eta\delta} - \frac{13}{8 \sinh \eta t/\gamma} \right). \end{aligned} \quad (4.33)$$

The variance in the plateau height is obtained by taking the late time limit of the above expression:

$$\text{var } \tilde{G}(\infty) \approx \left(\frac{\eta^2}{2\pi^2} \right)^2 \cdot \frac{8}{\eta} \left(\frac{1}{\sinh \eta\delta} + \frac{5}{8 \sinh 2\eta\delta} \right) \propto \eta^2, \quad (4.34)$$

where we have expanded in small η (large N) in the last expression. So the standard deviation in the plateau height divided by the mean (4.13) scales as $1/\log(1/\eta) \sim 1/\log N$. Note that the primary sources of the deviation are the ‘relatively short long strings’ with $n \gtrsim 1$.

We can also estimate the variance of the slope of the ramp. From (4.17), we recognize that after sufficient coarse-graining, $d\tilde{G}(t)/dt \propto N_{t/\gamma}/N$. Therefore,

$$\text{var} \left(\frac{d\tilde{G}(t)}{dt} \right) \propto \frac{\text{var } N_{t/\gamma}}{N^2} \propto \frac{\eta^4 \cosh(\eta t/\gamma)}{\sinh^2(\eta t/\gamma)}. \quad (4.35)$$

At central times in the ramp $t \sim \sqrt{N}$. Since $\eta \sim 1/\sqrt{N}$ this means that the hyperbolic functions on the right hand side are $O(1)$. So the standard deviation in the slope is $O(1/N)$. At central times in the ramp, we showed above that the slope is also $O(1/N)$. Thus the slope varies significantly between occupation number eigenstates.

However, a typical Ramond ground state is a *superposition* of these eigenstates. Since $\tilde{G}(t)$ is not an eigenvalue, but an expectation value of a quantum mechanical operator, it makes sense to discuss the variances among all ensemble members, including superpositions. Such a variance, with superposition states weighted with a uniform measure over $\mathbb{C}\mathbb{P}^{\exp S}$, was computed in [26]. This paper showed that the variance in the expectation value of a quantum mechanical operator is suppressed relative to the variance among its eigenstates by an extra factor of the dimension of the Hilbert space. Thus, all the variances computed in the preceding paragraphs receive an additional factor:

$$\text{var}_{\text{superpositions}} = e^{-S} \text{var}_{N_n \text{ eigenstates}} = e^{-2\pi\sqrt{2N}} \text{var}_{N_n \text{ eigenstates}}. \quad (4.36)$$

Thus we can conclude that over the entire Hilbert space, almost all states will show a coarse-grained two point function that lies very close to the results that we have computed in the typical state.

5 Discussion

We have studied the time-ordered two-point correlation function of certain operators in typical states of the Ramond sector of the D1-D5 CFT. At strong coupling these are black hole microstates and the theory is expected to be chaotic. Here, we studied the weak coupling

limit of this theory, where it is integrable. After temporal coarse-graining, the late time two-point function displays a characteristic dip, ramp and plateau. These features are remarkably similar to those seen in random matrix theory (RMT) and the SYK model, showing that the qualitative form does not specifically arise from the chaos present in those models.

A key quantitative difference is that the slopes of the ramps in RMT and SYK are constant, while in our model the slope decreases with time. Also, while the RMT and SYK plateaus are exponentially suppressed in the entropy S , our plateau scales as $\log S/S$. Finally, the plateau in RMT and SYK is reached at a time that is exponential in the entropy, while in our case it is reached at times proportional to the entropy.

These quantitative differences arise from the different structures of the excitation spectra. In a chaotic theory the energy eigenvalues are typically non-degenerate and have spacings that are exponentially small in the entropy. Random matrix theories also demonstrate a phenomenon of spectral rigidity, in which repulsion between eigenvalues of the Hamiltonian produces long-range correlations in the spectrum. The exponentially small gap leads to the exponentially large plateau time, and the linear ramp is partially a consequence of the spectral rigidity [16]. By contrast, although the D1-D5 theory at the orbifold point has a dense spectrum, there is a very large degeneracy of each energy level and the gaps are not exponentially small. This leads to a much shorter timescale for the plateau. The plateau is also much higher because the theory explores its phase space less completely than a chaotic model.

The authors of [27] argue that in general 2d CFTs, the dip occurs at times proportional to the entropy. Likewise the authors of [28] predict a breakdown of the semiclassical description of the two point function at entropy times. (See also [29] for related work in the context of the D1-D5 system.) In contrast, the location of our dip scales with the entropy as \sqrt{S} . The reason for the difference is that all of these works address finite temperature states, and require generalization to apply to the zero temperature, large entropy system that we examine.¹⁰ It would also be useful to see what the results in [27, 28] imply for the late time, finite temperature two-point function in the orbifold D1-D5 theory.

It would be very interesting to see how these phenomena change as the D1-D5 theory is deformed from the integrable point that we studied to the strongly coupled region where it is expected to be chaotic and dual to weakly coupled AdS₃ gravity. One strategy for making progress is to turn on this marginal deformation perturbatively [30], although it may be challenging to sum the perturbation series with sufficient accuracy to capture the late time physics. Another interesting avenue is to consider correlation functions of twist operators that induce interaction between the long string components of the state. The resulting mixing should break degeneracies between energy levels and lead to much smaller gaps. This will in turn lead to much longer timescales for the ramp and the plateau in the two point function.

¹⁰In SYK, the range of parameters where there is both chaotic behavior and IR conformal symmetry is $1 \ll \beta J \ll N$, where β is the inverse temperature and J is the coupling [11]. We see that in the zero temperature limit we need to switch off the coupling to stay in this regime. Our situation is somewhat similar to this.

A D1-D5 two-point functions echo the spectral form factor

To highlight the similarity between

$$\hat{G}(t) = \frac{1}{N} \sum_{n=1}^N n N_n \sum_{k=0}^{n-1} \frac{\sin^4 \frac{t}{2}}{n^4 \sin^2 \left(\frac{t+2\pi k}{2n} \right) \sin^2 \left(\frac{t-2\pi k}{2n} \right)} \equiv \frac{1}{N} \sum_{n=1}^N N_n C_n(t) \quad (\text{A.1})$$

and the spectral form factor, we start by noting that

$$\frac{\sin \frac{t}{2}}{\sin \left(\frac{t-2\pi k}{2n} \right)} = (-1)^k \frac{q^n - q^{-n}}{q - q^{-1}} = (-1)^k \sum_{\ell=0}^{n-1} q^{2\ell+1-n} = (-1)^k \sum_{\ell=0}^{n-1} e^{i \frac{t-2\pi k}{2n} (2\ell+1) - i \frac{t-2\pi k}{2}}, \quad (\text{A.2})$$

where $q = \exp \left(i \frac{t-2\pi k}{2n} \right)$. Substituting into (A.1) yields

$$C_n(t) = \frac{1}{n^3} \sum_{\ell_1, \ell_2, \ell'_1, \ell'_2=0}^{n-1} e^{i \frac{\ell_1 + \ell'_1 - \ell_2 - \ell'_2}{n} t} \mathcal{G}_n(\ell_1 + \ell'_1 + \ell_2 + \ell'_2 + 2) \quad (\text{A.3})$$

with

$$\mathcal{G}_n(x) = \sum_{k=0}^{n-1} e^{2\pi i \left(2 - \frac{x}{n} \right) k} = \frac{e^{-2\pi i x} - 1}{e^{-2\pi i \frac{x}{n}} - 1}. \quad (\text{A.4})$$

Because x only takes integer values in (A.3), we effectively have $\mathcal{G}_n(x) = \sum_{q \in \mathbb{Z}} n \delta_{qn, x}$, which is eq. (4.5) in the main text.

Since the summand in (A.3) depends only on the combinations $m_1 = \ell_1 + \ell'_1$ and $m_2 = \ell_2 + \ell'_2$, we change two of the summation variables to these new variables. We exchange the sums according to

$$\sum_{\ell_1=0}^{n-1} \sum_{m_1=\ell_1}^{\ell_1+n-1} = \sum_{m_1=0}^{n-1} \sum_{\ell_1=0}^{m_1} + \sum_{m_1=n}^{2n-2} \sum_{\ell_1=m_1-n+1}^{n-1} = \sum_{m_1=0}^{n-1} (m_1+1) + \sum_{m_1=n}^{2n-2} (2n-1-m_1), \quad (\text{A.5})$$

where in the last step we perform the ℓ_1 sums as the (suppressed) summand does not depend on it. After a similar manipulation for ℓ_2 and m_2 , we find

$$C_n(t) = \frac{1}{n^3} \sum_{m_1=0}^{2n-2} \sum_{m_2=0}^{2n-2} \rho_n(m_1) \rho_n(m_2) e^{i t \frac{(m_1 - m_2)}{n}} \mathcal{G}_n(m_1 + m_2 + 2), \quad (\text{A.6})$$

where the spectral weights are given by

$$\rho_n(m) = \begin{cases} m + 1 & m < n \\ 2n - 1 - m & m \geq n. \end{cases} \quad (\text{A.7})$$

We plot this function in figure 6.

B More detailed ramp estimate

For all except very small values of n , the quantities $\tilde{C}_n(t)$ defined in (4.16) show a universal behavior.¹¹ Following a rapid decay from their initial values, the $\tilde{C}_n(t)$ hover near zero for a time $\sim 0.67n\pi$. At that time, the even n quantities undergo one sharp jump to near their asymptotic value of $3/2$ and, thereafter, many smaller jumps and gentle decays that keep the $\tilde{C}_n(t)$ near $3/2$. For odd n , the $\tilde{C}_n(t)$ rise to near their asymptotic value of 1 in two distinct sharp jumps that happen at approximately $0.67n\pi$ and $1.34n\pi$, also followed by many smaller jumps and gentle decays which keep the $\tilde{C}_n(t)$ near 1 . We have not derived these statements analytically, but they are manifest from the plots in figure 9.

As a coarse approximation to the time dependence of $\tilde{G}(t)$, we may model the $\tilde{C}_n(t)$ as simple step functions:

$$C_{n \text{ even}} = \frac{3}{2}\Theta(t - 0.67n\pi) \quad \text{and} \quad C_{n \text{ odd}} = 0.54\Theta(t - 0.67n\pi) + 0.46\Theta(t - 1.34n\pi). \quad (\text{B.1})$$

In this treatment, the ramp is built up as successive modes shoot up from zero to their final values. This leads to

$$\tilde{G}(t) \approx \frac{1}{N} \left(\frac{3}{2} \sum_{n \text{ even}}^{t/0.67\pi} N_n + 0.54 \sum_{n \text{ odd}}^{t/0.67\pi} N_n + 0.46 \sum_{n \text{ odd}}^{t/1.34\pi} N_n \right). \quad (\text{B.2})$$

As a next step, we substitute the occupation numbers for the typical state and replace the sums with integrals. After these approximations, it will not be meaningful to keep track of the various $\mathcal{O}(1)$ coefficients appearing in (B.2). Thus, we introduce a single $\mathcal{O}(1)$ coefficient γ that parameterizes the average rate at which the successive modes join the ramp:

$$\tilde{G}(t) \approx \frac{1}{N} \cdot \frac{5}{4} \sum_{n=1}^{t/\gamma} \frac{8}{\sinh \eta n} \approx \frac{10}{N\eta} \int_{\delta\eta}^{t\eta/\gamma} \frac{du}{\sinh u} = \frac{10}{N\eta} \log \frac{\tanh t\eta/2\gamma}{\tanh \delta\eta/2}. \quad (\text{B.3})$$

The factor of $5/4$ is the average height of the jumps undergone by the even ($3/2$) and odd ($1 = 0.54 + 0.46$) modes. Since $N = 2\pi^2/\eta^2 \gg 1$, this reduces to:

$$\tilde{G}(t) \approx \frac{5\eta}{\pi^2} \log \left(\frac{2}{\delta\eta} \tanh \frac{t\eta}{2\gamma} \right). \quad (\text{B.4})$$

¹¹Most features we discuss are clearly discernible already at $n \gtrsim 10$. We will not need to set the range of n more precisely, because our use of the grand canonical ensemble and approximating sums by integrals are greater sources of error.

Figure 9. The progressively time-averaged correlator contributions of individual modes $\tilde{C}_n(t)$ for even n (left; $n = 100, 500, 1500$) and odd n (right; $n = 101, 501, 1501$). We have also marked the Θ -functions from eq. (B.1).

Abstract: We consider the conformally invariant cubic wave equation on the Einstein cylinder $\mathbb{R} \times S^3$ for small rotationally symmetric initial data. This simple equation captures many key challenges of nonlinear wave dynamics in confining geometries, while a conformal transformation relates it to a self-interacting conformally coupled scalar in four-dimensional anti-de Sitter spacetime (AdS_4) and connects it to various questions of AdS stability. We construct an effective infinite-dimensional time-averaged dynamical system accurately approximating the original equation in the weak field regime. It turns out that this effective system, which we call the *conformal flow*, exhibits some remarkable features, such as low-dimensional invariant subspaces, a wealth of stationary states (for which energy does not flow between the modes), as well as solutions with nontrivial exactly periodic energy flows. Based on these observations and close parallels to the cubic Szegő equation, which was shown by Gérard and Grellier to be Lax-integrable, it is tempting to conjecture that the conformal flow and the corresponding weak field dynamics in AdS_4 are integrable as well.

1. Introduction

Propagation of nonlinear waves in confining geometries presents significant challenges because the key mechanism stabilizing the evolution of waves on unbounded domains, which is the dispersion of energy by radiation, is missing in confined settings. Consequently, an arbitrarily small perturbation of a ground state can lead to complicated long-time behavior. The central physical problem in this context is that of energy transfer, namely, understanding how the energy injected into the system gets distributed over the degrees of freedom in the course of its evolution. This problem has been studied in the physics literature from a statistical viewpoint under the name of wave (weak) turbulence [1, 2], but it has only recently emerged as an active research topic in dispersive PDE theory. In this deterministic mathematical approach, the energy cascades from low to high modes are quantified by the growth of higher Sobolev norms of solutions, and

the main question is whether these norms can become unbounded in finite or infinite time. The past few years have witnessed significant progress in the understanding of this issue in the context of nonlinear Schrödinger equations (and their variations) on tori [3–5]. However, almost nothing is known, as far as we can tell, about manifestations of these phenomena in other interesting evolution equations of mathematical physics.

Our attention in this article will be focused on the weak field dynamics for the conformally invariant cubic wave equation on the three-sphere. This very natural geometrical model describes relativistic scalar waves propagating on a compact manifold and interacting with the background geometry and among themselves. The spherical geometry prevents the waves from dispersing to infinity and thus ensures that the nonlinear self-interactions remain important for all times, inducing complicated energy transfer patterns. Another important circumstance is that all normal mode frequencies of the corresponding linearized theory are integer in appropriate units. Such a fully resonant spectrum ensures that nonlinearities can produce significant effects over long times for arbitrarily small perturbation amplitudes, generating highly nontrivial weak field dynamics.

The weak field dynamics of the system we are considering is closely related to investigations of nonlinear stability of anti-de Sitter (AdS) spacetime initiated in [6] (see [7, 8] for brief reviews and further references). A conformal transformation relates our considerations to the dynamics of the cubic Klein–Gordon equation with mass $m^2 = -2$ (conformally coupled self-interacting probe scalar) on the four-dimensional AdS space. In contrast to the bulk of AdS stability research, we do not consider the backreaction of perturbations on the AdS geometry. However, a number of features of the weak field dynamics remain unaffected by our simplification. (The weak field dynamics of a massless self-interacting probe scalar in AdS was introduced as a toy model for the AdS stability problem in [9].)

Our main tool for analyzing the weak field dynamics, given a fully resonant spectrum of the linearized system, is the time averaging method that goes back to Bogoliubov and Krylov and is described in many books on perturbation theory (e.g., [10]). For a contemporary treatment adapted to studies of nonlinear PDEs, see [11]. Applied to the PDE we are considering, the time averaging method produces a simplified infinite-dimensional dynamical system, which we shall refer to as the *conformal flow*. By standard theorems underlying time averaging, this effective system (in PDE theory sometimes called the *resonant* system) accurately approximates the dynamics of the original PDE for small amplitude fields of order $O(\varepsilon)$ on long time-scales of order $O(1/\varepsilon^2)$, and in particular it accurately captures the energy transfer patterns on such time scales. (Time averaging and related techniques were introduced to the AdS stability problem closely related to our current studies in [12–14].) The conformal flow displays a number of highly special features not apparently present in the original PDE and suggestive of integrability. This includes additional conserved quantities, low-dimensional invariant subspaces, a variety of stationary states without any energy transfer, as well as solutions with exactly periodic energy transfer patterns.

Our original PDE can be viewed as an infinite system of oscillators with integer frequencies and a quartic potential. We do not see any indications that it might be integrable; only the time-averaged system describing its weak field dynamics displays signs of integrability. While extensive searches for quartic integrable systems (i.e., integrable mechanical analogs of our original PDE) have been conducted in the past (see [15] for a review and references to earlier work and [16, 17] for some later contributions), we are

not aware of any broad scans for systems displaying *weak field integrability* of the type suggested by our results.

The conformal flow introduced in this paper bears a strong resemblance to the cubic Szegő equation that has been designed and studied in a series of papers by Gérard and Grellier, of which [18–21] are particularly relevant for our purposes. This equation also emerges as the resonant approximation of a nonlocal transport equation, called the cubic half-wave equation [19], which is a special case of one-dimensional models of wave turbulence introduced in [22]. In [18–21] and related publications, a number of remarkable properties were established for the cubic Szegő equation, in particular, a Lax pair structure, existence of finite-dimensional invariant subspaces, as well as some weak turbulence phenomena. The bulk of our effort will be directed at recovering analogs of a subset of these results for the conformal flow, a system with a natural geometric origin. We furthermore believe that the analogy goes deeper than what we are able to explicitly demonstrate in this article.

There are also close similarities between the conformal flow and resonant approximations for the cubic Schrödinger equation, either with harmonic trapping [23] or in the infinite volume limit on the 2-dimensional torus [24,25]. Another system that shares some properties with the conformal flow and the cubic Szegő equation is the Lowest Landau Level evolution equation, which appears in the studies of rapidly rotating Bose-Einstein condensates (see [26] and references therein). We furthermore mention the curious case of the Charney–Hasegawa–Mima (CHM) equation explored in [11]. Also in that case, effective integrable dynamics emerges in the time-averaged approximation (which the authors call the ‘effective equation’). However, a substantial difference is that the linearized spectrum of the CHM equation is not fully resonant and splits into disconnected resonant clusters. In such a situation, the resulting effective time-averaged system literally separates into independent finite-dimensional integrable subsystems. This simplification does not happen in our case because our linearized spectrum is fully resonant.

We comment on how our work is related to extensive investigations of the last decade in the area of ‘AdS/CFT Integrability’ (see [27] for a review). One of the central ingredients of that line of research is integrability of sigma models (describing string world-sheets) on target spaces involving AdS factors. While we are also presently talking about integrability emerging due to special features of the AdS geometry, there are also essential differences. We are considering a field system evolving in AdS, rather than a sigma model (whose fields are maps from a two-dimensional surface into AdS). We are furthermore not talking about exact integrability of our AdS field system, but rather about the integrability of the effective weak field theory (conformal flow) emerging from it within the standard time-averaged approximation.

Our exposition is organized as follows. In Sect. 2, we formulate our scalar field dynamics on a three-sphere, describe its connection to AdS stability problems and apply time averaging to derive the corresponding effective system, which we name the conformal flow. In Sect. 3, we give a very elementary pragmatic summary of some properties of the cubic Szegő equation relevant in our context, aimed mostly at the physics audience. In Sect. 4, we construct a three-dimensional invariant subspace of the conformal flow and discuss some complex plane properties of the generating functions that encode the conformal flow amplitudes. In Sect. 5, we analyze stationary states of the conformal flow, in which the initial conditions are adjusted to ensure that no energy transfer occurs. In Sect. 6, we exhibit explicit solutions with periodic energy flows on the three-dimensional invariant subspace of the conformal flow and discuss their properties. Finally, in Sect. 7,

we give a summary of what we have practically demonstrated and an outlook on more ambitious directions, keeping the likelihood of Lax-integrability in mind.

2. Conformally Coupled Scalar Field on the Einstein Cylinder and in AdS₄ and Its Weak Field Dynamics

As a simple model of confining geometry we consider the Einstein cylinder, which is the globally hyperbolic spacetime (\mathcal{M}, g) with topology $\mathbb{R} \times \mathbb{S}^3$ and metric

$$g = -dt^2 + r^2 \left(dx^2 + \sin^2 x d\omega^2 \right), \tag{1}$$

where $x \in [0, \pi]$, $d\omega^2$ is the round metric on the unit 2-sphere and r is the radius of \mathbb{S}^3 . This spacetime has a constant scalar curvature $R(g) = 6/r^2$.

As a model of nonlinear dynamics on \mathcal{M} , we consider the semilinear wave equation for the real scalar field $\phi : \mathcal{M} \mapsto \mathbb{R}$

$$\left(\square_g - \frac{1}{6} R(g) \right) \phi - \lambda \phi^3 = 0, \tag{2}$$

where $\square_g := g^{\mu\nu} \nabla_\mu \nabla_\nu$ is the wave operator associated with g and λ is a constant. For concreteness, we assume that $\lambda > 0$ (which corresponds to a defocusing nonlinearity); however, in the small data regime that we focus upon here, all the results below hold true in the focusing case $\lambda < 0$ as well. Due to the identity

$$\left(\square_{\Omega^2 g} - \frac{1}{6} R(\Omega^2 g) \right) (\Omega^{-1} \phi) = \Omega^{-3} \left(\square_g - \frac{1}{6} R(g) \right) \phi, \tag{3}$$

Eq. (2) is conformally invariant. After rescaling $t \rightarrow t/r$ and $\phi \rightarrow r\sqrt{\lambda} \phi$, it takes the dimensionless form

$$\phi_{tt} - \Delta_{\mathbb{S}^3} \phi + \phi + \phi^3 = 0, \tag{4}$$

which can be interpreted as the cubic Klein–Gordon equation on the unit \mathbb{S}^3 with a unit mass. For simplicity, we shall restrict our analysis to rotationally symmetric fields, which depend only on (t, x) . Substituting $\phi(t, x) = v(t, x) / \sin(x)$ into (4) we obtain a nonlinear string equation

$$v_{tt} - v_{xx} + \frac{v^3}{\sin^2 x} = 0, \tag{5}$$

with Dirichlet boundary conditions $v(t, 0) = v(t, \pi) = 0$, which are enforced by regularity of $\phi(t, x)$ on \mathcal{M} .

Remark 1. We could have arrived at the same equation considering the conformally coupled self-interacting scalar (2) in the 4-dimensional anti-de Sitter (AdS₄) spacetime with the metric

$$\tilde{g} = \frac{1}{\cos^2 x} \left(-dt^2 + dx^2 + \sin^2 x d\omega^2 \right), \tag{6}$$

where x varies between 0 and $\pi/2$. Indeed, $g = \cos^2 x \tilde{g}$, hence it follows from (3) that the field redefinition $\tilde{\phi}(t, x) = \phi(t, x) \cos x$ converts Eq. (2) from the Einstein cylinder to AdS. In order to define the evolution, one has to impose a boundary condition at $x = \pi/2$. Here, we shall impose the Dirichlet condition $\phi(\pi/2) = 0$ on the equator,

corresponding to the reflecting boundary conditions most commonly used in the AdS research context. This model is just a subsector of the model on the full Einstein cylinder, which can be implemented by imposing the reflection symmetry $\phi(t, x) = -\phi(t, \pi - x)$. We emphasize this connection because problems involving nonlinear dynamics of small AdS perturbations have received a significant amount of attention in recent years, and our objectives here have much in common with that body of work.

Our goal is to understand the evolution of small smooth initial data $v(0, x), \partial_t v(0, x)$. Decomposing the solution into a Fourier series,

$$v(t, x) = \sum_{n=0}^{\infty} c_n(t) \sin(n + 1)x, \tag{7}$$

we get from (5) an infinite system of coupled oscillators

$$\frac{d^2 c_n}{dt^2} + (n + 1)^2 c_n = - \sum_{jkl} S_{jkl n} c_j c_k c_l, \tag{8}$$

with the interaction coefficients

$$S_{jkl n} = \frac{2}{\pi} \int_0^\pi \frac{dx}{\sin^2 x} \sin(j + 1)x \sin(k + 1)x \sin(l + 1)x \sin(n + 1)x. \tag{9}$$

To factor out fast linear oscillations in (8), we change the variables using variation of constants

$$c_n = \beta_n e^{i(n+1)t} + \bar{\beta}_n e^{-i(n+1)t}, \tag{10}$$

$$\frac{dc_n}{dt} = i(n + 1) \left(\beta_n e^{i(n+1)t} - \bar{\beta}_n e^{-i(n+1)t} \right). \tag{11}$$

This transforms the system (8) into

$$2i(n + 1) \frac{d\beta_n}{dt} = - \sum_{jkl} S_{jkl n} c_j c_k c_l e^{-i(n+1)t}, \tag{12}$$

where each c_j in the sum is given by (10). Thus, each term in the sum has a factor $e^{-i\Omega t}$, where $\Omega = (n + 1) \pm (j + 1) \pm (k + 1) \pm (l + 1)$, with all the three plus-minus signs independent. The terms with $\Omega = 0$ correspond to resonant interactions, while those with $\Omega \neq 0$ are non-resonant.

Passing to slow time $\tau = \varepsilon^2 t$ and rescaling $\beta_n(t) = \varepsilon \alpha_n(\tau)$, we see that for ε going to zero the non-resonant terms $\propto e^{-i\Omega\tau/\varepsilon^2}$ are highly oscillatory, and therefore expected to be negligible (in a sense we are about to specify). Keeping only the resonant terms in (12) (which is equivalent to time-averaging), we obtain an infinite autonomous dynamical system

$$2i(n + 1) \frac{d\alpha_n}{d\tau} = -3 \sum_{jkl} S_{jkl n} \alpha_j \alpha_k \bar{\alpha}_l, \tag{13}$$

where the summation runs over the set of indices $\{j, k, l\}$ for which $\Omega = 0$. Evaluating the integrals for the S -coefficients, one finds that this set reduces to $\{jkl \mid j + k - l = n\}$ and for such resonant combinations of indices,

$$S_{jkl n} = \min(j, k, l, n) + 1. \tag{14}$$

Note that terms with $n = j + k + l + 2$ could have been present in principle, but the corresponding S -coefficients vanish, which can be verified by direct calculation. This is directly parallel to the selection rules that have been extensively discussed in the AdS stability literature [13, 14, 28, 29].

It is part of the standard lore in nonlinear perturbation theory that solutions to (12) starting from small initial data of size $\mathcal{O}(\varepsilon)$ are well approximated by solutions of (13) on timescales of order $\mathcal{O}(\varepsilon^{-2})$. More precisely, if $\beta_n(t)$ and $\alpha_n(\tau)$ are solutions of (12) and (13), respectively, and $\beta_n(0) = \varepsilon\alpha_n(0)$ for each n , then $|\beta_n(t) - \varepsilon\alpha_n(\tau(t))| \lesssim \mathcal{O}(\varepsilon^2)$ for $t \lesssim \mathcal{O}(\varepsilon^{-2})$. In other words, on this timescale the dynamics of solutions of Eq. (5) is dominated by resonant interactions. Straightforward proofs (normally phrased for systems with a finite number of degrees of freedom) can be found in textbooks on nonlinear perturbation theory, e.g., [10].

For convenience, we shall henceforth rescale τ to remove the numerical factors 2 and -3 from (13). Renaming so rescaled τ back to t and using $\dot{} = d/dt$, we finally arrive at the following system, which we call the *conformal flow*

$$i(n+1)\dot{\alpha}_n = \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] \bar{\alpha}_j \alpha_k \alpha_{n+j-k}. \tag{15}$$

Remark 2. Note that the AdS formulation described in *Remark 1* simply corresponds to setting all even-numbered modes to 0, while only keeping odd-numbered modes α_{2m+1} with m running from 0 to infinity. It is easy to see that if one implements this constraint in (15) and expresses everything through the new mode counting index m , one gets back Eq. (15). Thus, the conformal flow is equally applicable to the dynamics in $\mathbb{R} \times \mathbb{S}^3$ and in AdS_4 .

The conformal flow (15) is Hamiltonian with

$$H = \sum_{n=0}^{\infty} \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] \bar{\alpha}_n \bar{\alpha}_j \alpha_k \alpha_{n+j-k} \tag{16}$$

and symplectic form $\sum_n 2i(n+1) d\bar{\alpha}_n \wedge d\alpha_n$:

$$i(n+1)\dot{\alpha}_n = \frac{1}{2} \frac{\partial H}{\partial \bar{\alpha}_n}. \tag{17}$$

It enjoys the following one-parameter groups of symmetries (where λ, θ are real parameters):

$$\text{Scaling: } \alpha_n(t) \rightarrow \lambda \alpha_n(\lambda^2 t), \tag{18}$$

$$\text{Global phase shift: } \alpha_n(t) \rightarrow e^{i\theta} \alpha_n(t), \tag{19}$$

$$\text{Mode-dependent phase shift: } \alpha_n(t) \rightarrow e^{in\theta} \alpha_n(t). \tag{20}$$

The latter two symmetries respect the Hamiltonian structure and give rise to two conserved quantities (in addition to the Hamiltonian itself):

$$\text{‘Charge:’ } Q = \sum_{n=0}^{\infty} (n+1) |\alpha_n|^2, \tag{21}$$

$$\text{‘Linear energy:’ } E = \sum_{n=0}^{\infty} (n+1)^2 |\alpha_n|^2. \tag{22}$$

We emphasize that these two conservation laws have no obvious counterparts in the original wave equation (4). Their prototypes were presented in the AdS stability context in [9, 14].

3. An Elementary Introduction to the Cubic Szegő Equation

The main content of our current treatment will be in presenting a range of remarkably simple dynamical behaviors of the conformal flow system (15). In anticipation of these results, it is useful to contemplate for a moment the apparent special features of Eq. (15) itself.

One can trivially rewrite (15) as

$$i\dot{\alpha}_n = \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} \frac{\min(n, j, k, n+j-k) + 1}{n+1} \bar{\alpha}_j \alpha_k \alpha_{n+j-k}. \tag{23}$$

One notable property of this representation is that many coefficients of the trilinear form on the right hand side are simply 1. Indeed, this happens for the contribution of any triplet of modes with all frequencies higher than the recipient mode n . It turns out useful to consider the following simpler equation, in which *all* numerical coefficients are set to 1,

$$i\dot{\alpha}_n = \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} \bar{\alpha}_j \alpha_k \alpha_{n+j-k}. \tag{24}$$

We shall see that, while the systems (23) and (24) are distinct, their dynamics is qualitatively similar, with a number of parallels between the emerging algebraic structures.

Actually, the simplified system (24) is the Fourier representation of a simple paradifferential equation that has been studied before. To show this, let $u(t, e^{i\theta})$ be a complex function on the circle whose nonnegative Fourier coefficients are given by $\alpha_n(t)$ and negative Fourier coefficients vanish, i.e.

$$u(t, e^{i\theta}) = \sum_{n=0}^{\infty} \alpha_n(t) e^{in\theta}, \tag{25}$$

and assume that $\sum_{n=0}^{\infty} |\alpha_n|^2 < \infty$. Mathematically, this means that u belongs to the Hardy space on the circle $L^2_+(S^1) \subset L^2(S^1)$ [30]. Furthermore, we define an orthogonal projector $\Pi : L^2(S^1) \mapsto L^2_+(S^1)$ (called the Szegő projector) that filters out negative frequencies

$$\Pi \left(\sum_{n=-\infty}^{\infty} \alpha_n e^{in\theta} \right) := \sum_{n=0}^{\infty} \alpha_n e^{in\theta}. \tag{26}$$

Then, it is easy to see that the system (24) is equivalent to

$$i\partial_t u = \Pi(|u|^2 u). \tag{27}$$

This equation was introduced by Gérard and Grellier in [18] under the name of the cubic Szegő equation. They showed that this equation has a remarkably deep structure, including a Lax pair, finite-dimensional invariant subspaces and weakly turbulent solutions. We shall demonstrate below that the conformal flow exhibits at least some of this structure (in a modified form), and conjecture that the similarity goes even further. In view of these parallels, we shall present below a very elementary summary of the features of the cubic Szegő equation that are important to us. Readers interested in more details are referred to the original publications [18–21].

The cubic Szegő equation is Hamiltonian with

$$H = \sum_{n=0}^{\infty} \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} \bar{\alpha}_n \bar{\alpha}_j \alpha_k \alpha_{n+j-k} = \frac{1}{2\pi} \int_0^{2\pi} |u|^4 d\theta \tag{28}$$

and symplectic form $\sum_n 2i d\bar{\alpha}_n \wedge d\alpha_n$, and has the same symmetries (18–20) as (15). Hence, it possesses two conserved quantities analogous to (21) and (22), in addition to the Hamiltonian itself:

$$M = \sum_{n=0}^{\infty} |\alpha_n|^2 = \frac{1}{2\pi} \int_0^{2\pi} |u|^2 d\theta, \tag{29}$$

$$P = \sum_{n=0}^{\infty} n |\alpha_n|^2 = \frac{1}{2\pi} \int_0^{2\pi} (-i \partial_\theta u) \bar{u} d\theta. \tag{30}$$

Borrowing terminology from studies of the nonlinear Schrödinger equation, we shall refer to these charges as ‘mass’ and ‘momentum,’ respectively.

Note that $M + P = \|u\|_{H_{1/2}}^2$, where $H_s \subset L^2_+$ is the Sobolev space on the circle equipped with the norm

$$\|u\|_{H_s}^2 = \sum_{n=0}^{\infty} (n + 1)^{2s} |\alpha_n(t)|^2. \tag{31}$$

This fact can be used to control the growth in time of higher Sobolev norms and thereby prove that the Cauchy problem for the Szegő equation is globally well posed for smooth initial data in H_s with $s > 1/2$ [18].

Any function $u(e^{i\theta})$ of the form (25) in $L^2_+(S^1)$ can be identified with a holomorphic function $u(z)$ inside the unit disk $|z| < 1$ in the complex plane [30], hence we can write

$$u(t, z) = \sum_{n=0}^{\infty} \alpha_n(t) z^n. \tag{32}$$

In terms of $u(t, z)$, the cubic Szegő equation (27) takes the form

$$i \partial_t u(t, z) = \frac{1}{2\pi i} \oint_{|w|=1} \frac{dw}{w - z} \tilde{u}(t, w) u(t, w)^2, \tag{33}$$

where

$$\tilde{u}(t, z) = \sum_{n=0}^{\infty} \bar{\alpha}_n z^{-n}. \tag{34}$$

General properties of the Cauchy-type integral appearing in (33) suggest the existence of meromorphic solutions for u with a finite number of isolated poles moving in the complex plane outside the unit disk. Indeed, it was shown in [18] that the cubic Szegő equation admits finite-dimensional invariant subspaces given by rational functions of arbitrarily high degree. Moreover, due to the Lax-integrability (and, consequently, infinitely many conserved quantities), the Szegő flow restricted to such subspaces is completely integrable in the sense of Liouville. The simplest invariant manifold with nontrivial dynamics is parametrized by the following single pole ansatz

$$u(t, z) = \frac{b(t) + a(t)z}{1 - p(t)z}, \quad |p| < 1. \tag{35}$$

We shall now demonstrate explicitly by elementary means that the subspace given by such functions is indeed dynamically invariant under the flow, and analyze its evolution. The Fourier coefficients corresponding to (35) are

$$\alpha_0 = b \quad \text{and} \quad \alpha_n = (a + bp)p^{n-1} \quad \text{for } n \geq 1. \tag{36}$$

Expressed through the parameters of our ansatz, the mass and momentum take the form

$$M = |b|^2 + \frac{|a + bp|^2}{1 - |p|^2}, \quad P = \frac{|a + bp|^2}{(1 - |p|^2)^2}. \tag{37}$$

Substitution of (35) into (33) produces exactly three distinct dependences on z on both sides, namely, $(1 - pz)^{-2}$, $(1 - pz)^{-1}$ and a z -independent term, resulting in the following three equations for $a(t)$, $b(t)$, and $p(t)$

$$i\dot{a} = Ma, \tag{38}$$

$$i\dot{b} = (M + P)b + Pa\bar{p}, \tag{39}$$

$$i\dot{p} = Mp + a\bar{b}, \tag{40}$$

where we used the conservations laws (37) to simplify some terms. These equations describe a three-dimensional Liouville-integrable system which can be easily solved (in [20] an explicit formula for the general solution was derived using harmonic analysis tools). One first integrates (38) to find a , whereupon the remaining equations become linear. The solution corresponding to initial conditions $a(0) = a_0$, $b(0) = b_0$, $p(0) = p_0$ (for simplicity assumed to be real) is

$$a(t) = a_0 e^{-iMt}, \tag{41}$$

$$b(t) = \left(b_0 \cos \omega t - i \frac{b_0(M + P) + 2a_0 p_0 P}{2\omega} \sin \omega t \right) e^{-\frac{i}{2}(M+P)t}, \tag{42}$$

$$p(t) = \left(p_0 \cos \omega t - i \frac{p_0(M + P) + 2a_0 b_0}{2\omega} \sin \omega t \right) e^{-\frac{i}{2}(M-P)t}, \tag{43}$$

where $\omega = \frac{1}{2}\sqrt{(M + P)^2 - 4Pa_0^2}$ and the expressions for M and P in terms of (a_0, b_0, p_0) are given in (37). Thus, the solution is quasiperiodic for all initial conditions, while the corresponding ‘mass’ spectrum,

$$|\alpha_0|^2 = M - P(1 - |p|^2) \quad \text{and} \quad |\alpha_n|^2 = P(1 - |p|^2)^2 |p|^{2(n-1)} \quad \text{for } n \geq 1, \tag{44}$$

is expressible through $|p|^2$ and the conserved quantities, and hence exactly periodic. In the special case $M = P = a_0^2$, we have $\omega = 0$ and then

$$a(t) = a_0 e^{-iMt}, \quad b(t) = -a_0 p_0 e^{-iMt}, \quad p(t) = p_0. \tag{45}$$

The evolution of two-mode initial data $a_0 = 1, b_0 = 2\varepsilon, p_0 = 0$ was used in [18] to illustrate a very interesting instability phenomenon. For these data, (43) gives

$$p(t) = -\frac{i}{\sqrt{1 + \varepsilon^2}} \sin(\omega t) e^{-2i\varepsilon^2 t}, \quad \omega = 2\varepsilon\sqrt{1 + \varepsilon^2}, \tag{46}$$

hence, in the regime of $\varepsilon \rightarrow 0, |p(t_n)| \sim 1 - \varepsilon^2/2$ for a sequence of times $t_n = \frac{n\pi}{2\omega}$, meaning that the energy goes periodically to arbitrarily high modes. Put differently, although all solutions are quasiperiodic, their radius of analyticity is not uniformly bounded from below. Note that (46) implies instability of the one-mode stationary state $u(t, z) = a_0 e^{-iMt} z$.

As mentioned above, one can consider more general meromorphic solutions with an arbitrary number of time-dependent simple poles outside the unit disk

$$u(t, z) = \sum_{k=1}^N \frac{b_k(t)}{1 - p_k(t)z}, \quad |p_k| < 1, \quad N \geq 2. \tag{47}$$

One can convince oneself that the ansatz is consistent in the sense that substituting it in (33) results only in z -dependences of the form $(1 - p_k z)^{-1}$ and $(1 - p_k z)^{-2}$ on both sides, producing $2N$ ordinary differential equations for the $2N$ functions b_k and p_k . It is possible to consistently impose $p_N = 0$, producing an ansatz with one parameter less. The single pole ansatz (35) is precisely of such a form. The equations of motion within the subspace defined by (47) were written down explicitly in [18]. As in the simplest case of the three-dimensional invariant subspace discussed above, the dynamics on all finite-dimensional invariant subspaces is Liouville-integrable and bounded, and hence quasiperiodic.

Among the quasiperiodic solutions there exist special solutions with time-independent amplitudes $|\alpha_n|$. Such solutions, which we call stationary states, were classified in [18] in the case of finite dimensional invariant manifolds. They are given by either finite Blaschke products

$$u(t, z) = c e^{-i|c|^2 t} \prod_{k=1}^N \frac{\bar{p}_k - z}{1 - p_k z}, \quad |p_k| < 1, \quad c \in \mathbb{C}, \tag{48}$$

or

$$u(t, z) = \frac{cz^\ell}{1 - p^N z^N} e^{-i\lambda t}, \quad p(t) = p(0) e^{-i\omega t}, \quad \lambda = \frac{|c|^2}{(1 - |p|^{2N})^2},$$

$$N\omega = \frac{|c|^2}{1 - |p|^{2N}}, \tag{49}$$

where $N \geq 1$ and $\ell \leq N - 1$ are nonnegative integers.

It was recently shown in [21] that outside the finite-dimensional invariant subspaces there exists a dense set of smooth solutions whose radius of analyticity tends to zero for a sequence of times $t_n \rightarrow \infty$. Consequently, the Sobolev norms with $s > 1/2$ are

unbounded. Such a weakly turbulent behavior is somewhat surprising in a completely integrable model. The coexistence of integrability and turbulence is possible because the infinitely many conserved quantities are too weak to control higher regularity properties of solutions.

4. Three-Dimensional Invariant Subspaces of the Conformal Flow

We now return to the conformal flow (15) and attempt to treat it along the lines applied above to the cubic Szegő equation. While the treatment is closely parallel, we shall be able to immediately recover only a part of the results available for the cubic Szegő equation. Using the generating function $u(t, z)$ and its conjugate $\tilde{u}(t, z)$ defined as in (32) and (34), we find that the system (15) is equivalent to the integro-differential equation

$$i \partial_t \partial_z(zu) = \frac{1}{2\pi i} \oint_{|w|=1} \frac{dw}{w} \tilde{u}(w) \left(\frac{wu(w) - zu(z)}{w - z} \right)^2. \tag{50}$$

The following summation formula has been used while obtaining this complex plane representation:

$$\begin{aligned} \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n + j - k) + 1] \rho^j \theta^k &= \frac{1 - \theta^{n+1}}{(1 - \theta)(1 - \rho)(1 - \theta\rho)} \\ &= \frac{1 + \theta + \dots + \theta^n}{(1 - \rho)(1 - \theta\rho)}. \end{aligned} \tag{51}$$

Derivations of (50) and (51) and further comments are given in Appendix A.

Although Eq. (50) looks like a somewhat more elaborate version of (33), we do not see an immediate way to characterize its meromorphic solutions and defer it to future work. Nonetheless, the lowest-dimensional nontrivial invariant subspace is easy to construct, as we shall explicitly demonstrate now.

The ansatz relevant for the three-dimensional invariant subspace, analogous to (36), is

$$\alpha_n = (b + an)p^n, \tag{52}$$

where b, a, p are complex-valued functions of time. The corresponding generating function has the following combination of poles outside the unit disk

$$u(t, z) = \frac{b(t) - a(t)}{1 - p(t)z} + \frac{a(t)}{(1 - p(t)z)^2} = \frac{b(t) + (a(t) - b(t))p(t)z}{(1 - p(t)z)^2}. \tag{53}$$

We note that the two-mode initial data ($\alpha_n = 0$ for $n \geq 2$) are accommodated within this ansatz as a special limiting case $p \rightarrow 0$ with b and $(a - b)p$ finite. All of our general statements about the dynamics on the three-dimensional invariant subspace apply to solutions starting with such initial configurations.

While we could have used the complex plane representation (50) to establish the validity of our ansatz, it is instructive to apply brute force summations in this case. Substitution of (52) into (15) yields

$$\begin{aligned}
 & i(1+n) \left(\dot{b} + \dot{a}n + n(b+an) \frac{\dot{p}}{p} \right) \\
 &= \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] (\bar{b} + \bar{a}j)(b+ak)(b+a(n+j-k)) |p|^{2j}.
 \end{aligned} \tag{54}$$

Note that the p^n factor has consistently cancelled on the two sides. It remains to show that different n -dependences on both sides can be matched and produce a sufficiently small number of equations. All summations in (54) can be performed by applying the relation

$$\begin{aligned}
 & \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] j^K k^L |p|^{2j} \\
 &= (\rho \partial_{\rho})^K (\theta \partial_{\theta})^L \frac{1 + \theta + \dots + \theta^n}{(1 - \rho)(1 - \theta\rho)} \Big|_{\substack{\theta=1 \\ \rho=|p|^2}},
 \end{aligned} \tag{55}$$

which follows from (51). While we give explicit expressions for the sums involved in (54) in Appendix B, the only thing one needs to know about these sums to establish the validity of our ansatz is that they are all polynomials of degree L in n , times $(n+1)$, the latter factor coming from Faulhaber’s sums $1 + 2^l + \dots + n^l$, with $l \leq L$, originating from $1 + \theta + \dots + \theta^n$ in (55). Therefore, explicit counting tells us that, upon substituting the summation formulas of Appendix B in (54), the factor $(n+1)$ will cancel on the two sides, leaving behind a statement that two quadratic polynomials in n equal each other. Matching the coefficients of these polynomials produces three ordinary differential equations for three functions b, a, p , confirming the validity of our ansatz.

The explicit equations for b, a and p are given by

$$\frac{i \dot{p}}{(1+y)^2} = \frac{p}{6} \left(2y|a|^2 + \bar{b}a \right), \tag{56}$$

$$\frac{i \dot{a}}{(1+y)^2} = \frac{a}{6} \left(5|b|^2 + (18y^2 + 4y)|a|^2 + (6y - 1)\bar{b}a + 10y\bar{a}b \right), \tag{57}$$

$$\frac{i \dot{b}}{(1+y)^2} = b \left(|b|^2 + (6y^2 + 2y)|a|^2 + 2yb\bar{a} \right) + a \left(2y|b|^2 + (4y + 2)y^2|a|^2 + y^2\bar{b}a \right), \tag{58}$$

where we have introduced the following notation, which will turn out to be useful later:

$$y = \frac{|p|^2}{1 - |p|^2}. \tag{59}$$

The conservation laws (21) and (22) take the form

$$Q = (1+y)^2 \left(|b|^2 + 4y \operatorname{Re}(\bar{b}a) + 2y(3y+1)|a|^2 \right), \tag{60}$$

$$E = (1+y)^2 \left((1+2y)|b|^2 + 4y(3y+2) \operatorname{Re}(\bar{b}a) + 4y(6y^2+6y+1)|a|^2 \right). \tag{61}$$

We remark that if $u(t, z)$ is a solution of the conformal flow, so is $z^N u(t, z^{N+1})$ for any non-negative integer N . This automatically generates an infinite number of other three-dimensional invariant subspaces of the conformal flow, in which only subsets of modes are activated.

We shall return to equations (56–58) in sect. 6, and analyze the dynamics within the three-dimensional dynamically invariant subspace (52) explicitly. Before proceeding in that direction, we shall discuss special solutions for which $|\alpha_n|$ are time-independent.

5. Stationary States

The conformal flow (15) admits solutions of the form

$$\alpha_n(t) = A_n e^{-i\lambda_n t}, \tag{62}$$

where the frequencies λ_n and complex amplitudes A_n are time-independent, and λ_n are linear in n , that is $\lambda_n = \lambda - n\omega$ for some real λ and ω . For such solutions there is no energy transfer between the modes, hence we call them *stationary states*. The cubic Szegő equation admits a variety of stationary states [18]; such solutions have also been considered in the context of AdS stability [12,31,32], where they were referred to as ‘quasiperiodic’ solutions.

Substituting (62) into (15) we get a nonlinear ‘eigenvalue’ problem

$$(n + 1)(\lambda - n\omega)A_n = \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n + j - k) + 1] \bar{A}_j A_k A_{n+j-k}. \tag{63}$$

The simplest solutions of this algebraic system, easily seen by inspection, $A_n = c \delta_{Nn}$, $\lambda = |c|^2$, $\omega = 0$ for $c \in \mathbb{C}$, give the one-mode stationary states for any non-negative integer N

$$\alpha_n = c \delta_{Nn} e^{-i|c|^2 t}. \tag{64}$$

We will see shortly that these trivial solutions are the endpoints of two-parameter families of stationary solutions. We note in passing that they are seeds for time-periodic solutions of the original equation (5) whose construction will be described elsewhere along the lines of [33].

Within the ansatz (52), stationary states take the form

$$b(t) = b(0)e^{-i\lambda t}, \quad a(t) = a(0)e^{-i\lambda t}, \quad p(t) = p(0)e^{i\omega t}. \tag{65}$$

Plugging this into the system (56–58), we obtain a system of algebraic equations that can be solved explicitly. The case $a(0) = 0$ yields

$$b(t) = c \exp\left(-\frac{i|c|^2 t}{(1 - |p|^2)^2}\right). \tag{66}$$

For this solution $Q = \frac{|c|^2}{(1 - |p|^2)^2}$, hence $\lambda = Q$. The corresponding generating function reads

$$u(t, z) = \frac{c}{1 - pz} e^{-i\lambda t}. \tag{67}$$

For nonzero a we get the following two-parameter family of stationary states with $\omega = 0$

$$b(0) = -2c|p|^2, \quad a(0) = c(1 - |p|^2), \quad \lambda = \frac{|c|^2|p|^2}{(1 - |p|^2)^2} \tag{68}$$

For this solution

$$Q = \frac{2|c|^2|p|^2}{(1 - |p|^2)^2}, \quad E = \frac{4|c|^2|p|^2(1 + |p|^2)}{(1 - |p|^2)^3}, \tag{69}$$

hence $\lambda = \frac{1}{2}Q$. The corresponding generating function reads

$$u(t, z) = c \frac{-2|p|^2 + (1 + |p|^2) pz}{(1 - pz)^2} e^{-i\lambda t}. \tag{70}$$

In addition, for $|p| \leq p_* := 2 - \sqrt{3} \approx 0.268$, there is a pair of two-parameter families of stationary states with nonzero ω . The range of $|p|$ is restricted by the condition that $\kappa := \sqrt{|p|^4 - 14|p|^2 + 1}$ should be real, so we have a tangential bifurcation at p_* . These two solutions (labelled by \pm) are given by

$$b_{\pm}(0) = -c(1 + 5|p|^2 \pm \kappa), \quad a_{\pm}(0) = 2c(1 - |p|^2), \tag{71}$$

$$\omega_{\pm} = \frac{|c|^2}{3} \frac{1 + |p|^2 \pm \kappa}{1 - |p|^2}, \tag{72}$$

$$\lambda_{\pm} = \frac{2|c|^2}{3} \left(\frac{3 - 4|p|^2}{1 - |p|^2} \pm \frac{(3 + 4|p|^2)\kappa}{(1 - |p|^2)^2} \right), \tag{73}$$

and their conserved quantities are

$$Q_{\pm} = \frac{6}{7}(\lambda_{\pm} + \omega_{\pm}), \quad E_{\pm} = 6\omega_{\pm}. \tag{74}$$

The corresponding generating function reads

$$u(t, z) = c \frac{-(1 + 5|p|^2 \pm \kappa) + (3 + 3|p|^2 \pm \kappa) pz}{(1 - pz)^2} e^{-i\lambda_{\pm} t}, \tag{75}$$

where $p(t) = p(0)e^{i\omega_{\pm} t}$.

Outside the three-dimensional invariant subspace given by (52) there exist many other stationary states. For instance, we verified that, in close parallel to the cubic Szegő equation, any finite Blaschke product

$$u(t, z) = c e^{-i|c|^2 t} \prod_{k=1}^N \frac{\bar{p}_k - z}{1 - p_k z} \tag{76}$$

yields a stationary state. There are also stationary states where only every N th mode is activated, for instance

$$u(t, z) = \frac{cz^{N-1}}{1 - p^N z^N} e^{-i\lambda t}, \quad \lambda = \frac{|c|^2}{(1 - |p|^2)^2}. \tag{77}$$

Remark 3. For all the above stationary states with $\omega = 0$ we have $\lambda = \frac{Q}{N+1}$, where N is the number of zeroes of the generating function (counted with multiplicity). It would be interesting to find a reason that underlies this ‘quantization’ structure.

It is well known that stationary states of Hamiltonian systems admit a variational characterization. In our case, it follows from the Hamilton equation (17) that stationary states (62) are the critical points of the functional

$$K := \frac{1}{2}H - \lambda Q + \omega(E - Q), \tag{78}$$

hence stationary states with $\omega = 0$ are extrema of H for fixed Q , while stationary states with nonzero ω are extrema of H for fixed Q and E . This fact is very helpful in determining stability properties of stationary states, as will be described elsewhere.

6. Dynamics on the Three-Dimensional Invariant Subspace

We now return to equations (56–58) describing the dynamics on the three-dimensional invariant subspace of the conformal flow and demonstrate how to solve them explicitly. Once again, the situation is closely parallel to the three-dimensional invariant subspace of the cubic Szegő equation with its underlying one-dimensional periodic motion.

From (56), we obtain for y defined by (59)

$$\dot{y} = \frac{1}{3}y(1+y)^3 \operatorname{Im}(\bar{b}a). \tag{79}$$

This equation and (57) imply that

$$S = |a|^2 y(1+y)^3 \tag{80}$$

is conserved. This quantity is related to the conformal flow Hamiltonian (16) by

$$H = Q^2 - 2S^2. \tag{81}$$

Equations (60), (61) and (80) can be resolved to express $|b|^2$, $|a|^2$ and $\operatorname{Re}(\bar{b}a)$ through Q , E , S and y as follows

$$\begin{aligned} |b|^2 &= \frac{2Q - E + 3y(Q + 2S)}{(1+y)^3}, & |a|^2 &= \frac{S}{y(1+y)^3}, \\ \operatorname{Re}(\bar{b}a) &= \frac{E - Q - 2S - 2y(Q + 6S)}{4y(1+y)^3}. \end{aligned} \tag{82}$$

From these relations, together with (79), one obtains

$$\dot{y}^2 = -\frac{Q^2 + 12S^2}{36} \left(y^2 + \left(1 - \frac{E(Q + 2S)}{Q^2 + 12S^2} \right) y + \frac{(E - Q - 2S)^2}{4(Q^2 + 12S^2)} \right). \tag{83}$$

Note that this equation has the algebraic form of energy conservation for an ordinary one-dimensional harmonic oscillator. The solution of (83) reads

$$y(t) = B + A \sin(\Omega t + \psi), \quad \Omega = \frac{1}{6} \left(Q^2 + 12S^2 \right)^{1/2}, \tag{84}$$

where B and A are constants depending on E , Q , and S ; ψ is a phase that must be determined from the entire set of initial conditions. By Eq. (82), this exactly periodic motion is transferred to $|b|^2$, $|a|^2$ and $\text{Re}(\bar{b}a)$, and hence to the mode energy spectrum

$$|\alpha_n|^2 = |b + na|^2 |p|^{2n} = \left(|b|^2 + 2n \text{Re}(\bar{b}a) + n^2 |a|^2 \right) |p|^{2n}. \tag{85}$$

One will thus observe exact returns of the energy spectrum to the initial configurations for *all* solutions within the three-dimensional invariant subspace of the conformal flow.

The turning points of the periodic motion of y described by (84), $y_{\pm} = B \pm A$, are given by the roots of the quadratic polynomial appearing on the right-hand side of (83) (the special case $A = 0$ corresponds to stationary states). In terms of the energy spectrum (85), these turning points provide lower and upper bounds for the inverse and direct cascades of energy, respectively. One of the key questions in this context is how large can y grow starting from some small y . To answer this question, we consider the ratio

$$\frac{1 + y_+}{1 + y_-} = \frac{(1 + y_+)^2}{(1 + y_-)(1 + y_+)} \leq \frac{(1 + y_+ + y_-)^2}{1 + y_- + y_+ + y_- y_+}. \tag{86}$$

An advantage of the last representation is that it only contains combinations of y_+ and y_- directly expressible through the coefficients of the quadratic polynomial on the right-hand side of (83). One thus gets

$$\frac{(1 + y_+ + y_-)^2}{1 + y_- + y_+ + y_- y_+} = \frac{4E^2(Q + 2S)^2}{(Q^2 + 12S^2)(E + Q + 2S)^2} \leq \frac{4(Q + 2S)^2}{Q^2 + 12S^2}. \tag{87}$$

We furthermore notice that

$$Q = (1 + y)^2 |b + 2ya|^2 + 2S \geq 2S. \tag{88}$$

Therefore, dividing the numerator and denominator of (87) by Q^2 and replacing the numerator by its maximum and denominator by its minimum, we obtain a simple uniform upper bound (which very likely can be tightened with extra work)

$$\frac{1 + y_+}{1 + y_-} \leq 16. \tag{89}$$

This proves that the transfer of energy to high frequencies (or, equivalently, the growth of the higher Sobolev norms (31)) is uniformly bounded. We recall from Sect. 3 that there is no such bound for the Szegő flow on the three-dimensional invariant subspace (35). In this sense, the conformal flow is much less ‘turbulent’ than the Szegő flow. Heuristically, this is not very surprising in view of the fact that the interaction coefficients in (23)

$$\frac{\min(n, j, k, n + j - k) + 1}{n + 1} \tag{90}$$

decay when the recipient mode number n is large and at least one of the source mode numbers is small, undermining the efficiency of energy transfer from low to high frequencies. This is in contrast to the Szegő flow where all coupling coefficients are equal to 1.

7. Summary and Open Questions

Starting with a naturally defined geometric PDE (4) on a three-sphere describing a self-interacting conformally coupled scalar field, we have considered its effective time-averaged weak field dynamics, arriving at the conformal flow (15). The conformal flow is both structurally similar and displays a number of dynamical parallels to the previously known cubic Szegő equation (24). Building on these analogies, we have revealed the dynamics on the three-dimensional invariant subspace of the conformal flow described by the ansatz (52). Within this subspace, the dynamics is Liouville-integrable and bounded, and hence quasiperiodic, with exactly periodic energy flows (85) displaying an alternating sequence of direct and inverse cascades. Unlike the cubic Szegő case, the conformal flow dynamics within the three-dimensional invariant subspace does not display turbulent behaviors (not even the ‘weak weak turbulence’ of [3]). Other similar three-dimensional subspaces can be immediately constructed, as follows from simple properties of the conformal flow equation. There are furthermore direct parallels between the structure of stationary states of the Szegő and conformal flows (these states are special solutions for which no energy transfer between the modes occurs). Of these, the Blaschke product states (76) are particularly intriguing, as they clearly demonstrate that the parallels between the Szegő and conformal flows extend beyond the three-dimensional invariant subspaces that have been our main focus here.

We conclude with a list of open questions that we leave for future investigations:

- Is the conformal flow (15) Lax-integrable?
- Is there a way to re-express the conformal flow through a projector similar to the Szegő projector? Apart from the conceptual importance, such a projector should make calculations easier. The complex plane representation of the conformal flow (50) can be seen as a first step in this direction.
- Are there higher dimensional invariant subspaces? The three-dimensional subspace we have considered, with its double-pole generating function (53), and parallels to the cubic Szegő case strongly suggest that more elaborate meromorphic ansätze should work; however, we have not been able to find them.
- Are there weakly turbulent solutions? We have explicitly demonstrated that no turbulent behavior occurs within the three-dimensional invariant subspace (52). This does not in principle exclude turbulence for other initial conditions; however, we find it unlikely because the conformal flow generally appears to display less energy spread than the Szegő flow.
- Complete classification of stationary states and analysis of their stability properties would contribute to the overall picture of the conformal flow dynamics.
- To what extent can the properties of the conformal flow, both explicitly demonstrated and putative, be structurally stable with respect to variations of the flow equation? Do these dynamical patterns have applications to the weak field limit of other related systems? Can the Szegő and conformal flows be just two representative members of a large hierarchy of equations?
- To what extent can the highly structured dynamics of the conformal flow be transferred to the original conformally invariant cubic wave equation (5) on the three-sphere? Standard results on time averaging guarantee that in the weak field regime the conformal flow accurately approximates our original wave equation for a long but limited time. Can our findings have further implications on longer time scales?

A. Complex Plane Representation for the Conformal Flow

We first introduce the generating functions u and \tilde{u} according to (32) and (34). It is true for any contour enclosing the origin but not enclosing the singularities of u , and any contour enclosing all singularities of \tilde{u} that

$$\alpha_m = \frac{1}{2\pi i} \oint \frac{dz}{z} u(z) z^{-m}, \quad \bar{\alpha}_m = \frac{1}{2\pi i} \oint \frac{dz}{z} \tilde{u}(z) z^m. \tag{91}$$

Substituting these expressions to the right-hand side of conformal flow (15), one gets

$$\begin{aligned} i(n+1)\dot{\alpha}_n &= \frac{1}{(2\pi i)^3} \oint \frac{ds}{s} \frac{dv}{v} \frac{dw}{w^{n+1}} \tilde{u}(s)u(v)u(w) \\ &\times \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] \left(\frac{s}{w}\right)^j \left(\frac{w}{v}\right)^k. \end{aligned} \tag{92}$$

The summation can be performed using the following master formula

$$\begin{aligned} &\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] \rho^j \theta^k \\ &= \frac{1 - \theta^{n+1}}{(1-\theta)(1-\rho)(1-\theta\rho)} = \frac{1 + \theta + \dots + \theta^n}{(1-\rho)(1-\theta\rho)}. \end{aligned} \tag{93}$$

This summation formula can be derived by many methods, for example, by noticing that

$$2 \min(n, j, k, n+j-k) = n + j - |k-n| - |k-j|, \tag{94}$$

and performing brute force resummations of geometric series. The best way to understand it, however, is essentially combinatorial in nature. The right-hand side of (93) can be rewritten as

$$(1 + \theta + \dots + \theta^n) \sum_{m=0}^{\infty} \rho^m (1 + \theta + \dots + \theta^m). \tag{95}$$

The coefficient of $\rho^j \theta^k$ in this expression is just the coefficient of θ^k in the product

$$(1 + \theta + \dots + \theta^n) (1 + \theta + \dots + \theta^j). \tag{96}$$

Counting the number of relevant pairings of powers of θ in the two polynomials of the product reproduces the coefficient on the left-hand side of (93), thus verifying the summation formula.

Using (93), one can rewrite (92) as

$$i(n+1)\dot{\alpha}_n = \frac{1}{(2\pi i)^3} \oint \frac{ds}{s} \frac{dv}{v} dw \tilde{u}(s)u(v)u(w) \frac{w^{-(n+1)} - v^{-(n+1)}}{(1-s/v)(1-s/w)(1-w/v)}. \tag{97}$$

(One must have $|s| < |v|$ and $|s| < |w|$ in order for the sum to converge.) Multiplying by z^n (with $|z| < |v|$ and $|z| < |w|$) and summing over n , one obtains after elementary simplification

$$i\partial_t\partial_z(zu) = \frac{1}{2\pi i} \oint \frac{ds}{s} \tilde{u}(s) \left[\frac{1}{2\pi i} \oint dv \frac{u(v)}{(1-s/v)(v-z)} \right]^2. \tag{98}$$

Since by construction, the v -integration contour must not enclose any singularities of u , the integral inside the square brackets is simply given by a sum of two residues, resulting in the complex plane representation we have quoted in the main text:

$$i\partial_t\partial_z(zu) = \frac{1}{2\pi i} \oint \frac{ds}{s} \tilde{u}(s) \left(\frac{su(s) - zu(z)}{s-z} \right)^2. \tag{99}$$

B. A Few Summation Formulas

We assemble below the explicit summation formulas necessary for deriving (56–58) from (54). A crucial feature of these expressions in our context is that all of them are proportional to $(n+1)$.

$$\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] |p|^{2j} = \frac{n+1}{(1-|p|^2)^2}, \tag{100}$$

$$\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] j |p|^{2j} = \frac{2(n+1)|p|^2}{(1-|p|^2)^3}, \tag{101}$$

$$\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] k |p|^{2j} = \frac{n(n+1)}{2(1-|p|^2)^2} + \frac{(n+1)|p|^2}{(1-|p|^2)^3}, \tag{102}$$

$$\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] j^2 |p|^{2j} = \frac{2(n+1)|p|^2}{(1-|p|^2)^3} + \frac{6(n+1)|p|^4}{(1-|p|^2)^4}, \tag{103}$$

$$\begin{aligned} \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] k^2 |p|^{2j} \\ = \frac{n(n+1)(2n+1)}{6(1-|p|^2)^2} + \frac{(n+1)^2|p|^2}{(1-|p|^2)^3} + \frac{2(n+1)|p|^4}{(1-|p|^2)^4}, \end{aligned} \tag{104}$$

$$\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] jk |p|^{2j} = \frac{(n+1)^2|p|^2}{(1-|p|^2)^3} + \frac{3(n+1)|p|^4}{(1-|p|^2)^4}, \tag{105}$$

$$\begin{aligned} \sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] j^2 k |p|^{2j} \\ = \frac{(n+1)^2|p|^2}{(1-|p|^2)^3} + \frac{3(n+1)(n+3)|p|^4}{(1-|p|^2)^4} + \frac{12(n+1)|p|^6}{(1-|p|^2)^5}, \end{aligned} \tag{106}$$

$$\sum_{j=0}^{\infty} \sum_{k=0}^{n+j} [\min(n, j, k, n+j-k) + 1] jk^2 |p|^{2j}$$

$$= \frac{(n+1)(2n^2+4n+3)|p|^2}{3(1-|p|^2)^3} + \frac{(n+1)(3n+7)|p|^4}{(1-|p|^2)^4} + \frac{8(n+1)|p|^6}{(1-|p|^2)^5}. \quad (107)$$

ABSTRACT: Out-of-time-order correlators (OTOCs) that capture maximally chaotic properties of a black hole are determined by scattering processes near the horizon. This prompts the question to what extent OTOCs display chaotic behaviour in horizonless microstate geometries. This question is complicated by the fact that Lyapunov growth of OTOCs requires nonzero temperature, whereas constructions of microstate geometries have been mostly restricted to extremal black holes.

In this paper, we compute OTOCs for a class of extremal black holes, namely maximally rotating BTZ black holes, and show that on average they display “slow scrambling”, characterized by cubic (rather than exponential) growth. Superposed on this average power-law growth is a sawtooth pattern, whose steep parts correspond to brief periods of Lyapunov growth associated to the nonzero temperature of the right-moving degrees of freedom in a dual conformal field theory.

Next we study the extent to which these OTOCs are modified in certain “superstrata”, horizonless microstate geometries corresponding to these black holes. Rather than an infinite throat ending on a horizon, these geometries have a very deep but finite throat ending in a cap. We find that the superstrata display the same slow scrambling as maximally rotating BTZ black holes, except that for large enough time intervals the growth of the OTOC is cut off by effects related to the cap region, some of which we evaluate explicitly.

1 Introduction

The nature of the microstates of black holes in quantum gravity is a matter of ongoing debate. Some take recent progress on recovering the Page curve of evaporating black holes from semiclassical gravity [1–4] (see [5] for a review) as evidence that black hole microstates have a smooth horizon and an interior region. Others are convinced that many or all black hole microstates correspond to horizonless geometries (see [6] for a review), and point to explicit constructions of increasingly large families of such geometries in string theory (see e.g. [7]).

If black hole microstates correspond to horizonless geometries, one expects that observables computed in such geometries should approximately reproduce those computed in the “naïve” black hole geometry. Nevertheless, sufficiently accurate computations or measurements should be able to distinguish them. Examples include studies of the approximate thermality of probes in ensembles of gravitational microstates [8, 9], an analogue of Hawking radiation in special microstate geometries of a non-extremal black hole [10], and the behaviour of retarded two-point functions in certain microstates of extremal black holes [11].

Figure 1. Schematic plot (based on [14]) of the expected behaviour of the normalized commutator squared $C(t)$ over time.

Black hole horizons have played a central role in recent connections between gravity and quantum chaos. Out-of-time-order correlators (OTOCs) in holographic field theories in a thermal ensemble display transient Lyapunov growth, with Lyapunov exponent equal to 2π times the temperature [12]. Such systems have been argued to be maximally chaotic [13]. In the dual gravitational description, the OTOC corresponds to a scattering process very close to a black hole horizon. In contrast to quasinormal mode (QNM) decay, which depends on what happens within a few Schwarzschild radii of the horizon, chaos probes what happens *at* the horizon [14]. This makes it very interesting to investigate how OTOCs distinguish between black hole geometries and horizonless microstate geometries.

An important complication is that so far constructions of microstate geometries that closely resemble black holes have been mostly restricted to extremal black holes, which are under better control due to supersymmetry. Such black holes have zero temperature, which requires modification of the above discussion. While it would be interesting from various points of view to have microstate geometries corresponding to non-extremal black holes, constructing them is not an easy task. In the present paper, we will therefore extend computations of chaos as measured by OTOCs to the case of certain extremal black holes and associated microstate geometries.

To set the stage, we briefly review some aspects of quantum chaos and OTOCs, mainly following [14]. In classically chaotic systems, neighboring phase space trajectories diverge exponentially, $\partial q(t)/\partial q(0) \sim \exp(\lambda t)$. Since $\partial q(t)/\partial q(0) = \{q(t), p(0)\}$, this motivates the study in quantum mechanics of commutators of operators at different times. More specifically, one is interested in $-\langle [V(0), W(t)]^2 \rangle_\beta$, which we will refer to as the commutator squared, and where β is the inverse temperature. As displayed in figure 1, in theories with a chaotic semi-classical limit and for operators that commute at $t = 0$ this quantity typically displays two exponential behaviours, namely transient Lyapunov growth followed by saturation, where the latter is described by Ruelle resonances. Holographically, Ruelle resonances correspond to quasinormal mode decay, also visible in two-point functions, while the Lyapunov growth is due to near-horizon blueshifts, which manifest themselves in 2-to-2 scattering amplitudes that can be associated to OTOCs [15]. For times large compared to the inverse temperature, the normalized commutator squared $C(t)$ is simply given by 1

minus the real part of the out-of-time-order correlator,

$$C(t) \equiv \frac{-\langle [V(0), W(t)]^2 \rangle_\beta}{2\langle VV \rangle_\beta \langle WW \rangle_\beta} \approx 1 - \text{Re OTOC}(t) \quad (t \gg \beta), \quad (1.1)$$

where the normalized OTOC is defined as

$$\text{OTOC}(t) \equiv \frac{\langle V(0)W(t)V(0)W(t) \rangle_\beta}{\langle VV \rangle_\beta \langle WW \rangle_\beta}. \quad (1.2)$$

This is due to the fact that contributions like $\langle V(0)W(t)W(t)V(0) \rangle_\beta$ can be interpreted as the 2-point function of $W(t)$ in a state created by acting with $V(0)$ on the thermal state; this state behaves thermally after one waits a few thermal times, so this contribution factorizes.

In fact, the commutator squared contains more structure than shown in figure 1. In a 2d holographic Conformal Field Theory (CFT), if the conformal dimensions satisfy $h_W \gg h_V \gg 1$ and the time is large compared to both the spatial separation and the inverse temperature, the OTOC was computed in [16],

$$\frac{\langle V(i\epsilon_1, x)W(t + i\epsilon_3, 0)V(i\epsilon_2, x)W(t + i\epsilon_4, 0) \rangle_\beta}{\langle V(i\epsilon_1, 0)V(i\epsilon_2, 0) \rangle_\beta \langle W(i\epsilon_3, 0)W(i\epsilon_4, 0) \rangle_\beta} \approx \left(\frac{1}{1 - \frac{24\pi i h_W}{\epsilon_{12}^* \epsilon_{34} c} e^{\frac{2\pi}{\beta}(t-|x|)}} \right)^{2h_V}. \quad (1.3)$$

Here c is the central charge, which is large, and

$$\epsilon_{ij} = i \left(e^{\frac{2\pi}{\beta} i\epsilon_i} - e^{\frac{2\pi}{\beta} i\epsilon_j} \right). \quad (1.4)$$

At sufficiently early times, one gets Lyapunov behaviour from the $1/c$ expansion,

$$\frac{\langle V(i\epsilon_1, x)W(t + i\epsilon_3, 0)V(i\epsilon_2, x)W(t + i\epsilon_4, 0) \rangle_\beta}{\langle V(i\epsilon_1, 0)V(i\epsilon_2, 0) \rangle_\beta \langle W(i\epsilon_3, 0)W(i\epsilon_4, 0) \rangle_\beta} \approx 1 + \frac{48\pi i h_W h_V}{\epsilon_{12}^* \epsilon_{34} c} e^{\frac{2\pi}{\beta}(t-|x|)}. \quad (1.5)$$

Note that this exponential growth is suppressed by a prefactor that is small in the large- c semi-classical limit. This growth will persist until it competes with the small prefactor at the scrambling time

$$t_s = |x| + \frac{\beta}{2\pi} \log \frac{|\epsilon_{12}^* \epsilon_{34}| c}{48\pi h_W h_V}, \quad (1.6)$$

which is the time at which the commutator squared, $C(t)$, first becomes $O(1)$.

After the scrambling time there is a region of oscillatory behaviour, which subsequently decays away. This decay is also controlled by the Lyapunov exponent and occurs well before the quasi-normal regime. Nonetheless, at sufficiently late times one sees the faster exponential quasi-normal mode decay in the tail of this decay. The details of this intermediate regime are described in more detail in appendix A and the behaviour of the OTOC described by (1.3) is depicted in figure 2.

At very late times, the quasi-normal mode decay is expected to stop as the OTOC cannot continue to decay forever in a unitary theory [17]. The result (1.3) was derived

Figure 2. Behaviour of the normalized commutator squared in a 2d holographic CFT. In this plot, $\frac{h_W}{c\epsilon_{12}\epsilon_{34}} = \exp(-24.5)$ and $h_V = \exp(9)$.

assuming that only the contribution from the Virasoro conformal block of the identity is important and this approximation is expected to breakdown at very late times [18–21].

To get a feeling for what to expect for extremal black holes, which involve zero temperature, we first review what happens in vacuum. In [16] it was found that for infinite β and $t \gg |x|$

$$\frac{\langle V(i\epsilon_1, x)W(t+i\epsilon_3, 0)V(i\epsilon_2, x)W(t+i\epsilon_4, 0) \rangle}{\langle V(i\epsilon_1, 0)V(i\epsilon_2, 0) \rangle \langle W(i\epsilon_3, 0)W(i\epsilon_4, 0) \rangle} \approx \left(\frac{1}{1 - \frac{24\pi i h_W}{c(\epsilon_1 - \epsilon_2)(\epsilon_3 - \epsilon_4)}(t - |x|)^2} \right)^{2h_V}. \quad (1.7)$$

At early times, we again see a period of growth suppressed by a small prefactor,

$$\left(\frac{1}{1 - \frac{24\pi i h_W}{c(\epsilon_1 - \epsilon_2)(\epsilon_3 - \epsilon_4)}(t - |x|)^2} \right)^{2h_V} \approx 1 + \frac{48\pi i h_V h_W}{c(\epsilon_1 - \epsilon_2)(\epsilon_3 - \epsilon_4)}(t - |x|)^2. \quad (1.8)$$

This result for the OTOC is qualitatively similar to the finite temperature case, except that the exponential Lyapunov growth is replaced by quadratic growth in time. The link between the OTOC and the commutator squared is now less straightforward, because contributions like $\langle V(0)W(t)W(t)V(0) \rangle$ need not factorize at zero temperature.

In this paper, we will focus on maximally rotating BTZ black holes and some of their microstate geometries. In the dual CFT, the left-movers are at zero temperature while the right-movers are at finite temperature T_R . To guide our expectations for computing OTOCs in BTZ geometries, we refer to earlier studies of non-maximally rotating BTZ black holes, including [22, 23], where Lyapunov growth alternates between the left and right-moving temperatures [23] at small time scales, yet the overall growth is controlled by the Bekenstein-Hawking temperature. These results cannot be applied directly to the extremal case, since they assume the regime where $t \gg \beta$ whereas β diverges in the extremal limit. Yet our results are compatible with extrapolating their conclusion to our setting, since for sufficiently high right-moving temperature one finds a small sawtooth-like modulation on top of power law growth, where the steep parts of the sawtooth correspond to brief periods of Lyapunov growth at the nonzero right-moving temperature. Nonetheless, on average

the scrambling is slow. It is worth emphasizing that the sawtooth-like modulation is tied to the compactness of the spatial direction of the dual CFT. In contrast, the results (1.3) and (1.7) obtained in [16] were derived in the decompactified limit such that they do not display such a sawtooth-like modulation.

In [24], the gravitational modes responsible for scrambling corresponding to the zero left moving temperature and the non-zero right moving temperature were identified using an effective action. However, as emphasised in [23], identifying the overall rate of growth relevant for scrambling requires the detailed computation of the OTOC we present in this work. The instantaneous Lyapunov exponent in rotating ensembles has been bounded in [25]. Scrambling in BTZ has also been studied from the perspective of mutual information in [26]. In the context of microstate geometries resembling maximally rotating BTZ black holes, note that an interesting recent paper [27] has described a different kind of Lyapunov behaviour associated to geodesic instability near photon spheres. This latter Lyapunov exponent is related to quasi-normal decay [28], while the focus of our work is on the Lyapunov growth displayed by OTOCs, which is of a different nature.

A method to compute OTOCs within AdS/CFT, which is based on the geodesic approximation to the propagation of bulk fields in asymptotically AdS spacetimes, has been developed in [29]. We give a brief summary thereof in section 2. In practice, this method requires one to consider a particle falling in from the earlier boundary insertion point of the OTOC, together with the linearised gravitational shock wave that it sources. Similarly, an outgoing particle reaching the later boundary insertion point needs to be considered. Within the geodesic approximation, the OTOC is then determined by

$$\text{OTOC} \sim e^{i\delta}, \quad (1.9)$$

where the *eikonal phase* δ encodes the interaction of each particle with the gravitational shock wave emitted by the other one. Compared to the original method put forward by Shenker and Stanford [15] or follow up works such as [22, 23], this approach allows us to work at zero temperature. The difference is that the original method makes the approximation, well motivated at finite temperature, that the shock wave propagates exactly on the horizon. However, this approximation clearly does not apply in the vacuum where there is no horizon. The applicability of the new approach summarized in section 2 to the zero temperature case was demonstrated in [29] where the quadratic growth associated to *slow scrambling* in vacuum was obtained, finding agreement with earlier CFT results [16]. Similarly, the results of [23] show that the shock wave diverges in the extremal limit when the approximation of placing it on the horizon is made. Therefore, working with a method valid at zero temperature which accurately computes the shock wave without making the approximation of placing it on the horizon, is again crucial to the study of extremal BTZ and microstate geometries which we initiate in this paper.

The gravitational scattering amplitude of highly energetic particles turns out to be generically proportional to the corresponding center-of-mass energy. Hence, at finite temperature a rough estimate of the time-dependence of an OTOC may be obtained by computing this simple quantity; see also [30]. We will find that the story is more subtle in the zero temperature case, nevertheless the center-of-mass energy gives useful intuition in

Figure 3. The growth of the eikonal phase δ , related to the OTOC through (1.9), of two scalar operators at a fixed spatial separation in extremal BTZ, computed within the geodesic approximation (solid blue line). The growth is cubic on average and can be very well approximated by the functional dependence depicted in orange (dashed), which scales as $\sim \frac{4r_+^2 t^3}{3\pi} - \frac{2r_+}{\pi} t^2 \log(4r_+ t) + 2r_+^2 t^2$. On top of this average growth, we find a sawtooth-like modulation that starts with a quadratically growing piece, followed by an exponential growth that catches up with the overall t^3 growth. One of the phases of t^2 growth is depicted by superimposing the dashed green (dotted) line, obtained by summing the quadratic contributions of a fixed 20 images. This figure is discussed in detail in section 3.2.

instances where gravitational shock waves are difficult to compute, as is the case when the source particles propagate in microstate geometries. In appendix B, we compute the center of mass energy in rotating BTZ and find an early time period of power-law growth. This early time period persists for longer and longer as we approach the extremal BTZ limit, leading to slow scrambling.

In section 3 we provide a detailed holographic computation of the OTOC of scalar operators within the geodesic approximation, in CFT states dual to maximally rotating BTZ black holes. First, we review the properties of geodesics in this spacetime. Then we consider the shock waves emitted by the scattered particles along their trajectories, computed in appendix C. We deal with the angular periodicity in BTZ by first computing the shock wave in the black brane geometry and then using the method images to find the periodic solution. We find that a large but finite number of these images contribute to the shock wave at any given time and that the number of images grows linearly with time. This explains the divergence found when taking the zero-temperature limit of the result found using the earlier approach — the late time approximation necessary to place the shock wave on the horizon leads to a diverging sum over images. This sum over images yields an enhancement factor in the strength of the gravitational interaction which, controlled by the center-of-mass energy of the interaction, would otherwise have grown quadratically with time. All in all, we find that the OTOC displays approximately cubic growth in time, with a sawtooth-like modulation that alternates between quadratic and exponential growth. In addition, the latter exponential Lyapunov growth is associated to the nonzero right-moving temperature T_R . This is displayed in figure 3. The scrambling associated to scalar operators is therefore slow on average. In particular, for the scrambling time defined

Figure 4. Schematic representation of a spatial slice of the superstrata geometry described by the metric (4.1). Each point in the picture corresponds to an S^3 in the six-dimensional geometry. Coming in from infinity, there is an asymptotic $\text{AdS}_3 \times S^3$ region, followed by an $\text{AdS}_2 \times S^1 \times S^3$ throat region which then ends in a smooth cap region. For geodesics falling in from a large radius in the asymptotic region, the tidal forces are in danger of invalidating the geodesic approximation at a radius ρ_{tidal} in the throat region.

as the time at which the eikonal phase δ becomes $O(1)$, we obtain

$$t_s \simeq \left(\frac{c \varepsilon^2}{16 h_V h_W} \right)^{\frac{1}{3}}. \tag{1.10}$$

Here, the time is expressed in units such that the spatial circle on which the boundary CFT lives has unit radius and ε is a holographic regulator to be introduced in (3.3).

Next, in section 4, we turn to the microstate geometries studied in [7, 11]. We focus on the $(1, 0, n)$ -superstrata whose salient geometric features are described in section 4.1. They are constructed from a BPS configuration of N_1 D1-branes and N_5 D5-branes. These geometries have an asymptotic $\text{AdS}_3 \times S^3 \times T^4$ region. They closely approximate an $S^3 \times T^4$ trivially fibred over an extremal BTZ outside of a cap region. In the cap region, the fibration becomes non-trivial and the S^3 pinches off in a smooth way. This allows the geometry to smoothly end outside of the would-be horizon of extremal BTZ. This geometry can be pictured by considering a spatial slice like that of figure 4. In extremal BTZ, this spatial slice is comprised of a near-horizon $\text{AdS}_2 \times S^1$ throat of infinite proper length attached to the asymptotic AdS_3 region. These microstates also exhibit a long throat attached to an asymptotic region, but this throat is capped off at a finite proper distance, before the would-be horizon is reached. These geometries are dual to a class of states in a two-dimensional CFT with central charge $c = 6N_1 N_5$ [7].

In section 4.4 we describe the first steps towards computing the OTOC within the geodesic approximation in these microstate geometries. First, we study null geodesics with zero angular momentum in order to understand what regions of the geometry are probed

by the OTOC as a function of the time separation between the operator insertions on the boundary. We find that for early times the interaction happens in the region of the geometry well described by extremal BTZ and so we expect the OTOC to be well described by the computations of section 3. At a time scale

$$t_{\text{cap}} \simeq \frac{N_1 N_5}{T_R}, \tag{1.11}$$

the OTOC starts to probe the cap region of the geometry and so we expect it to strongly deviate from the extremal BTZ answer. There are two main effects that will cause it to deviate: the blueshift in the center-of-mass energy will stop increasing since the geodesics cannot fall any further into the throat and the shock wave controlling the gravitational interaction between the scattered geodesics will be modified by the presence of the cap. These effects are discussed further in section 4.4.

Another effect can invalidate the geodesic approximation before either of these effects of the cap manifest themselves. In [31], it was found that the tidal forces in the throat region become Planckian well before the cap region. These tidal forces have been subsequently studied in a number of works including [32–34]. The geodesic approximation requires that the volume expansion of a particular congruence of geodesics be much smaller than the mass of the particle, which will generically be violated in a region of large tidal forces. These tidal forces become important, and are therefore in danger of invalidating the geodesic approximation, at a time scale

$$t_{\text{tidal}} \simeq \sqrt{\frac{\pi T_R}{\pi^2 T_R^2 + 1} \min(h_V, h_W) \varepsilon N_1 N_5}. \tag{1.12}$$

We have not tried to compute the shock wave produced by these geodesics in the cap region, since in any case the geodesic approximation does not hold in that region. Instead, the exact bulk-to-boundary propagators would need to be combined with the bulk-to-bulk graviton propagators to access the cap region, a computation we leave for future work.

The most relevant question for our purposes is whether the effects of the cap appear before or after the scrambling time. Indeed, given (1.10) with the appropriate central charge, we find that $t_s \ll t_{\text{tidal}}$ for large black holes in the semi-classical limit as long as the right-moving temperature is not too high

$$T_R \ll \min(h_V, h_W) \left(\frac{h_V^2 h_W^2 N_1 N_5}{\varepsilon} \right)^{\frac{1}{3}}. \tag{1.13}$$

As long as this condition holds, we expect the commutator squared to stop growing well before the interaction region reaches the part of the superstrata geometry where it deviates from extremal BTZ. In this case, we do not expect the details of the cap to affect the scrambling behaviour. They only come in far into the tail of the decay of the OTOC in the details of how the commutator squared saturates. However, for sufficiently high right-moving temperature, there does seem to be a regime where the effects of the cap will be felt before the scrambling time. We are not aware of any limit on the parameter n appearing in the superstrata solutions, which means that such large temperatures are allowed. This

region of large temperature would be an interesting regime to probe more precisely with a computation that goes beyond the geodesic approximation so that it can take into account the effects of the cap.

In section 5, we collect a number of open problems and directions for future work.

Conventions. We work in units such that the AdS length $\ell_{\text{AdS}} = 1$. The time coordinate in terms of which we express the various time scales agrees with the time coordinate of the dual CFT on a spatial circle with unit radius.

2 Geodesic approximation to the OTOC

We consider an asymptotically AdS background spacetime on which two massive Klein-Gordon real scalar fields ϕ_V and ϕ_W propagate. We are interested in computing the out-of-time-order correlator

$$\text{OTOC} \equiv \langle \psi | \phi_V(X_1) \phi_W(X_2) \phi_V(X_3) \phi_W(X_4) | \psi \rangle, \tag{2.1}$$

where the insertion points X_2, X_4 lie in the future of X_1, X_3 or are spacelike-separated from them. The state $|\psi\rangle$ corresponds to the background geometry on which the scalar fields propagate. All insertion points are also taken to lie asymptotically close to the spacetime conformal boundary in order to reproduce the OTOC of a dual conformal field theory. A method based on the geodesic approximation has been developed in a previous paper [29], which may be viewed as a position-space version of the one originally presented by Shenker and Stanford [15]. It was similarly constructed as the overlap

$$\text{OTOC} = \langle \text{out} | \text{in} \rangle, \tag{2.2}$$

between the in- and out-states

$$|\text{in}\rangle \equiv \phi_V(X_3) \phi_W(X_4) | \psi \rangle, \quad |\text{out}\rangle \equiv \phi_W(X_2) \phi_V(X_1) | \psi \rangle. \tag{2.3}$$

The operator $\phi_W(X_4)$ used to create the in-state is represented on an early time slice Σ_- by free propagation backward in time using the advanced propagator. In the same way, the operator $\phi_V(X_1)$ used to create the out-state is represented on a late time slice Σ_+ by free propagation forward in time using the retarded propagator. Note that the choice of these time slices is completely arbitrary and does not affect the end result. The overlap (2.2) then equals the *time-ordered* transition amplitude

$$\langle \psi | \phi_V(X_+) \phi_W(X_2) \phi_V(X_3) \phi_W(X_-) | \psi \rangle \sim e^{i\delta}, \tag{2.4}$$

convoluted with boundary-bulk propagators encoding the backward and forward propagation in time described above. Within the geodesic approximation $m_V, m_W \gg 1$ and the high-energy (eikonal) regime $G_N s \lesssim 1$, where s is the center-of-mass energy of the corresponding 2-to-2 scattering, the time-ordered amplitude (2.4) reduces to a simple phase $e^{i\delta}$ which we describe below in more detail. This whole construction, originally presented in [29], is illustrated for the case of an extremal BTZ background geometry in figure 5. For

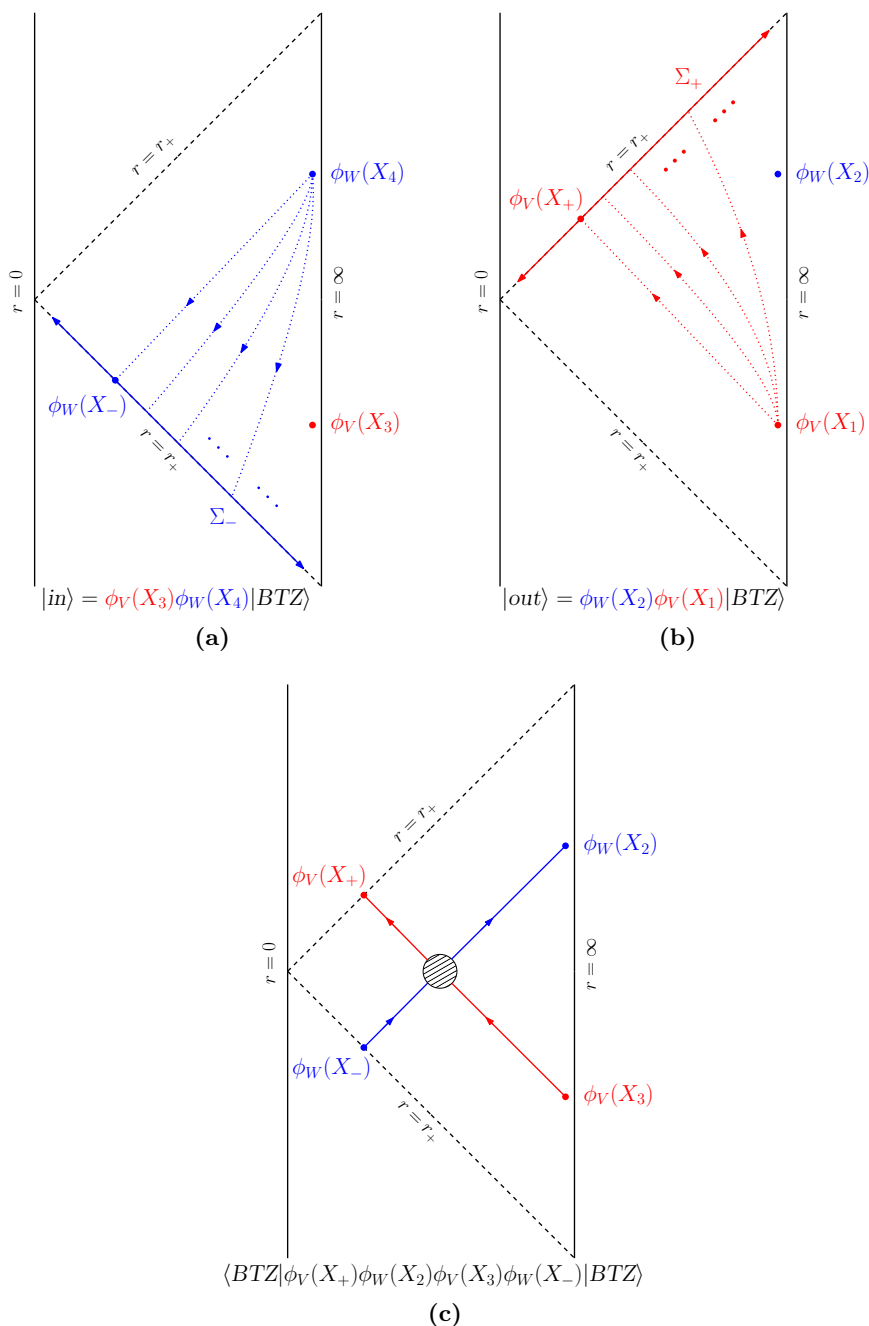

Figure 5. Steps involved in the derivation of formula (2.5) for the OTOC written as the state overlap $\langle out|in\rangle$, illustrated in the case where the background geometry is an extremal BTZ black hole, i.e. $|\psi\rangle = |BTZ\rangle$. (a)-(b) The operator $\phi_W(X_4)$ ($\phi_V(X_1)$) used to create the in-state (out-state) may be represented on the early (late) time slice Σ_- (Σ_+) by free propagation backward (forward) in time. The slices Σ_- and Σ_+ are chosen to coincide with the past and future horizons, respectively. (c) The state overlap $\langle out|in\rangle$ reduces to *time-ordered* transition amplitudes involving all points $X_- \in \Sigma_- \cap J^-(X_4)$ and $X_+ \in \Sigma_+ \cap J^+(X_1)$.

a more detailed description of the extremal BTZ geometry, we refer the reader to section 3, where we apply the general method presented here to this particular background spacetime. All in all, this construction yields the formula

$$\begin{aligned} \text{OTOC} &= -4m_W m_V \int_{\Sigma_- \cap J^-(X_4)} d\Sigma \cdot k_W \Psi_W(X_2, X_-) \Psi_W(X_4, X_-)^* \\ &\quad \times \int_{\Sigma_+ \cap J^+(X_1)} d\Sigma \cdot k_V \Psi_V(X_+, X_3) \Psi_V(X_+, X_1)^* e^{i\delta}, \end{aligned} \quad (2.5)$$

where $J^+(X_1)$ ($J^-(X_4)$) denotes the causal future (past) of the insertion point X_1 (X_4).

In the geodesic approximation which we consider, boundary-bulk propagators appearing in the above formula are given by

$$\Psi(X, Y) \equiv \langle \psi | \phi(X) \phi(Y) | \psi \rangle = A(X, Y) e^{imS(X, Y)}, \quad (2.6)$$

where the point X is assumed to lie in the causal future of the point Y , and with the phase given by the action of a timelike geodesic going from Y to X with velocity k ,

$$S(X, Y) = \int_Y^X dx \cdot k. \quad (2.7)$$

According to (2.5), each point X_- (X_+) within the time slice Σ_- (Σ_+) that can be connected by a timelike geodesic to the future (past) insertion points X_2, X_4 (X_1, X_3) must be considered. Finally, the *eikonal phase shift* δ encodes the gravitational interaction between the outgoing geodesic going from X_- to X_2 and the ingoing geodesic going from X_3 to X_+ . The stress-energy tensor $T_{\mu\nu}^V$ of an ingoing V particle is the source of a gravitational field $h_{\mu\nu}^V$ that propagates and interacts with the outgoing geodesic, and conversely. For the eikonal phase shift, this yields the formula [29]

$$\delta = \frac{1}{4} \int \left(h_{\mu\nu}^V T_W^{\mu\nu} + h_{\mu\nu}^W T_V^{\mu\nu} \right) + O(G_N^2). \quad (2.8)$$

If it were not for the eikonal phase factor, the OTOC (2.5) would simply factorize into the product of two boundary propagators,

$$\langle \psi | \phi_V(X_1) \phi_V(X_3) | \psi \rangle = 2m_V \int_{\Sigma_+ \cap J^+(X_1)} d\Sigma \cdot k_V \Psi_V(X_+, X_3) \Psi_V(X_+, X_1)^*, \quad (2.9a)$$

$$\langle \psi | \phi_W(X_2) \phi_W(X_4) | \psi \rangle = -2m_W \int_{\Sigma_- \cap J^-(X_4)} d\Sigma \cdot k_W \Psi_W(X_2, X_-) \Psi_W(X_4, X_-)^*. \quad (2.9b)$$

Stress tensor and shock wave of a particle. The stress-energy tensor of a massive particle with trajectory $x^\mu(\tau)$ and velocity $k^\mu(\tau)$ may be conveniently written [29]

$$T_{\mu\nu} = \frac{m}{\sqrt{-g}} \left(\frac{dx^0}{d\tau} \right)^{-1} k_\mu k_\nu \delta(x^1 - x^1(\tau)) \dots \delta(x^d - x^d(\tau)) \Big|_{x^0=x^0(\tau)}. \quad (2.10)$$

It sources a gravitational field which one may compute by solving the linearized Einstein's equations

$$D_{\text{lin}} h_{\mu\nu} = 8\pi G_N T_{\mu\nu}, \quad (2.11)$$

where D_{lin} is a differential operator whose definition involves the background geometry. For a single particle source with arbitrarily high energy, $h_{\mu\nu}$ is known as a gravitational *shock wave*. Although it is found by solving the above linearized Einstein's equations, it is usually also a nonlinear solution [35].

Ultraviolet regulators. We further restrict our attention to a configuration of infinitesimally separated boundary insertion points of the form

$$X_3^\mu = X_1^\mu - \epsilon_V \xi^\mu, \quad X_4^\mu = X_2^\mu - \epsilon_W \xi^\mu, \quad (2.12)$$

where ξ is a future-directed timelike vector of our choice that is tangent to the conformal boundary.¹ The role of ϵ_V, ϵ_W is to avoid UV divergences due to the insertion of operators at the same boundary points. When working in the limit of small UV regulators $\epsilon_W, \epsilon_V \ll 1$, the WKB phases in the overlap formula (2.5) simply differ by

$$S_V(X_+, X_3) = S_V(X_+, X_1) + \epsilon_V \xi \cdot k_V(X_1) + \mathcal{O}(\epsilon_V^2), \quad (2.13a)$$

$$S_W(X_4, X_-) = S_W(X_2, X_-) - \epsilon_W \xi \cdot k_W(X_4) + \mathcal{O}(\epsilon_W^2), \quad (2.13b)$$

such that

$$\Psi_V(X_+, X_3)\Psi_V(X_+, X_1)^* = |A_V(X_+, X_1)|^2 e^{im_V \epsilon_V \xi \cdot k_V(X_1)}, \quad (2.14a)$$

$$\Psi_W(X_2, X_-)\Psi_W(X_4, X_-)^* = |A_W(X_4, X_-)|^2 e^{im_W \epsilon_W \xi \cdot k_W(X_4)}. \quad (2.14b)$$

Hence, the OTOC (2.5) simplifies to

$$\begin{aligned} \text{OTOC} &= -4m_W m_V \int_{\Sigma_- \cap J^-(X_4)} d\Sigma \cdot k_W |A_W(X_4, X_-)|^2 e^{im_W \epsilon_W \xi \cdot k_W(X_4)} \\ &\quad \times \int_{\Sigma_+ \cap J^+(X_1)} d\Sigma \cdot k_V |A_V(X_+, X_1)|^2 e^{im_V \epsilon_V \xi \cdot k_V(X_1)} e^{i\delta}. \end{aligned} \quad (2.15)$$

It is customary to perform this integral by stationary phase approximation in the regime of large field masses m_V, m_W [15, 29].²

Early-time saddle point. If one is only interested in the early-time Lyapunov growth, the eikonal phase can be neglected in determining the saddle point of the integral (2.15), and one simply has to extremize the initial component velocities $\xi \cdot k_V(X_1)$ and $\xi \cdot k_W(X_4)$ over the whole set of timelike geodesics connecting the boundary insertion points X_1 and X_4 to the time slices Σ_- and Σ_+ . We present a significant simplification in the determination of the dominant pair of geodesics compared to the method used in a previous publication [29]. This new method highlights that the arbitrary choice of time slices Σ_- and Σ_+ does not affect the location of the saddle, since they do not enter the determination process at any

¹More precisely, $X_3 = \exp(-\epsilon_V \xi)$, where \exp is the exponential map at the point X_1 .

²As we explain in section 3.1, the velocities $k_{V,W}$ of particles inserted at a radial Schwarzschild coordinate $r = \epsilon^{-1}$ scale like $O(\epsilon^{-1})$ in the regime $\epsilon \ll 1$. Thus, the stationary phase approximation to the integral (2.15) holds within the regime $m_{V,W} \epsilon_{V,W} \gg \epsilon$. Since $\epsilon_{V,W}$ and ϵ both act as UV regulators, it is natural to consider them on the same footing, in which case the stationary phase approximation can be performed within the regime of large field masses $m_{V,W} \gg 1$.

point. Instead of extremizing directly over the geodesic endpoints $X_- \in \Sigma_-$ and $X_+ \in \Sigma_+$, we equivalently extremize over their initial velocities k_V and k_W , respectively. Thus, we need to determine the geodesic whose initial velocity k^μ is an extremum of the ‘energy’ functional

$$E_\xi \equiv \xi \cdot k. \quad (2.16)$$

Its variation with respect to the initial velocity is given by

$$\delta E_\xi = \xi \cdot \delta k, \quad (2.17)$$

which is required to vanish for all allowed velocity variations δk^μ . In fact, the only restriction on δk^μ comes from the timelike condition $k^2 = -1$, whose variation yields

$$k \cdot \delta k = 0. \quad (2.18)$$

From (2.17) and (2.18), we conclude that the initial velocity k^μ is a saddle point of E_ξ if

$$k^\mu \propto \xi^\mu, \quad (2.19)$$

where we recall that ξ is the future-directed timelike vector introduced in (2.12), and the normalization is easily found by imposing $k^2 = -1$. The interpretation of this result is clear: the initial velocity of the geodesic inserted at X_3 (X_4) must point towards X_1 (X_2). Note that the same condition determines the saddle point of the two-point functions (2.9). As a result, the *normalized* OTOC takes a particularly simple form,

$$\frac{\langle \phi_V(t_{\text{in}}, x_-) \phi_W(t_{\text{out}}, x_+) \phi_V(t_{\text{in}}, x_-) \phi_W(t_{\text{out}}, x_+) \rangle}{\langle \phi_V \phi_V \rangle \langle \phi_W \phi_W \rangle} \approx e^{i\delta} \Big|_{\text{saddle}}, \quad (2.20)$$

where we have made implicit that all insertions happen arbitrarily close to the conformal boundary. The pair of geodesics corresponding to the dominant saddle in (2.20) is determined from the condition (2.19) on their initial velocity at the boundary insertion points. In the limit where their insertion points are taken to the conformal boundary, these geodesics become approximately null. This is also precisely the regime in which the geodesic approximation to field propagation is most reliable and the gravitational field they create takes the form of shock waves [29]. However, note that the parameter ε measuring how close to the conformal boundary the operators are inserted, to be introduced in section 3, acts as another UV regulator and cannot be taken to zero without introducing an appropriate renormalization scheme. We will not attempt to do this in the present paper.

The above approximation scheme breaks down in the regime where the eikonal phase shift itself significantly contributes to the determination of the dominant saddle of the integral (2.5), i.e., when $\delta \gg 1$. Since δ is a growing function of time, which we describe in the next paragraph, this usually happens for late enough times. In particular, the quasi-normal decay of an OTOC (if it happens at all) lies within this late-time regime [15]. We refer the reader to appendix A for further comments and details on the treatment needed in order to describe the quasi-normal decay of OTOCs.

Early-time Lyapunov growth. Computation of OTOCs in the early-time regime through formula (2.20) instructs one to consider the stress tensor and gravitational field associated to one pair of highly energetic geodesics reaching the associated boundary insertion points, and to evaluate the eikonal phase shift (2.8) encoding their gravitational interaction. In the context of non-rotating BTZ black holes, it has been previously found that the latter scales with the center-of-mass energy s of the 2-to-2 particle scattering [15, 30]

$$\delta \sim G_N s, \tag{2.21}$$

where

$$s = -(m_V k_V + m_W k_W)^2 \approx -2m_V m_W k_V \cdot k_W, \quad k_W^2 = k_V^2 = -1. \tag{2.22}$$

The exponential Lyapunov growth originates from the exponential blueshift experienced by these particles in the neighborhood of a black hole. Indeed, one has

$$k_V(t_*) \sim e^{\kappa(t_* - t_{in})} k_V(t_{in}), \quad k_W(t_*) \sim e^{\kappa(t_{out} - t_*)} k_W(t_{out}), \tag{2.23}$$

where t_* is the time of interaction and κ is the surface gravity of the black hole background. Hence, one generically finds

$$\delta \sim G_N s \sim G_N m_W m_V e^{\kappa(t_{out} - t_{in})}, \tag{2.24}$$

which yields an exponential growth in the commutator squared, with Lyapunov exponent

$$\lambda_L = \kappa = \frac{2\pi}{\beta}. \tag{2.25}$$

This simple reasoning is useful to estimate the exponential Lyapunov growth, but is in no way rigorous nor accurate. As an example, it has been shown that (2.25) only holds on average in the context of non-maximally rotating BTZ black holes [23].

The above description does not apply to states at zero temperature $\beta \rightarrow \infty$, however. In the case of empty AdS dual to the CFT ground state, it has been shown that the eikonal phase δ grows quadratically with time [29], finding agreement with earlier results obtained by CFT techniques [16]. This sort of polynomial growth has been associated to a form of *slow scrambling*, in contrast to fast scrambling in case of exponential growth. In this paper we focus on extremal black holes to which a zero temperature is also associated. We study the case of a maximally rotating BTZ black hole in section 3, and show that the growth in time of the eikonal phase alternates between quadratic and exponential — with Lyapunov exponent associated to the nonzero ‘right-moving’ temperature. On average, the growth is cubic so that the scrambling may be qualified as slow. We will phrase this latter result in terms of the center-of-mass energy of the corresponding 2-to-2 particle scattering together with the topology of the black hole. We turn to superstratum microstate geometries in section 4, and point to the various effects that potentially distinguish the behaviour of the eikonal phase and OTOC, compared to the case of an extremal BTZ geometry.

3 OTOC in extremal BTZ

We now focus on the OTOC computation in the particular case of maximally rotating BTZ black holes. The latter being extremal and therefore having zero temperature, we expect additional subtleties compared to the computation of OTOCs in non-extremal BTZ black holes [15, 22, 23, 29].

The exterior region of extremal BTZ is commonly described using Schwarzschild coordinates (t, r, φ) with metric³

$$ds^2 = \ell_{\text{AdS}}^2 \left[- (r^2 - 2r_+^2) dt^2 + \frac{r^2 dr^2}{(r^2 - r_+^2)^2} - 2r_+^2 dt d\varphi + r^2 d\varphi^2 \right], \quad (3.1)$$

where the angular coordinate is periodically identified, $\varphi \sim \varphi + 2\pi$. The black hole horizon lies at $r = r_+$ while a timelike singularity lies at $r = 0$. The AdS conformal boundary lies at $r \rightarrow \infty$, has cylinder topology and is covered by the coordinate system (t, φ) . The Penrose diagram of extremal BTZ is displayed in figure 5. See [37, 38] for thorough reviews of three-dimensional BTZ black holes. In what follows, we will display time scales in terms of the time coordinate t , which is also the time coordinate of the dual CFT with a spatial circle of unit radius.

Being extremal, this black hole has zero Bekenstein-Hawking temperature. However, because it corresponds to a rotating ensemble, one can associate distinct temperatures to right- and left-moving modes,

$$T_L = 0, \quad T_R = \frac{r_+}{\pi}. \quad (3.2)$$

In particular, right-movers are at nonzero temperature. Extrapolating earlier results found in the case of non-maximally rotating BTZ black holes [22, 23], we can expect that the OTOC of scalar operators alternates between a polynomial growth associated to a zero left-moving temperature T_L and an exponential growth associated to a nonzero right-moving temperature T_R . We will show in section 3.2 that this is indeed the case.

We specify the coordinates of the boundary insertion points X_1 and X_2 of the OTOC as follows:

$$t_1 \equiv t_{\text{in}}, \quad \varphi_1 \equiv \varphi_{\text{in}}, \quad r_1 = \varepsilon^{-1}, \quad (3.3)$$

$$t_2 \equiv t_{\text{out}}, \quad \varphi_2 \equiv \varphi_{\text{out}}, \quad r_2 = \varepsilon^{-1}. \quad (3.4)$$

Here, we consider $\varepsilon \ll 1$ as a holographic regulator measuring how close to the conformal boundary operators are inserted. The specification of the other two boundary insertion points X_3 and X_4 is made through a choice of point-splitting regulator ξ of the type (2.12), which we make in such a way that both ingoing and outgoing geodesics connecting the above insertion points have zero angular momentum. This is always possible to achieve, and we leave the expression of ξ implicit. Following the geodesic approximation described in section 2, the computation of the OTOC at early times $\delta \lesssim 1$ (see section 2) amounts

³Useful formulae may be found in [36].

to the evaluation of the eikonal phase factor (2.8) encoding the gravitational interaction of the two geodesics. As we will show, the energy E of the associated particles scales like $E \sim \varepsilon^{-1}$ such that, in the limit $\varepsilon \rightarrow 0$, they follow null trajectories.

3.1 Highly energetic particles

Evaluation of the OTOC through the geodesic approximation scheme presented in section 2 requires one to consider the ingoing timelike geodesic connecting the insertion point $(\varepsilon^{-1}, t_{\text{in}}, \varphi_{\text{in}})$, with initial velocity k^μ proportional to the point-splitting regulator ξ^μ as shown in (2.19). The outgoing timelike geodesic connecting the insertion point $(\varepsilon^{-1}, t_{\text{out}}, \varphi_{\text{out}})$ has to be considered similarly. We start by showing that at leading order in $\varepsilon \ll 1$, we can switch to a description in terms of null geodesics. We then give the expressions of the stress tensor and gravitational shock wave associated to each one of these null geodesics, which will be needed in section 3.2 in order to compute the eikonal phase and OTOC.

Timelike geodesics. A timelike geodesic with velocity $k^\mu = \dot{x}^\mu = dx^\mu/d\tau$ has conserved energy⁴ E and angular momentum L associated to the Killing vectors ∂_t and ∂_φ of the extremal BTZ metric (3.1),

$$E = -(\partial_t)^\mu k_\mu, \quad L = (\partial_\varphi)^\mu k_\mu, \quad k^2 = -1. \quad (3.5)$$

In terms of these conserved quantities, the radial velocity of a timelike geodesic satisfies [39]

$$r^2 \dot{r}^2 = -(r^2 - r_+^2)^2 + (E^2 - L^2) r^2 + 2(L^2 - EL) r_+^2. \quad (3.6)$$

The choice of point-splitting regulator ξ^μ determines the velocity k^μ of the geodesics at the insertion points. Since ξ^μ is tangent to the (cutoff) boundary, the latter necessarily has vanishing radial component, $\dot{r} = 0$. In addition, we choose the orientation of ξ^μ in such a way that these geodesics also have zero angular momentum $L = 0$. Plugging these requirements into (3.6), we find the value of the energy,

$$E = \varepsilon^{-1} \left(1 - \varepsilon^2 r_+^2\right). \quad (3.7)$$

In the limit $\varepsilon \rightarrow 0$ where the insertion points are taken to the conformal boundary, the energy of these geodesics simply diverges and their trajectories coincide with those of the corresponding null geodesics; see also [29]. In the following, we work at leading order in $\varepsilon \ll 1$, at which we can simply approximate the trajectories of the highly energetic particles of interest by null geodesics with energy $E = \varepsilon^{-1}$ and angular momentum $L = 0$. We switch to this leading order approximation in what follows.

Null geodesics and shock waves. We thus restrict our attention to null geodesics. In terms of the null velocity k^μ , the conserved energy and angular momentum are

$$E = -(\partial_t)^\mu k_\mu, \quad L = (\partial_\varphi)^\mu k_\mu, \quad k^2 = 0. \quad (3.8)$$

⁴Following the choice of normalization $k^2 = -1$, E and L are the conserved energy and angular momentum *per unit mass*.

The null geodesic equations are then given by [39]

$$\dot{t} = \frac{Er^2 - Lr_+^2}{(r^2 - r_+^2)^2}, \quad (3.9a)$$

$$\dot{\phi} = \frac{Er_+^2 + L(r^2 - 2r_+^2)}{(r^2 - r_+^2)^2}, \quad (3.9b)$$

$$r^2\dot{r}^2 = (E^2 - L^2)r^2 + 2(L^2 - EL)r_+^2. \quad (3.9c)$$

To describe the ingoing geodesic, it is convenient to define retarded coordinates (r, v, ϕ) through

$$t = v + \frac{r}{2(r^2 - r_+^2)} - \frac{1}{4r_+} \ln \frac{r - r_+}{r + r_+}, \quad (3.10a)$$

$$\varphi = \phi + v + \frac{r}{2(r^2 - r_+^2)} + \frac{1}{4r_+} \ln \frac{r - r_+}{r + r_+}, \quad (3.10b)$$

such that the extremal BTZ metric becomes

$$ds^2 = 2drdv + 2(r^2 - r_+^2)d\phi dv + r^2d\phi^2. \quad (3.11)$$

In these coordinates, the coefficient of $d\phi dv$ vanishes at the horizon so that these coordinates give the co-rotating frame for infalling particles at the horizon. In retarded coordinates, the ingoing geodesic of interest with $E = \varepsilon^{-1}$ and $L = 0$ takes a particularly simple form. By differentiating equations (3.10a) and (3.10b) and using the negative root of (3.9c) for \dot{r} , one finds that its velocity is purely radial,

$$k_V = -\varepsilon^{-1}\partial_r, \quad (3.12)$$

such that its trajectory is

$$v(r) = v_{\text{in}} = t_{\text{in}}, \quad \phi(r) = \phi_{\text{in}} = \varphi_{\text{in}} - t_{\text{in}}. \quad (3.13)$$

From (2.10), its stress tensor has only one non-trivial component,

$$T_V^{rr} = -\frac{m_V \varepsilon^{-1}}{\sqrt{-g}} \delta(v - v_{\text{in}}) \delta(\phi - \phi_{\text{in}}). \quad (3.14)$$

On the other hand, the velocity of the outgoing geodesic with $E = \varepsilon^{-1}$ and $L = 0$ is

$$k_W = \varepsilon^{-1} \left(\frac{2r^2\partial_v}{(r^2 - r_+^2)^2} + \partial_r - \frac{2\partial_\phi}{r^2 - r_+^2} \right), \quad (3.15)$$

while its trajectory can be found by integrating the velocity and can be parametrized by

$$v(r) = t_{\text{out}} - \frac{r}{r^2 - r_+^2} + \frac{1}{2r_+} \ln \frac{r - r_+}{r + r_+}, \quad (3.16a)$$

$$\phi(r) = \varphi_{\text{out}} - t_{\text{out}} - \frac{1}{r_+} \ln \frac{r - r_+}{r + r_+}. \quad (3.16b)$$

Retarded coordinates are well suited to compute the term $h_{\mu\nu}^W T_V^{\mu\nu}$ in the eikonal phase (2.8), due to the simple form of the stress tensor (3.14). On the other hand, to compute the other term $h_{\mu\nu}^V T_W^{\mu\nu}$ in (2.8), it is more convenient to turn to the advanced coordinate system (r, u, ϕ') defined through

$$t = u - \frac{r}{2(r^2 - r_+^2)} + \frac{1}{4r_+} \ln \frac{r - r_+}{r + r_+}, \quad (3.17a)$$

$$\varphi = \phi' + u - \frac{r}{2(r^2 - r_+^2)} - \frac{1}{4r_+} \ln \frac{r - r_+}{r + r_+}. \quad (3.17b)$$

In the following we focus on the $h_{\mu\nu}^W T_V^{\mu\nu} = h_{rr}^W T_V^{rr}$ contribution. We have checked that, as in previous work [15], this is also equal to the $h_{\mu\nu}^V T_W^{\mu\nu}$ contribution.

The relevant component of the shock wave sourced by the outgoing particle is computed in appendix C and is obtained from (C.17),

$$h_{rr}^W = -\frac{4\pi G_N m_W}{r_+^2 \varepsilon} \sum_{n \in \mathbb{Z}} f(r_+ \Delta v, r_+ (\Delta v + \Delta \phi_n)) \delta(r - r_0(v, \phi)) \Theta(-\Delta \phi_n) \Theta(2\Delta v + \Delta \phi_n), \quad (3.18)$$

with

$$r_0(v, \phi) = \frac{1}{2\Delta v + \Delta \phi_n} - r_+ \coth(r_+ \Delta \phi_n), \quad (3.19)$$

and

$$f(t, x) \equiv \begin{cases} (t+x)^2, & t+x < \sinh(t-x), \\ \sinh^2(t-x), & t+x \geq \sinh(t-x), \end{cases} \quad (3.20)$$

where $\Delta v = v_{\text{out}} - v$, $\Delta \phi_n = \phi_{\text{out}} - \phi + 2\pi n$ and Θ denotes the Heaviside function. Note that, due to the ϕ -direction being periodic, the shock wave includes the contribution of many ‘images’ of the outgoing geodesic, appearing in (3.18) through the summation over $n \in \mathbb{Z}$. The shock wave of a single image geodesic has support on a surface determined by the Dirac delta function and the Heaviside functions in (3.18), in such a way that a given bulk point (v, r, φ) lies at most on a finite number of shock wave images. Indeed, for fixed values of the coordinates, only a finite number of images satisfy $-2\Delta v \leq \Delta \phi_n \leq 0$.

3.2 Eikonal phase

With the analysis of the previous section, we are in a position to compute the eikonal phase (2.8). Using (3.14) and (3.18), we find

$$\delta = \frac{1}{4} \int \sqrt{-g} (h_{\mu\nu}^V T_W^{\mu\nu} + h_{\mu\nu}^W T_V^{\mu\nu}) = \frac{2\pi G_N m_V m_W}{r_+^2 \varepsilon^2} \sum_{\substack{n \in \mathbb{Z} \\ |\Delta \varphi_n| \leq \Delta t}} f(r_+ \Delta t, r_+ \Delta \varphi_n), \quad (3.21)$$

with $\Delta t = t_{\text{out}} - t_{\text{in}}$ and $\Delta \varphi_n = \varphi_{\text{out}} - \varphi_{\text{in}} + 2\pi n$. Note that in terms of the boundary coordinates (t, φ) , the condition $-2\Delta v \leq \Delta \phi_n \leq 0$ on the sum translates to $|\Delta \varphi_n| \leq \Delta t$. Thus boundary causality determines which images should be included in the sum. Figure 6 displays the level sets of the eikonal phase. In figure 6 (a), we see the contribution of the first image. The orange line tracks the cusp in the eikonal phase, and corresponds to boundary insertions such that the dual particles collide in the bulk. The distinct accumulation of contour lines on each side of this orange line is due to the piecewise behaviour of the

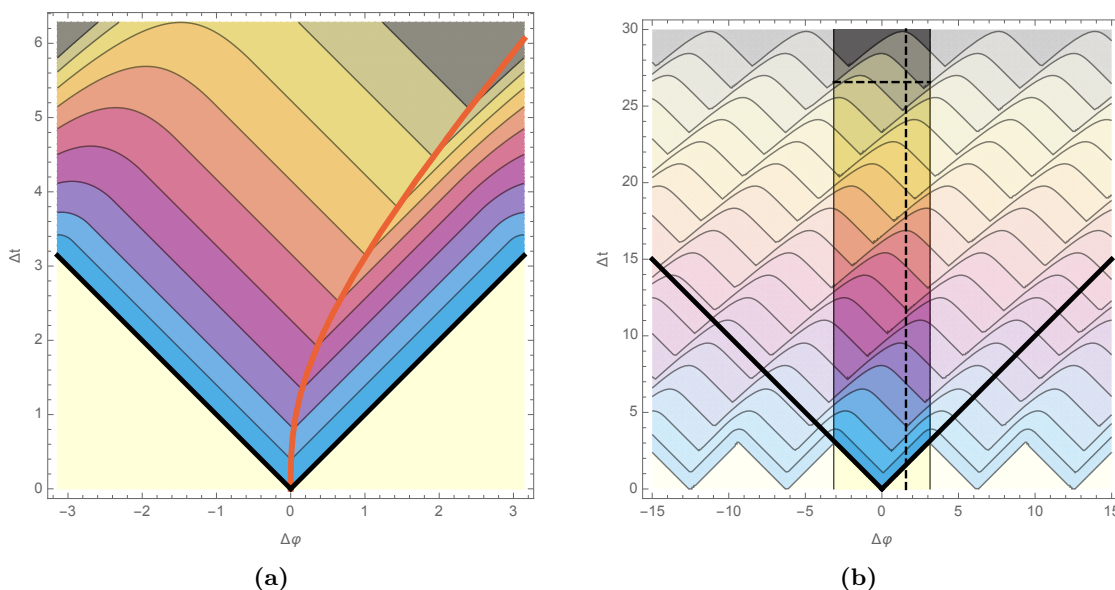

Figure 6. Contour plots of the eikonal phase $\delta(\Delta\varphi, \Delta t)$ in extremal BTZ, for $r_+ = 1$, and where the n^{th} contour level is given by a cubic function $(cn + d)^3$ with $c = 10^{-7}$ and $d = 10^{-7}$ in (a) and $(cn + d)^3$ with $c = 10^{-7}$ and $d = 15 \cdot 10^{-7}$ in (b). A cubic function would therefore have equidistant contour lines. (a) At small times, a single image contributes to the eikonal phase. The orange line characterizes the spatial separation for which δ is maximal at a fixed time separation, which corresponds to the boundary insertions for which the two geodesics cross with zero impact parameter in the bulk. On the right of this line, the growth as a function of time is exponential, while on the left there is power law growth. (b) The contour plot is extended for larger time separations, involving multiple images, while highlighting the physical domain $\Delta\varphi \in]-\pi, \pi]$. The behaviour of the eikonal phase along the vertical and horizontal dashed lines are shown in figures 3 and 7, respectively.

function $f(t, x)$ defined in (3.20), which is quadratic on the left and exponential on the right. Figure 6 (b) shows the full result which involves a sum over images. The fictitious region from which ‘image particles’ are emitted is represented in lighter colors, while the physical periodic region corresponding to $\Delta\varphi \in]-\pi, \pi]$ is brighter, with $\Delta\varphi = \varphi_{\text{out}} - \varphi_{\text{in}}$.

The time-dependence of the eikonal phase is easier to visualize from figure 3, which corresponds to the dashed vertical cut of figure 6. To properly understand the various features that appear, it is useful to further analyze the result (3.21). Consider the sum appearing in (3.21). It can be split into two elementary sums according to the two cases of the piecewise function,

$$\sum_{\substack{n \in \mathbb{Z} \\ |\Delta\varphi_n| \leq \Delta t}} f(r_+ \Delta t, r_+ \Delta\varphi_n) = \text{II} + \text{III}, \tag{3.22}$$

$$\text{II} = \sum_{n = -\lfloor \frac{\Delta t + \Delta\varphi}{2\pi} \rfloor}^{\lfloor n_* \rfloor} r_+^2 (\Delta t + \Delta\varphi + 2\pi n)^2, \quad \text{III} = \sum_{n = \lfloor n_* \rfloor}^{\lfloor \frac{\Delta t - \Delta\varphi}{2\pi} \rfloor} \sinh^2 [r_+ (\Delta t - \Delta\varphi - 2\pi n)], \tag{3.23}$$

where n_* is the real number at which the transition between the two cases occurs, and satisfies

$$r_+(\Delta t + \Delta\varphi + 2\pi n_*) = \sinh[r_+(\Delta t - \Delta\varphi - 2\pi n_*)]. \quad (3.24)$$

These sums are simple to evaluate, but the full expression is a bit involved so we will not write it out in full here. We will focus instead on the behaviour in the late time regime. The transition point n_* can be approximated in the large $\Delta t \gg 1$ regime by,

$$2\pi n_* = \Delta t - \Delta\varphi - \frac{\log(4r_+\Delta t)}{r_+} + O\left(\frac{\log(r_+\Delta t)}{r_+^2\Delta t}\right). \quad (3.25)$$

Using this approximation along with the fact that $[x] = x - (x \bmod 1)$, we obtain

$$\delta = \frac{4\pi G_N m_V m_W}{\varepsilon^2} \left\{ \frac{2\Delta t^3}{3\pi} - \frac{\Delta t^2 \log(4r_+\Delta t)}{\pi r_+} + \left(1 - \frac{\left[\left(\Delta t - \Delta\varphi - \frac{\log(4r_+\Delta t)}{r_+} \right) \bmod 2\pi \right]}{\pi} + 2 \frac{e^{2r_+ \left[\left(\Delta t - \Delta\varphi - \frac{\log(4r_+\Delta t)}{r_+} \right) \bmod 2\pi \right]}}{e^{4\pi r_+} - 1} \right) \Delta t^2 + O(\Delta t) \right\}. \quad (3.26)$$

Average slow scrambling. The average growth of the eikonal phase for times $\Delta t \gg 1$ is well described by equation (3.26). In particular, it is cubic up to subleading contributions. One of these subleading contributions is of the form (periodic function) $\times \Delta t^2$, which suggests a sawtooth-like behaviour around this average cubic growth. Indeed, we can observe in figure 3 that the average value of the eikonal phase follows the cubic orange dashed line, with sawtooth-modulation around this cubic growth. The scrambling time Δt_s defined as the time at which $\delta \sim 1$, is inferred from this average cubic growth,

$$\Delta t_s \simeq \left(\frac{3\varepsilon^2}{8G_N m_V m_W} \right)^{\frac{1}{3}} = \left(\frac{c\varepsilon^2}{16h_V h_W} \right)^{\frac{1}{3}}. \quad (3.27)$$

The second equality gives the expression of the scrambling time in terms of CFT quantities, namely the central charge $c = \frac{3}{2G_N}$ and the conformal weights $2h_{V,W} \approx m_{V,W} \gg 1$ and reproduces (1.10) from the introduction.

The average cubic growth could have been obtained in a much simpler fashion by considering the dependence of the center-of-mass energy of the scattered particles on the time separation of their boundary insertion points, together with the angular periodicity of the background spacetime leading to contributions from multiple image particles. Indeed, the center-of-mass energy s associated to the scattering of the two null geodesics with momentum (3.12) and (3.15) and colliding at $r = r_*$ is proportional to

$$k_V \cdot k_W = -\frac{2r_*^2}{\varepsilon^2(r_*^2 - r_+^2)^2}. \quad (3.28)$$

From the trajectories of the geodesics given by (3.13) and (3.16), one can relate r_* to the time separation of the boundary points,

$$\Delta t = t_{\text{out}} - t_{\text{in}} = \frac{r_*}{r_*^2 - r_+^2} - \frac{1}{2r_+} \ln \frac{r_* - r_+}{r_* + r_+}. \quad (3.29)$$

At late times, the geodesics scatter close to the horizon so that the separation is given at leading order by

$$\Delta t = \frac{1}{2(r_* - r_+)} + O\left(\ln\left(\frac{r_*}{r_+} - 1\right)\right), \quad (3.30)$$

such that the center-of-mass energy scales like

$$k_V \cdot k_W = \frac{\varepsilon^{-2}}{2(r_* - r_+)^2} + O\left(\left(\frac{r_*}{r_+} - 1\right)^{-1}\right) \approx 2\varepsilon^{-2}\Delta t^2. \quad (3.31)$$

Hence, the center-of-mass energy of the particle scattering grows quadratically with Δt . The discrepancy between this estimate and the cubic growth found from (3.26) is explained by the angular periodicity of the solution. Indeed, the number n of image particles contributing to the sum (3.22) actually grows linearly with time. Equivalently, the two physical scattered particles are seen to circle around the black hole and the number of times they meet grows linearly with Δt . In summary, the average cubic growth of the eikonal phase δ may be inferred from the quadratic growth of the center-of-mass energy s together with the linear growth in the number of particle images.

Sawtooth pattern. We would now like to understand the sawtooth pattern appearing on top of the average growth in figure 3. For this it is useful to analyze (3.22) in more detail. The two sums, II and III, have very different behaviours. First, we note that for $\Delta t \gg 1$ the range of n in II scales as $\Delta t/\pi$ whereas in III it scales as $r_+^{-1} \log(4r_+\Delta t)$. Since the summand in II is a $O(\Delta t^2)$ polynomial, a sum over Δt terms leads to a Δt^3 scaling. On the other hand, the summand in III is exponential and so its scaling is controlled by the largest term at $n = \lceil n_* \rceil$. The logarithmic term in n_* leads to an overall Δt^2 growth for this sum,

$$\sinh^2[r_+(\Delta t - \Delta\varphi - 2\pi\lceil n_* \rceil)] \sim 4r_+^2\Delta t^2 e^{-4\pi r_+} e^{2r_+ \left[\left(\Delta t - \Delta\varphi - \frac{\log 4r_+\Delta t}{r_+} \right) \bmod 2\pi \right]}. \quad (3.32)$$

This explains why II dominates the overall value of the eikonal phase.

Let us now consider the sum II in more detail. On small time intervals, this sum has a fixed number of terms, each contributing an $O(\Delta t^2)$ growth, so it exhibits quadratic growth. An example of such quadratic growth is represented by the dotted green line in figure 3. On larger time scales, the number of terms jumps discretely as additional images are included, and grows on average as $O(\Delta t)$. Thus the locally quadratic but overall cubic growth comes from a behaviour that can be schematically written as

$$\text{II} \sim \lfloor \Delta t \rfloor \Delta t^2. \quad (3.33)$$

A sawtooth pattern appears because both sums compete in the time derivative of the eikonal phase. First, note that the bounds of the sums involve floors such that they are mostly constant except for discontinuities when a new image must be included. Therefore, except at these cusps in δ , a time derivative only acts on the summands. This means that the time derivative of the sum \mathbb{I} is reduced to $O(\Delta t^2)$, at which order it will have to compete with the time derivative of \mathbb{III} . Indeed,

$$\frac{d\delta}{d\Delta t} \sim \frac{4G_N m_V m_W}{\varepsilon^2} \left(1 + 4\pi r_+ \frac{e^{2r_+ \left[\left(\Delta t - \Delta\varphi - \frac{\log 4r_+ \Delta t}{r_+} \right) \bmod 2\pi \right]}}{e^{4\pi r_+} - 1} \right) \Delta t^2 + O(\Delta t), \quad (3.34)$$

where the two terms in parentheses come from the two sums, respectively. The relative size of the two terms changes depending on whether we look right before or after the cusp. These correspond to whether $\left[\left(\Delta t - \Delta\varphi - \frac{\log 4r_+ \Delta t}{r_+} \right) \bmod 2\pi \right]$ is just below 2π or just above 0, respectively,

$$\frac{d\delta}{d\Delta t} = \frac{4G_N m_V m_W}{\varepsilon^2} \begin{cases} \left(1 + \frac{4\pi r_+}{1 - e^{-4\pi r_+}} \right) \Delta t^2 + O(\Delta t), & \left[\left(\Delta t - \Delta\varphi - \frac{\log 4r_+ \Delta t}{r_+} \right) \bmod 2\pi \right] \lesssim 2\pi, \\ \left(1 + \frac{4\pi r_+}{e^{4\pi r_+} - 1} \right) \Delta t^2 + O(\Delta t), & \left[\left(\Delta t - \Delta\varphi - \frac{\log 4r_+ \Delta t}{r_+} \right) \bmod 2\pi \right] \gtrsim 0. \end{cases}$$

Right before the cusp, the contribution to the derivative from \mathbb{III} is biggest since $\frac{4\pi r_+}{1 - e^{-4\pi r_+}} > 1$ for $r_+ > 0$. Conversely, right after the cusp, the contribution to the derivative from \mathbb{I} is biggest since $\frac{4\pi r_+}{e^{4\pi r_+} - 1} < 1$ for $r_+ > 0$. At $r_+ = 0$ the two terms become equal, as we return to the vacuum answer. The sawtooth is sharpest when r_+ is large and there is a sharp hierarchy between the two contributions.

The cross-over between the two behaviours, seen in figure 7, occurs when the two terms in (3.34) are equal, i.e.

$$\left[\left(\Delta t - \Delta\varphi - \frac{\log 4r_+ \Delta t}{r_+} \right) \bmod 2\pi \right] = \pi + \frac{1}{2r_+} \log \left(\frac{\sinh(2\pi r_+)}{2\pi r_+} \right), \quad (3.35)$$

such that the part of the sawtooth with exponential growth decreases as r_+ increases. This is compatible with the fact that the rate of exponential growth is $2r_+$ and so when r_+ is increased the same amount of catch-up growth to interpolate between the local quadratic and overall cubic growth can be achieved in a shorter time.

The OTOC in non-maximally rotating BTZ. We would also like to comment on a connection with previous work which has studied the OTOC in rotating ensembles [22, 23]. In those works the OTOC was computed by multiplying the center-of-mass energy with a shock wave profile computed by assuming that the scattering occurs on the horizon. In the finite temperature case, this is a good approximation in the regime $\Delta t \gg \beta$. However, in the extremal limit, this shock wave profile (denoted $f(\phi)$ in [22] and $h(\phi)$ in [23]) diverges. This can be seen by looking at equation (5.17) in [23] for example. This is why in our approach, it was important that we did not approximate the shock wave by putting it on the horizon in the description of the gravitational scattering. Nonetheless, the shock wave profile from [23] can be regulated by subtracting a term that diverges in the near extremal

Figure 7. The spatial dependence of the eikonal phase in extremal BTZ at $r_+ = 1$, for a fixed time separation, $\Delta t \gg 1$, corresponding to the horizontal dashed line in figure 6. The time separation has been chosen such that the cusp would be on the edges $\Delta\varphi = \pm\pi$. The cross-over between the exponential and power-law behavior is also visible in this figure, with the location of the trough given by (3.35). The φ -dependence of the eikonal phase is encoded in the subleading $O(t^2)$ terms of (3.26). Up to a redefinition $\phi \rightarrow \Delta t - \Delta\varphi - \frac{\log 4r_+ \Delta t}{r_+}$, this precisely matches the shape of the shockwave in the extremal limit in [23], after subtracting the divergent piece (although the latter shockwave is a priori only valid for $t \gg \beta \rightarrow \infty$).

limit, yet is constant in Δt and $\Delta\varphi$.⁵ The regulated shock wave then corresponds to the terms of $O(\Delta t^2)$ in parentheses in (3.26). This regulated shock wave does not help with computing the leading growth of Δt^3 in (3.26), which arose from the sum of an interaction of strength $O(\Delta t^2)$ over Δt images. The number of images is controlled by how deep the interaction happens in the bulk and taking the approximation that the scattering happens on the horizon would correspond to including an infinite number of these images. Since in the extremal case the shock wave has a power-law tail, this cutoff regulating the sum over images is important to track. On the other hand, the sawtooth pattern on top of this overall growth, contained in the $O(\Delta t^2)$ term, does correspond to considering the regulated

⁵Using the conventions of (5.17) in [23], in the near extremal limit,

$$h(\phi) \simeq \frac{1}{2\pi(r_+ - r_-)} + \frac{1}{2} \left(1 - \frac{(\phi \bmod 2\pi)}{\pi} + \frac{2e^{2r_+(\phi \bmod 2\pi)}}{e^{4\pi r_+} - 1} \right) + O(r_+ - r_-).$$

Notice that this matches the $O(\Delta t^2)$ term in parentheses in (3.26) up to the replacement $\phi \rightarrow \Delta t - \Delta\varphi - \frac{\log(4r_+ \Delta t)}{r_+}$. The constant factors multiplying the parentheses can be understood by comparing the relevant conventions and using the expression (3.31) for the center-of-mass energy in extremal BTZ. The variable ϕ in that work corresponded to a co-rotating coordinate. In the extremal limit, that co-rotating coordinate becomes null. Similarly, the expression $\Delta t - \Delta\varphi - \frac{\log(4r_+ \Delta t)}{r_+}$ appearing in our result can be thought of as a type of co-rotating coordinate slightly regulated so that it does not become null in the extremal limit. This is also related to the retarded coordinates defined in (3.10), where an additional logarithmic term was required compared to the similar coordinates in the non-extremal case. This term was required to ensure that a radially infalling null geodesic stays at constant ϕ . Alternatively, it can be understood as the term required for the infalling coordinates to be co-rotating at the horizon rather than at the boundary. Notice that the $d\varphi dt$ term is subleading at the conformal boundary in (t, r, φ) coordinates, (3.1), whereas the $d\phi dv$ vanishes at the horizon in (v, r, ϕ) coordinates, (3.11).

extremal limit of the shock wave computed on the horizon in the non-extremal geometry times the center-of-mass energy of two colliding geodesics in extremal BTZ. The spatial dependence of the eikonal phase, which coincides with the dependence of the shockwave, is displayed in figure 7.

4 Microstate geometries

We have seen above that the OTOC can be computed within a WKB approximation by studying the exchange of a gravitational shock wave between two boundary anchored geodesics. The strength of the interaction was controlled by the energy of the interacting geodesics in the center-of-mass frame. The form of the gravitational shock wave also played an important role in controlling the sum over images that appears due to the periodic spatial direction on the boundary.

In this section, we will consider a family of three-charge microstate geometries constructed in [7, 40]. These are 10-dimensional IIB supergravity solutions reduced to 6 dimensions on a T^4 dual to BPS states of $\mathcal{N} = 4$ SYM. These geometries have the form of a 3-sphere fibred over an extremal BTZ black hole. At large radial coordinate of the BTZ base, they approach an asymptotic $\text{AdS}_3 \times S^3$. At intermediate radii they have a throat region which approximates the $\text{AdS}_2 \times S^1 \times S^3$ characteristic of the near horizon region of extremal BTZ. However at small radius, the throat region ends in a smooth cap at a finite proper distance.

In section 4.1, we introduce the metric of these geometries. In section 4.2, we discuss the black hole limit of the superstrata and how the quantities derived in this section can be compared to the computations in extremal BTZ black holes. In section 4.3, we study null geodesics in the superstrata, which will be required to compute the OTOC within the WKB approximation. In section 4.4, we use these results to discuss how the presence of the cap potentially modifies the behaviour of the OTOC in different regimes and identify a time scale where our geodesic approximation breaks down due to tidal forces. We find that these effects only become relevant after the time scale associated with scrambling when the commutator squared becomes $\mathcal{O}(1)$.

4.1 (1,0,n) superstrata

The superstrata are solutions of six-dimensional supergravity, with metric given by [11]

$$\begin{aligned}
 ds_6^2 = \sqrt{Q_1 Q_5} \Lambda \left[\frac{d\rho^2}{\rho^2 + a^2} - \frac{F_1(\rho)}{a^2(2a^2 + b^2)^2 F_2(\rho)} \left(dt - d\varphi + \frac{a^2(a^4 + (2a^2 + b^2)\rho^2)}{F_1(\rho)} (dt + d\varphi) \right)^2 \right. \\
 + \frac{a^2 \rho^2 (\rho^2 + a^2)}{F_1(\rho)} (dt + d\varphi)^2 + d\theta^2 + \frac{1}{\Lambda^2} \sin^2 \theta \left(d\phi_1 - \frac{2a^2}{(2a^2 + b^2)} dt \right)^2 \\
 \left. + \frac{F_2(\rho)}{\Lambda^2} \cos^2 \theta \left(d\phi_2 - \frac{1}{(2a^2 + b^2) F_2(\rho)} \left[-2a^2 dt + b^2 F_0(\rho) (dt - d\varphi) \right] \right)^2 \right], \tag{4.1}
 \end{aligned}$$

where φ goes around an S^1 with periodicity $\varphi \sim \varphi + 2\pi$. We have made the coordinate redefinition $t \rightarrow R_y t$ and $y \rightarrow R_y \varphi$ compared to the notation in [11]. This eliminates the parameter R_y from their solution in order to be consistent with the conventions used in the previous section. The following functions enter the above metric:

$$F_0(\rho) = 1 - \frac{\rho^{2n}}{(\rho^2 + a^2)^n}, \tag{4.2a}$$

$$F_1(\rho) = a^6 - b^2(2a^2 + b^2)\rho^2 F_0(\rho), \tag{4.2b}$$

$$F_2(\rho) = 1 - \frac{a^2 b^2}{2a^2 + b^2} \frac{\rho^{2n}}{(\rho^2 + a^2)^{n+1}}, \tag{4.2c}$$

$$\Lambda = \sqrt{1 - \frac{a^2 b^2}{2a^2 + b^2} \frac{\rho^{2n}}{(\rho^2 + a^2)^{n+1}} \sin^2 \theta}. \tag{4.2d}$$

In addition to the metric, there are various other supergravity fields turned on which we will not need here.

The superstrata solution is specified by the 3 parameters (a, b, n) . There are a number of conserved charges in supergravity which have non-zero values in this solution. The D-brane charges Q_1 and Q_5 only appear in the metric in the combination $Q_1 Q_5$, which is fixed in terms of the parameters of the superstrata solution by the regularity condition

$$Q_1 Q_5 = \left(a^2 + \frac{1}{2} b^2 \right). \tag{4.3}$$

This solution also has momentum charge along the S^1 parametrized by φ and angular momentum $J_L = J_R = J$ in planes that straddle both the BTZ and S^3 parts of the fibration. These charges are given by

$$Q_P = \frac{1}{2} b^2, \quad J = \frac{1}{2} \mathcal{N} a^2, \quad \mathcal{N} = \frac{\text{Vol}(T^4)}{\ell_{10}^8}, \tag{4.4}$$

where $\text{Vol}(T^4)$ is the normalised volume of the T^4 as defined in [11] and ℓ_{10} is the 10-dimensional Planck length. An effective 6-dimensional Planck length can be introduced

$$\ell_6^4 \equiv \frac{\ell_{10}^8}{\text{Vol}(T^4)}, \tag{4.5}$$

in terms of which

$$J = \frac{a^2}{2\ell_6^4}. \tag{4.6}$$

These supergravity solutions have well understood CFT duals which are described in [7, 11]. Their central charge is controlled by two quantised numbers N_1 and N_5 corresponding to the number of units of D-brane charge in the supergravity solution. We will not discuss these CFTs in detail here except to note that the supergravity charges $Q_{1,5}$ are related to the central charge of the CFT by

$$c = 6N_1 N_5 = 6 \frac{Q_1 Q_5}{\ell_6^4}. \tag{4.7}$$

Note that we can also relate the central charge to the three-dimensional Newton constant through the Brown-Henneaux formula [41],

$$c = \frac{3}{2G_N}. \tag{4.8}$$

4.2 Black hole limit of the superstrata

We now study the $a \rightarrow 0$ limit of the superstrata, where it approaches the extremal BTZ black hole. This allows the parametrization of the superstrata used so far to be related to r_+ parametrizing the extremal BTZ black hole.

In the limit $a \rightarrow 0$, the metric (4.1) becomes

$$ds^2 = \sqrt{Q_1 Q_5} \left[\frac{d\rho^2}{\rho^2} - \frac{2\rho^2}{b^2} (dt^2 - d\varphi^2) + n(dt - d\varphi)^2 + d\theta^2 + \sin^2 \theta d\phi_1^2 + \cos^2 \theta d\phi_2^2 \right]. \tag{4.9}$$

To make contact with the extremal BTZ black hole in the form (3.1), one can use the regularity condition (4.3) and the fact that $a \ll b$, to identify

$$\rho^2 = \frac{b^2}{2}(r^2 - n), \quad n = r_+^2, \quad Q_1 Q_5 = \ell_{\text{AdS}}^4 \simeq \frac{1}{2} b^2. \tag{4.10}$$

In other words, b controls the overall scale of the geometry through ℓ_{AdS} and n controls the right-moving temperature (3.2) of the approximate extremal BTZ geometry,

$$T_R = \frac{\sqrt{n}}{\pi}. \tag{4.11}$$

At the conformal boundary, $r \rightarrow \infty$, t is equal to the dimensionless time on the boundary measured in units of the radius of the boundary circle (taken to be unity), while φ is an angular coordinate on that same circle. To be consistent with the previous section, we should set $\ell_{\text{AdS}} = 1$ which means that $b = \sqrt{2}$, however since the existing literature on these geometries keeps b in expressions we will do so as well.

The remaining parameter, a , controls the deviations from this extremal BTZ. More concretely, let us investigate the region where the superstrata closely approximates the throat of extremal BTZ. This throat sets in for

$$\rho \ll \frac{\sqrt{nb}}{\sqrt{2}} \equiv \rho_{\text{throat}}, \tag{4.12}$$

which is where the radius of the S^1 is approximately constant. In BTZ, this translates to $r^2 - r_+^2 \ll r_+^2$. It provides a good approximation for the geometry as long as $\rho \gg \sqrt{na}$, after which the radius of the throat starts to shrink again until it pinches off at the tip of this cap region as described in detail in [11]. Therefore the relevant length scale associated with the start of the cap region is

$$\rho_{\text{cap}} \equiv \sqrt{na}. \tag{4.13}$$

The proper length along the radial direction of the throat region, depicted in figure 4, is

$$(Q_1 Q_5)^{\frac{1}{4}} \log \left(\frac{\rho_{\text{throat}}}{\rho_{\text{cap}}} \right). \tag{4.14}$$

The ratio controlling the depth of the throat can also be expressed as

$$\frac{\rho_{\text{throat}}^2}{\rho_{\text{cap}}^2} = \frac{b^2}{2a^2} = \frac{Q_1 Q_5}{2\ell_6^4 J} = \frac{N_1 N_5}{2J}. \quad (4.15)$$

For a fixed value of the central charge, or equivalently $N_1 N_5$, the longest throats are obtained by setting J to be as small as possible. Since it is quantised, this is $J = \frac{1}{2}$ [11]. This corresponds to the regime of superstrata parameter space which is closest to the extremal BTZ ensemble, since it has the minimal extra angular momentum in the extra dimensions. In the following, we set $J = \frac{1}{2}$.

With this top-down understanding of how an extremal BTZ appears as a limit of these microstate geometries, the scrambling time computed in (3.27) can be expressed in terms of the parameters of the dual CFT state,

$$\Delta t_s = \left(\frac{3\varepsilon^2 N_1 N_5}{8h_V h_W} \right)^{\frac{1}{3}}. \quad (4.16)$$

Note that in this section we have worked in the regime $a \ll b$, where the physical identification of a long extremal BTZ throat makes sense. In extending the definition of these parameters away from this regime, it may be natural to include additional terms that are subleading in the $a \ll b$ limit.

4.3 Geodesics of the superstrata

The geodesic method for computing the OTOC, outlined in section 2 and applied in section 3 to extremal BTZ, involves an ingoing and an outgoing null geodesic that are both anchored on the boundary and interact in the bulk of the geometry. In this section, we will analyze such geodesics in the microstate geometries described by (4.1). Geodesics in the superstrata geometries were studied in [27, 32]. The present analysis is based on the results of [32], which analyzed timelike geodesics dropped into the throat region of these geometries. As was done there, we will also restrict ourselves to geodesics with $\theta = \frac{\pi}{2}$, which is a fixed point of the $\theta \rightarrow \pi - \theta$ symmetry.

Working in $(t, \varphi, \rho, \theta, \phi_1, \phi_2)$ coordinates, the Killing vectors associated to the isometries of the metric (4.1) are given by ∂_t , ∂_φ , ∂_{ϕ_1} and ∂_{ϕ_2} , with associated conserved momenta

$$E = -(\partial_t)^\mu k_\mu, \quad P_\varphi = (\partial_\varphi)^\mu k_\mu, \quad L_1 = (\partial_{\phi_1})^\mu k_\mu, \quad L_2 = (\partial_{\phi_2})^\mu k_\mu, \quad (4.17)$$

where $x^\mu(\tau)$ is a parametrization of the geodesic in question and $k^\mu = dx^\mu/d\tau$. We set $P_\varphi = 0$ as was done in the previous section when studying the extremal BTZ black hole. We also set $L_1 = 0$ and $L_2 = 0$ so that the geodesic does not have extra angular momentum in the S^3 .

The equations (4.17) can be solved to express components of the velocity in terms of the energy E ,

$$\frac{dt}{d\tau} = \frac{(2a^2 + b^2)((2a^2 + b^2)(\rho^2 + a^2)^n - b^2\rho^{2n})}{2\sqrt{2}a^2(\rho^2 + a^2)^{n+1}\sqrt{(2a^2 + b^2) - a^2b^2\rho^{2n}(\rho^2 + a^2)^{-(n+1)}}} E, \quad (4.18a)$$

$$\frac{d\varphi}{d\tau} = \frac{(2a^2 + b^2)b^2(\rho^2 + a^2)^{-\frac{1}{2}(n+1)}((\rho^2 + a^2)^n - \rho^{2n})}{2\sqrt{2}\sqrt{(2a^2 + b^2)(\rho^2 + a^2)^{n+1} - a^2b^2\rho^{2n}}} E, \quad (4.18b)$$

$$\frac{d\phi_1}{d\tau} = \frac{(2a^2 + b^2)(\rho^2 + a^2)^n - b^2\rho^{2n}}{\sqrt{2}(\rho^2 + a^2)^{n+1}\sqrt{(2a^2 + b^2)(\rho^2 + a^2)^{n+1} - a^2b^2\rho^{2n}}} E, \quad (4.18c)$$

and $d\theta/d\tau = d\phi_2/d\tau = 0$. The condition that the geodesic be null, $k^2 = 0$, can be solved for the remaining component of the velocity

$$\left(\frac{d\rho}{d\tau}\right)^2 = \frac{2a^2 + b^2}{2a^2} \frac{(\rho^2 + a^2)((2a^2 + b^2)(\rho^2 + a^2)^n - b^2\rho^{2n})}{(2a^2 + b^2)(\rho^2 + a^2)^{n+1} - a^2b^2\rho^{2n}} E^2. \quad (4.19)$$

In order to find the trajectory of the geodesics we simply need to integrate the ratio of the velocities (4.18a) and (4.19)

$$t(\rho) - t(\infty) = \pm \int_{\rho}^{\infty} d\rho \frac{\sqrt{2a^2 + b^2}\sqrt{(2a^2 + b^2)(\rho^2 + a^2)^n - b^2\rho^{2n}}}{2a(\rho^2 + a^2)^{\frac{n}{2}+1}}. \quad (4.20)$$

This expression gives the coordinate time at which a null geodesic emitted from the boundary will probe a given radius of the geometry. Now consider two geodesics, one which leaves the boundary at t_{in} and one that is absorbed at the boundary at t_{out} . These two geodesics will rotate around the compact φ and ϕ_1 directions, but they will most strongly interact in the bulk when the ingoing and outgoing geodesics meet at the same radius, ρ_* .

A full computation of their interaction would require computing the dependence on the compact directions of the gravitational shock wave produced by geodesics in the superstrata geometry. However, here we will simply take the first steps towards understanding the difference between the superstrata and the extremal BTZ black hole. We will therefore focus on the motion in the ρ - t directions in order to better understand the effect of the cap in the superstrata geometry without the additional complication of the effects of these compact directions.

The radius where the two geodesics meet, ρ_* , is related to the difference of their insertion times at the boundary by

$$\Delta t(\rho_*) \equiv t_{\text{out}} - t_{\text{in}} = 2 \int_{\rho_*}^{\infty} d\rho \frac{\sqrt{2a^2 + b^2}\sqrt{(2a^2 + b^2)(\rho^2 + a^2)^n - b^2\rho^{2n}}}{2a(\rho^2 + a^2)^{\frac{n}{2}+1}}. \quad (4.21)$$

We will now proceed to study this expression in various regimes.

BTZ region. First, let us consider the region well outside the cap, where the geometry is well approximated by extremal BTZ $\times S^3$, for $\rho_*, b \gg a$,

$$\Delta t \simeq 2 \int_{\rho_*}^{\infty} \frac{\sqrt{2\rho^2 + nb^2}b}{2\rho^3} d\rho = \frac{b}{2\rho_*^2} \sqrt{2\rho_*^2 + nb^2} + \frac{1}{\sqrt{n}} \operatorname{arcsinh} \frac{\sqrt{nb}}{\sqrt{2}\rho_*}. \quad (4.22)$$

The OTOC will start probing the throat when $\rho_* = \rho_{\text{throat}}$, corresponding to a time separation on the boundary of

$$\Delta t_{\text{throat}} \simeq \left(\sqrt{2} + \text{arcsinh } 1\right) \frac{1}{\sqrt{n}} \implies \Delta t_{\text{throat}} \propto T_R^{-1}. \quad (4.23)$$

This timescale is controlled by the right-moving temperature of the extremal BTZ black hole approximated by this geometry. As expected, this time scale only depends on BTZ parameters and does not involve details of the cap region.

In this regime the motion of the geodesic along the BTZ factor of the geometry closely follows the trajectory of a geodesic in extremal BTZ, that is $(t(\rho), \varphi(\rho))_{\text{superstrata}} \simeq (t(\rho), \varphi(\rho))_{\text{BTZ}}$. In this asymptotic region, the geometry is approximately a product of BTZ and a homogeneous S^3 . The geodesics we consider do not have any angular momentum along the S^3 , such that they sit at a constant value of the sphere coordinates (θ, ϕ_1, ϕ_2) .

To understand where the corrections to the geometry first start to significantly affect the trajectory, the ratio of the first subleading term to this leading term must be examined. In the regime where $a \ll \rho_* \ll b$, by expanding $t(\rho)$ in (4.21) to subleading order, we find that this ratio is

$$-\frac{(n+5)a^2}{8\rho^2}. \quad (4.24)$$

By using a similar approach to compute $\varphi(\rho)$, we find the same ratio. The perturbative expansion used in (4.22) breaks down when this ratio is $O(1)$ at $\rho \sim \sqrt{n+5}a \sim \rho_{\text{cap}}$.

Cap region. In order to access the cap region, we can instead expand (4.21) in the regime where $\rho_*, a \ll b$. To do so, we must split the integral into two parts somewhere in the overlap of the applicability of the two approximations, at a radius ρ_{split} obeying both $\rho_{\text{split}}, b \gg a$ and $\rho_{\text{split}}, a \ll b$, i.e. $a \ll \rho_{\text{split}} \ll b$,

$$\Delta t \simeq 2 \int_{\rho_{\text{split}}}^{\infty} \frac{\sqrt{2\rho^2 + nb^2}b}{2\rho^3} d\rho + 2 \int_{\rho_*}^{\rho_{\text{split}}} \frac{\sqrt{(\rho^2 + a^2)^n - \rho^{2n}b^2}}{2a(\rho^2 + a^2)^{\frac{n}{2}+1}} d\rho \simeq \frac{b^2}{a^2} \chi_n \left(\frac{\rho_*}{a}\right) \quad (4.25)$$

where only the leading term in $\frac{b}{a} \gg 1$ has been kept and the following dimensionless integral was introduced,

$$\chi_n(x) \equiv \int_x^{\infty} \frac{\sqrt{(\xi^2 + 1)^n - \xi^{2n}}}{(\xi^2 + 1)^{\frac{n}{2}+1}} d\xi. \quad (4.26)$$

The minimal separation between the insertions on the boundary so that the OTOC can directly probe the cap occurs when $\rho_* = \rho_{\text{cap}}$, so that

$$\Delta t_{\text{cap}} \simeq \frac{b^2}{a^2} \chi_n(\sqrt{n}). \quad (4.27)$$

At large x , $\chi_n(x) \simeq \frac{\sqrt{n}}{2x^2}$, so that at large n , $\chi_n(\sqrt{n}) \simeq \frac{1}{2\sqrt{n}}$. In fact, numerical investigation shows that for any $n \geq 1$,

$$\frac{1}{4} < \sqrt{n} \chi_n(\sqrt{n}) < \frac{1}{2}. \quad (4.28)$$

Therefore the time scale to reach the cap region is given by

$$\Delta t_{\text{cap}} \propto \frac{1}{\sqrt{n}} \frac{b^2}{a^2} \propto \frac{N_1 N_5}{T_R}, \tag{4.29}$$

reproducing the result quoted in the introduction in (1.11).

4.4 OTOC in the superstrata

Now that we have understood the trajectory of the relevant geodesics, we can see how this affects the computation of the OTOC in the superstrata geometry. First of all, we should be clear about the OTOC we wish to compute. In the asymptotic region, reducing on the compact $S^3 \times T^4$ of the 10-dimensional geometry leads to a Kaluza-Klein tower of fields from the 3-dimensional BTZ perspective. Each of the 3-dimensional fields in this tower corresponds to an operator in the dual 2-dimensional CFT. We will restrict ourselves to considering OTOCs of operators dual to the lowest field in this tower of Kaluza-Klein modes, which are completely delocalised along these extra compact dimensions. More precisely, this means that in the bulk-to-boundary propagators used to compute the OTOC, such as in equation (2.6), the boundary insertion point is integrated over $S^3 \times T^4$. In the part of the geometry well approximated by extremal BTZ $\times S^3 \times T^4$, this leads to fields which are completely homogeneous in the compact dimensions and which source a homogeneous shock wave. This is compatible with the fact that the geodesics in this region with no angular momentum along the S^3 follow BTZ geodesics as discussed in the previous section, so that the WKB approximation applied to the 3-dimensional reduction is consistent with the 6-dimensional picture. With this set up in mind, there are three major effects which will cause the computation of the OTOC in the superstrata to differ from the computation in extremal BTZ and we will discuss each one in turn.

First, the center-of-mass energy of the interacting geodesics will be modified once the bottom of the throat is reached. In BTZ, the center-of-mass energy continues to grow in an unbounded fashion as the interaction gets closer and closer to the horizon. In the superstrata, this growth is cut off by the depth of the throat once the interaction moves into the cap region. Below, we will compute the center-of-mass energy of two colliding geodesics as they fall down the throat of the superstrata and see how the growth in this quantity saturates. This will occur at the time scale set by Δt_{cap} . This time scale can be compared to the scrambling time, to determine whether the effect of the cap will be felt before scrambling,

$$\frac{\Delta t_{\text{cap}}}{\Delta t_s} = \left(\frac{8h_V h_W (N_1 N_5)^2}{3\epsilon T_R^3} \right)^{\frac{1}{3}}. \tag{4.30}$$

We conclude that the OTOC will have exited the slow scrambling regime before the interaction reaches the cap, unless the right-moving temperature is very large,

$$T_R \gtrsim \left(\frac{h_V h_W (N_1 N_5)^2}{\epsilon} \right)^{\frac{1}{3}}. \tag{4.31}$$

Second, the shock wave will be modified by the presence of the cap. The geometry away from the cap is well approximated by a geometry with an extremal BTZ factor. Within this part of the geometry, all the fields remain homogeneous in the extra compact dimensions. Therefore the gravitational shock wave does not depend on these extra dimensions and the BTZ result can be used. In particular, the average time growth is cubic since the number of images contributing to the gravitational interaction grows linearly while each individual contribution is proportional to the center-of-mass energy $s \sim \Delta t^2$. Once the cap region is reached, the fibration of the S^3 over BTZ becomes non-trivial and the shock wave must be computed using the full 6-dimensional geometry.⁶

In the following, we will argue more carefully that the deformation of the geometry in the cap region does not affect the gravitational shock wave relevant to the OTOC at times before the interaction reaches the cap region. Consider the time slice where the first operator is inserted at t_{in} . On this slice we can find a solution to Einstein's equations that is compatible with this source and that is only supported near the boundary. As we evolve time forward, the shock wave will not probe deeper into the geometry than the null geodesic that sources it (the support of the shock wave is depicted in figure 9 in appendix C for non-compact φ). We can stop evolving time once we reach the interaction region. If this interaction occurs well outside the cap, $\rho_* \gg a$, the shock wave we needed to consider is only supported in the region where $\rho \gg a$. Since we know that this shock wave is a solution to Einstein's equations with a source at the geodesic for an extremal BTZ background and that the metric of the superstrata for $\rho \gg a$ is well approximated by extremal BTZ, then the shock wave will still be a solution in the superstrata up to subleading terms in a/ρ and a/b . The same argument can be run in reverse for the shock wave sourced by the outgoing geodesic, by starting at the time where it reaches the boundary, t_{out} and evolving the shock wave backwards in time to the interaction region.

Once the interaction reaches the cap region, this approximation will no longer be valid. Since the number of images included in the sum was essentially controlled by boundary causality, one may not expect this to change the overall scaling with Δt . However, the detailed form of the OTOC once the interaction reaches the cap region will be affected by the precise form of the shock wave in the 6 dimensional geometry. We will not compute this precise form in this work, but we are optimistic that it may be tractable to do so due to the successes in computing two-point functions in the superstrata in [11] thanks to the approximately separable form of the wave equation.

Finally, [31–34] found that probes falling into the throat of the superstrata feel strong tidal forces well before reaching the cap region. In fact, these strong tidal forces potentially invalidate the WKB approximation we have made in computing the OTOC. In particular, we expect the expansion of the geodesic congruence to quickly grow in the presence of strong tidal forces, violating the assumption that it is much smaller than the mass of the probe required for the WKB approximation to hold, as described in more detail below. Below,

⁶Note that the OTOC of an operator localised in the S^3 would correspond to a computation using a single geodesic in the 6-dimensional geometry with no smearing and the resulting gravitational shock wave would propagate in the S^3 . From the perspective of the boundary CFT, localising the insertion in the S^3 requires a sum over a tower of primary operators so this is not the most natural OTOC to consider.

we adapt their computation to the present setup and find that the tidal stresses are in danger of invalidating the WKB approximation at a time scale Δt_{tidal} , given in (4.54), well before the center-of-mass energy of the interaction starts to saturate at Δt_{cap} . Since we lose control of the computation beyond Δt_{tidal} , we cannot say for certain what the behaviour of the OTOC will be past this time. We expect, however, that whatever happens beyond this point, the OTOC cannot continue to grow beyond the bound identified below in (4.44), since the center-of-mass energy, which controls the strength of gravitational interactions, is bounded by the presence of the cap in any case.

In the above discussion, we have focused on boundary time scales. In the bulk, it is more natural to think instead of the radial coordinate at which the interaction occurs. Although the cap deforms the near-horizon region, in the careful treatment of the OTOC needed for zero temperature states, we find that the OTOC is controlled by an interaction centered at a small but finite distance from the horizon. The scrambling time is reached when this interaction is at a radial coordinate

$$r_{\text{sat}} - r_+ \sim \left(\frac{G_N m_W m_V}{\varepsilon^2} \right)^{\frac{1}{3}}, \quad (4.32)$$

whereas the tidal forces become important at a radial coordinate

$$r_{\text{tidal}} - r_+ \sim \sqrt{\frac{G_N(\pi^2 T_R^2 + 1)}{\pi T_R \varepsilon \min(h_V, h_W)}}, \quad (4.33)$$

these are both intermediate distance scales between the Planck and AdS scales away from the horizon.

Center-of-mass energy. Given the relationship between the velocities and the conserved quantities in (4.18) and (4.19), the center-of-mass energy can be expressed in terms of the conserved quantities and the radius, ρ_* , where the collision occurs,

$$s = -(m_V k_V + m_W k_W)^2 \Big|_{\rho=\rho_*}, \quad (4.34)$$

$$= \frac{b(2a^2 + b^2) ((2a^2 + b^2)(\rho_*^2 + a^2)^n - b^2 \rho_*^{2n})}{a^2(\rho_*^2 + a^2)^{n+1} \sqrt{2a^2 + b^2 - a^2 b^2 \rho_*^{2n} (\rho_*^2 + a^2)^{-(n+1)}}} \frac{m_V m_W}{\varepsilon^2} + O(\varepsilon^0), \quad (4.35)$$

where m_V and m_W are the masses of the in- and outgoing geodesics respectively and we set $E_V = E_W = \sqrt{\frac{b}{\sqrt{2}}}\varepsilon^{-1}$ where we have restored the factors of b in the energy computed in (3.7). In order to make the connection with the OTOC, the location of the collision must be re-expressed in terms of the times at which the perturbations are inserted at the boundary. This is straightforward in principle by inverting (4.21), however it is not tractable to perform this inversion analytically. The relation between s and Δt is plotted in figure 8.

We can find approximate answers by dividing the microstate geometry into three regions: an asymptotic region $\rho \gg \sqrt{n}b$, a throat region $\sqrt{n}a \ll \rho \ll \sqrt{n}b$ and a cap region $\rho \ll \sqrt{n}a$. We emphasize again that the overall time growth of the OTOC also depends on the number of images contributing to the gravitational interaction. As argued above,

Figure 8. The solid blue line is the full numeric answer for the center-of-mass energy, while the dashed lines are the analytic approximations in the respective regimes. In the grey area, the tidal forces become large. The parameters used are $n = 3$, $a = 10^{-3}$, $b = \sqrt{2}$, $m_V = m_W = 10$ and $\varepsilon = 10^{-2}$.

the BTZ result should apply in the asymptotic and throat regions, yielding an additional factor of Δt . With this in mind, below we only study the behavior of the center-of-mass energy.

- In the asymptotic region, $\rho_* \gg \sqrt{n}b \gg \sqrt{n}a$, we can approximate the integral (4.21) by

$$\Delta t \simeq 2 \int_{\rho_*}^{\infty} d\rho \frac{b}{\sqrt{2}\rho^2} = \frac{\sqrt{2}b}{\rho_*}. \quad (4.36)$$

For the center-of-mass energy this yields quadratic growth in this region:

$$s \simeq 2 \frac{b^2}{\rho_*^2} \frac{m_V m_W}{\varepsilon^2} \simeq \frac{m_V m_W}{\varepsilon^2} \Delta t^2 = \frac{4\sqrt{2}}{b} \frac{h_V h_W}{\varepsilon^2} \Delta t^2. \quad (4.37)$$

In the last equality we have used $2h_{V,W} = \sqrt{b/\sqrt{2}}m_{V,W}$ where we have again restored factors of b compared to section 3.

- In the throat region, $\sqrt{n}a \ll \rho_* \ll \sqrt{n}b$, we get

$$\Delta t \simeq \Delta t_{\text{throat}} + 2 \int_{\rho_*}^{\sqrt{\frac{n}{2}}b} d\rho \frac{\sqrt{n}b^2}{2\rho^3} \simeq \frac{\sqrt{n}b^2}{2\rho_*^2}, \quad (4.38)$$

which, for the center-of-mass energy, yields

$$s \simeq \frac{nb^4}{\rho_*^4} \frac{m_V m_W}{\varepsilon^2} = \frac{16\sqrt{2}}{b} \frac{h_V h_W}{\varepsilon^2} \Delta t^2. \quad (4.39)$$

This leads again to a growth in the center-of-mass energy that is quadratic in time.

- In the deep cap region, $\rho_* \ll \sqrt{n} a \ll \sqrt{n} b$, we get

$$\Delta t \simeq \Delta t_{\text{bottom}} - 2 \int_0^{\rho_*} d\rho \frac{b^2}{2a^3} \simeq \frac{b^2}{a^2} \left(\chi_n(0) - \frac{\rho_*}{a} \right), \quad (4.40)$$

where Δt_{bottom} was approximated using (4.25)

$$\Delta t_{\text{bottom}} \equiv 2 \int_0^\infty \frac{dt}{d\rho} \simeq \chi_n(0) \frac{b^2}{a^2} \sim \frac{b^2}{a^2}, \quad (4.41)$$

and where $\chi_n(0)$ was estimated by using

$$\frac{1}{2\sqrt{n}} < \frac{\pi}{2} - \chi_n(0) < \frac{2}{3\sqrt{n}}, \quad (4.42)$$

which can be verified numerically. The behaviour of the center-of-mass energy in this regime is then approximated by

$$s \simeq \begin{cases} \frac{(2a^2 - 3\rho_*^2)b^4}{2a^6} \frac{m_V m_W}{\varepsilon^2} & \text{for } n = 1 \\ \frac{(a^2 - \rho_*^2)b^4}{a^6} \frac{m_V m_W}{\varepsilon^2} & \text{for } n > 1 \end{cases} \quad (4.43a)$$

$$\simeq \begin{cases} \left(\frac{b^4}{a^4} - \frac{3}{2} (\Delta t_{\text{bottom}} - \Delta t)^2 \right) \frac{m_V m_W}{\varepsilon^2} & \text{for } n = 1 \\ \left(\frac{b^4}{a^4} - (\Delta t_{\text{bottom}} - \Delta t)^2 \right) \frac{m_V m_W}{\varepsilon^2} & \text{for } n > 1 \end{cases} \quad (4.43b)$$

At the bottom of the cap, the center-of-mass energy is given by

$$s_{\text{bound}} \simeq \frac{m_V m_W b^4}{\varepsilon^2 a^4} = \frac{16\sqrt{2}}{b} \frac{h_V h_W (N_1 N_5)^2}{\varepsilon^2}. \quad (4.44)$$

After the geodesics reach the bottom of the cap, they bounce off and start to move back up the throat. This therefore gives an upper bound on the center-of-mass energy of the interaction in the superstrata geometry.

These various approximate regimes are compared to the numeric answer in figure 8.

Tidal stress. The geodesic approximation to field propagation, used in this work to compute OTOCs, has a limit of validity. Indeed, as any WKB-type approximation, it rests on the assumption that the amplitude variation of the wavefunction (2.6) does not compete with that of its phase factor (2.7),

$$|\partial_\mu A| \ll m |k_\mu A|, \quad (4.45)$$

where this condition must hold for each of the components individually, and so in particular it must hold for the component along the velocity k^μ of the geodesic,

$$\frac{d}{d\tau} A \equiv k^\mu \partial_\mu A. \tag{4.46}$$

By expanding the Klein-Gordon equation to first subleading order in $1/m$, it may be shown that the variation of the amplitude A along k^μ is related to the *volume expansion* θ of a congruence of geodesics [29]

$$\frac{d}{d\tau} A = -\frac{\theta}{2} A, \quad \theta \equiv \nabla_\mu k^\mu. \tag{4.47}$$

Therefore, the validity of the geodesic approximation through (4.45) requires in particular

$$|\theta| \ll m. \tag{4.48}$$

The evolution of the expansion θ is controlled by the Raychaudhuri equation

$$\dot{\theta} = -\frac{1}{2}\theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - R_{\mu\nu}k^\mu k^\nu, \tag{4.49}$$

where $\sigma_{\mu\nu}$ and $\omega_{\mu\nu}$ are the *shear* and *rotation* tensors, respectively; for more details, see textbooks such as [42]. The quantity $R_{\mu\nu}k^\mu k^\nu$ is known as the trace of the tidal tensor and quantifies the tidal forces felt by a congruence of geodesics. In the context of superstratum microstates, it has been shown that tidal forces on infalling particles are Planckian long before they reach the cap region [31–34]. In the presence of such Planckian tidal forces, one may quickly expect a violation of the condition (4.48) and a breakdown of the validity of the geodesic approximation.

The leading term in the trace of the tidal tensor can be computed in the throat region of the geometry, where $\sqrt{na} \ll \rho \ll \sqrt{nb}$,

$$-R_{\mu\nu}k^\mu k^\nu \sim -\frac{2\sqrt{2}}{b} - \frac{n(n+1)a^2b^2E^2}{\rho^6} = -\frac{2\sqrt{2}}{b} - \frac{n(n+1)a^2b^3}{\sqrt{2}\epsilon^2\rho^6}, \tag{4.50}$$

where all higher order terms in the small parameters $\frac{\rho}{b}$, $\frac{a}{\rho}$ and $\frac{a}{b}$ have been dropped. These two terms can compete depending on how deep into the throat we look. The first term does not depend on a and so it is what we would get for an extremal BTZ black hole. For $\rho \sim \sqrt{nb}$ the second term is suppressed by $\frac{a^2}{b^2} \sim (N_1N_5)^{-1}$ and so it is very small and cannot cause a large expansion. However, as the geodesic falls into the throat this second term grows and eventually gets bigger than the first.

Assuming that our congruence of geodesics obeys the condition (4.48) for BTZ,⁷ the danger comes from the additional term in the tidal tensor that grows as the geodesic falls

⁷We do not generically expect the condition (4.48) to be violated in the near horizon region of BTZ. Since the geometry is locally AdS, the tidal tensor is never large in BTZ (this fact was pointed out by [31]). Also, neglecting the shear and rotation in the Raychaudhuri equation allows it to be integrated in BTZ and the solutions are approximately constant in the throat region.

down the throat. As this additional term grows, it causes $\dot{\theta}$ to grow, which will cause a potential violation of the condition (4.48) when

$$\left| \int \frac{n(n+1)a^2b^3}{\sqrt{2}\varepsilon^2\rho^6} d\tau \right| \sim m. \tag{4.51}$$

We change variables from τ to ρ in this integral by using our known expressions for the velocity of the geodesic. Expanding (4.19) in the throat regime, $\sqrt{na} \ll \rho \ll \sqrt{nb}$,

$$\frac{d\rho}{d\tau} = -\frac{\sqrt{n}b^{\frac{3}{2}}}{2^{\frac{3}{4}}\varepsilon\rho}. \tag{4.52}$$

This will cause (4.48) to be violated at a radial coordinate,

$$\rho_{\text{tidal}}^4 \sim \frac{a^2b^{\frac{3}{2}}\sqrt{n}(n+1)}{2^{\frac{7}{4}}\varepsilon m}. \tag{4.53}$$

Using (4.38), this translates into a boundary time separation of

$$\Delta t_{\text{tidal}} \sim \sqrt{\frac{\pi T_R}{\pi^2 T_R^2 + 1} \min(h_V, h_W) \varepsilon N_1 N_5}, \tag{4.54}$$

where $\min(h_V, h_W)$ denotes the minimum of the conformal weights of the operators in the OTOC and appears because the condition (4.48) must be imposed on both the in- and outgoing geodesics. This reproduces the result (1.12) quoted in the introduction.

This time scale can be compared to the scrambling time,

$$\frac{\Delta t_{\text{tidal}}}{\Delta t_s} \sim \frac{2}{3^{\frac{1}{3}}} \sqrt{\frac{\pi T_R}{(\pi^2 T_R^2 + 1)}} \sqrt{\min(h_V, h_W)} \left(\frac{h_V^2 h_W^2 N_1 N_5}{\varepsilon} \right)^{\frac{1}{6}}. \tag{4.55}$$

In this expression, $N_1 N_5 \gg 1$ in order to have a hierarchy between the Planck and AdS scales (semi-classical regime), $\varepsilon \ll 1$ since it is the holographic regulator and $h_{V,W} \gg 1$ for the validity of the WKB approximation. All these scalings contribute to ensuring that $\Delta t_s \ll \Delta t_{\text{tidal}}$ so that we can reliably approximate the superstrata by BTZ during the slow scrambling phase of the OTOC. The only way this condition can be violated is for very small or very large right-moving temperature. Since the superstrata solutions only exist for integer n , the temperature is bounded from below by $\pi T_R \geq 1$ and we only need to worry about large temperatures. In that case, $\Delta t_{\text{tidal}} \lesssim \Delta t_s$ when

$$T_R \gtrsim \min(h_V, h_W) \left(\frac{h_V^2 h_W^2 N_1 N_5}{\varepsilon} \right)^{\frac{1}{3}}. \tag{4.56}$$

As far as we are aware, there is no obstruction to considering superstrata with arbitrarily large right-moving temperature. In this large right-moving temperature regime, we expect the WKB approximation to break down, leading to deviations from the BTZ result, before the scrambling time is reached.

5 Discussion

In the following, we point to some open problems and possible future directions.

Late-time regime and quasi-normal decay. We have described OTOCs in extremal geometries within the geodesic approximation scheme presented in section 2. This approach requires improvement if it is to accurately describe the late-time regime where quasi-normal decay may occur. It is very likely that the latter coincides with a regime where the assumption (4.45) does not hold anymore. This would be in line with earlier study of black hole quasi-normal modes within related WKB-type approximations [43]. We also refer the reader to [11, 44] for a description of quasi-normal decay of two-point functions in states dual to extremal BTZ and superstratum microstates.

Shock waves in microstate geometries. As described in section 4.4, we expect OTOCs in superstratum geometries to coincide with those in extremal BTZ as long as the dual particle scattering does not probe some of its distinctive features, including strong tidal forces and the existence of a cap region. This assumes that shock waves emitted by particles falling from infinity in these microstate geometries do not significantly differ from their analogue in extremal BTZ, at least far away from the throat region where strong tidal forces occur. Once the interaction probes sufficiently deep into the throat, we would need to understand the shock wave in the full 6-dimensional geometry of the cap. Two-point functions have been computed in the superstrata geometry by exploiting the almost separable form of the wave equation in [11], which suggests that the computation of this shock wave may be tractable.

Breakdown of the geodesic approximation due to tidal forces. The analysis performed in section 4.4 strongly suggests that tidal forces invalidate the geodesic approximation to field propagation at the timescale Δt_{tidal} given in (4.54). A fully rigorous proof of this fact would require a more detailed study of the Raychaudhuri equation describing the congruence of geodesics used to propagate bulk fields from their boundary insertion points, including the effect of shear and rotation associated to this congruence.

Right-moving operators. We have discovered that the OTOC of scalar operators, when evaluated in a state dual to extremal BTZ, displays a time-dependence which alternates between a quadratic growth associated to the zero left-moving temperature T_L and an exponential Lyapunov growth associated to the non-zero right-moving temperature T_R . It is interesting to contemplate the possibility that the OTOC of purely right-moving CFT operators could display a purely exponential growth. In the gravitational description, these right-moving CFT operators correspond to high spin fields with equal spin s and right conformal weight h_R . Since the geodesic approximation holds for large masses $m \gg 1$, high spin fields would have to be considered in order to see this purely exponential Lyapunov growth at the temperature T_R within this approximation.

Probes of higher complexity. Two-point functions in the superstrata were studied in [11], and were found to closely approximate the decay found in extremal BTZ until a

time scale $\sqrt{N_1 N_5}$, where they start to deviate. At a time scale equal to $\Delta t_{\text{cap}} \sim \frac{N_1 N_5}{T_R}$, they start to grow again and exhibit a sharp echo at a time scale $t_{\text{echo}} = N_1 N_5$. Thus, these probes exhibit the effects of the difference between the superstrata and extremal BTZ geometries at similar time scales as the OTOC. One might have expected more complex probes to be more sensitive to the difference between a microstate or a statistical ensemble, but that does not seem to be the case here. This may be related to the fact that the relevant time scales are powers rather than exponentials of $N_1 N_5$ so that the difference between $N_1 N_5$ and $2N_1 N_5$ is lost.

The new feature of the OTOC is the appearance of a new time scale, the scrambling time. We expect more complex probes to take longer to scramble and so it would be interesting to compare their scrambling time to the time where they start to feel the effects of the microstate.

Extremal black holes in higher spacetime dimensions. It would also be interesting to study the OTOC in higher dimensional black holes. The gravitational modes responsible for scrambling in these black holes have been identified in [45]. It would be interesting to determine whether there is a similar saw-tooth behaviour in the OTOC and whether the overall growth of the OTOC is consistent with slow scrambling or whether the mode with the largest rate of growth comes to dominate in that case.

Acknowledgments

A Oscillations and decay in the OTOC

In this appendix, we describe in more detail the existence of an intermediate region of damped rapid oscillatory behaviour for the OTOC in non-rotating BTZ, which lies between the Lyapunov growth and the quasi-normal mode decay. These damped oscillations appear before the quasi-normal mode decay whenever there is a hierarchy, controlled by the weight h_V , between the scrambling time t_s and the time scale t_{QN} at which the quasi-normal mode decay kicks in.

For a non-rotating BTZ black hole, the OTOC is given by ($h_W \gg h_V \gg 1$) [15]

$$\frac{\langle V(-i\epsilon_V, 0)W(t-i\epsilon_W, x)V(i\epsilon_V, 0)W(t+i\epsilon_W, x) \rangle_\beta}{\langle V(-i\epsilon_V, 0)V(i\epsilon_V, 0) \rangle_\beta \langle W(t-i\epsilon_W, x)W(t+i\epsilon_W, x) \rangle_\beta} = \left(1 - \frac{6\pi i h_W e^{\frac{2\pi}{\beta}(t-|x|)}}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} \right)^{-2h_V}, \quad (\text{A.1})$$

where h_V and h_W are the conformal weights of the operators. It is well known that (A.1) describes both the early-time Lyapunov growth and the quasi-normal mode decay of the OTOC. In the following, we will discuss the presence of an intermediate regime where the OTOC shows rapid damped oscillations, with a decay that is doubly-exponential.

We start by noting that for $x \ll 1$

$$\log(1+x) \simeq x - \frac{1}{2}x^2 + O(x^3). \quad (\text{A.2})$$

Therefore, in the regime where $\frac{6\pi h_W e^{\frac{2\pi}{\beta}(t-|x|)}}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} \ll 1$, we can write (A.1) as

$$\begin{aligned} & \left(1 - \frac{6\pi i h_W e^{\frac{2\pi}{\beta}(t-|x|)}}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} \right)^{-2h_V} \simeq \exp\left(i \frac{12\pi h_W h_V}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} e^{\frac{2\pi}{\beta}(t-|x|)} \right) \\ & \times \exp\left(-\frac{36\pi^2 h_W^2 h_V}{c^2 \sin^2\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin^2\left(\frac{2\pi}{\beta}\epsilon_W\right)} e^{\frac{4\pi}{\beta}(t-|x|)} + O\left(\frac{h_W^3 h_V e^{3t}}{c^3}\right) \right). \quad (\text{A.3}) \end{aligned}$$

Normally the second term in the exponent would be subleading, but since the first term is purely imaginary it does not contribute to the magnitude of the OTOC. Taking the real part of this expression, we obtain

$$\text{Re}(\text{OTOC}) \simeq \cos\left(\frac{12\pi h_W h_V e^{\frac{2\pi}{\beta}(t-|x|)}}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} \right) \exp\left(-\frac{36\pi^2 h_W^2 h_V}{c^2 \sin^2\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin^2\left(\frac{2\pi}{\beta}\epsilon_W\right)} e^{\frac{4\pi}{\beta}(t-|x|)} \right). \quad (\text{A.4})$$

This starts very near 1 and decreases exponentially, as is well known. The first zero of the cosine, which corresponds to the time scale at which the commutator squared first becomes order 1 and is known as the scrambling time, t_s , occurs at

$$t_s \simeq |x| - \frac{\beta}{2\pi} \log\left(\frac{24 h_W h_V}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} \right). \quad (\text{A.5})$$

After this time scale, the OTOC oscillates with a rapidly increasing frequency. At a time scale t_d the OTOC starts to decay double-exponentially,

$$t_d \simeq |x| - \frac{\beta}{2\pi} \log\left(\frac{6\pi h_W \sqrt{h_V}}{c \sin\left(\frac{2\pi}{\beta}\epsilon_V\right) \sin\left(\frac{2\pi}{\beta}\epsilon_W\right)} \right). \quad (\text{A.6})$$

The separation between these timescales is controlled by the conformal weight of the lighter V operator:

$$t_d - t_s \sim \frac{\beta}{\pi} \log h_V. \tag{A.7}$$

Finally at late times, $t \sim t_{QN}$, quasi-normal decay takes over

$$t_{QN} = |x| - \frac{\beta}{2\pi} \log \left(\frac{6\pi h_W}{c \sin\left(\frac{2\pi}{\beta} \epsilon_V\right) \sin\left(\frac{2\pi}{\beta} \epsilon_W\right)} \right). \tag{A.8}$$

In this regime, the OTOC decays exponentially at a rate controlled by h_V/β

$$\text{OTOC} \simeq \left(\frac{6\pi i h_W}{c \sin\left(\frac{2\pi}{\beta} \epsilon_V\right) \sin\left(\frac{2\pi}{\beta} \epsilon_W\right)} \right)^{-2h_V} e^{-\frac{4\pi h_V}{\beta}(t-|x|)}. \tag{A.9}$$

Note however that by this time, the OTOC has already been decaying doubly exponentially since t_d . This time scale is separated from the earlier decay by the same amount as the scrambling time was separated from the doubly-exponential decay,

$$t_{QN} - t_d \sim \frac{\beta}{\pi} \log h_V. \tag{A.10}$$

Although the geodesic approximation to the computation of the OTOC is not sensitive to the quasi-normal decay regime, we will show that in addition to the leading early-time behaviour given by

$$\text{OTOC} \simeq e^{i\delta} \Big|_{\text{saddle}}, \tag{A.11}$$

it correctly reproduces the first correction, i.e., the second factor in (A.3). The leading term is obtained by ignoring the back reaction of the geodesics on their trajectories and computing the dominating saddle point in (A.11) by a choice of point-splitting regulators together with condition (2.19), which is a local condition that does not include the effect of the eikonal phase factor. In [15], the late-time quasi-normal type decay arises by taking the eikonal phase into account when computing the saddle point, which can be interpreted in terms of the propagation of the light particle (V) in the background of the heavier particle (W). In the WKB approach used in this paper, a first correction to the OTOC in non-rotating BTZ can similarly be found by including the eikonal phase factor in the computing of the saddle of the V particle, such that one finds⁸

$$\frac{\langle V(0,0)W(t,x)V(-\epsilon_V,0)W(t-\epsilon_W,x) \rangle_\beta}{\langle V(0,0)V(-\epsilon_V,0) \rangle_\beta \langle W(t,x)W(t-\epsilon_W,x) \rangle_\beta} \simeq e^{i\frac{\beta^2 G_N m_W m_V}{2\pi \epsilon^2} e^{\frac{2\pi}{\beta}(t-|x|)} + i\frac{\beta^4 G_N^2 m_W^2 m_V}{2(2\pi)^3 \epsilon^3 \epsilon_V} e^{\frac{4\pi}{\beta}(t-|x|)}}, \tag{A.12}$$

with $m_i = 2h_i$ and where G_N is related to the central charge c of the CFT by the Brown-Henneaux relation $c = \frac{3}{2G_N}$, in units where the AdS length is set to 1. A few differences

⁸In [29], a detailed derivation of the saddles was given (without including the eikonal phase factor). (A.12) can be derived following those steps while including the effect of the eikonal phase.

are to be noted with respect to (A.3). First, a feature of our approach that is already present in the leading term, is that the (holographic) cutoff surface regulator ε appears in the denominator of the eikonal phase instead of the time regulators. Second, the regulators ϵ_i are taken to be real shifts to the times (see (2.12)). This type of time regulator leads to a correction to the phase of the OTOC and does not change its amplitude. In order to connect more directly with the result from [15], we need to consider Euclidean time regulators⁹ and send $\epsilon_i \rightarrow -i\epsilon_i$. Putting both types of regulators on the same footing, equations (A.3) and (A.12) are in agreement, provided we consider small shifts ϵ_i . As a consequence, the exact behaviour of the intermediate regime of the OTOC seems to be strongly dependent on the choice of regulator.

Note that the corrections to the leading early-time behaviour of the OTOC break the symmetry between V and W , because a hierarchy was chosen between the two particles ($h_W \gg h_V$). As a result, the two series (A.3) and (A.12) contain an increasing number of factors of h_W together with a single factor of h_V .

Slow scrambling in the vacuum The OTOC has been computed for the vacuum state of a CFT₂ on an infinite line, in the vacuum block approximation [16]:

$$\frac{\langle V(-i\epsilon_V, 0)W(t - i\epsilon_W, x)V(i\epsilon_V, 0)W(t + i\epsilon_W, x) \rangle_\infty}{\langle V(-i\epsilon_V, 0)V(i\epsilon_V, 0) \rangle_\beta \langle W(t - i\epsilon_W, x)W(t + i\epsilon_W, x) \rangle_\infty} = \left(1 - \frac{6\pi i h_W}{\epsilon_W \epsilon_V c} (t - |x|)^2\right)^{-2h_V}. \tag{A.13}$$

Again the same approximation scheme can be used in the regime where $\frac{6\pi h_W}{\epsilon_W \epsilon_V c} (t - |x|)^2 \ll 1$ to write this as

$$\left(1 - \frac{6\pi i h_W}{\epsilon_W \epsilon_V c} (t - |x|)^2\right)^{-2h_V} \simeq e^{i \frac{12\pi h_W h_V}{\epsilon_W \epsilon_V c} (t - |x|)^2 - \frac{36\pi^2 h_W^2 h_V}{\epsilon_W^2 \epsilon_V^2 c^2} (t - |x|)^4 + O\left(\frac{h_W^3 h_V t^6}{c^3}\right)}. \tag{A.14}$$

Taking the real part of the OTOC, we see the same sort of damped oscillations, but with a power law instead of exponential dependence on t in the argument,

$$\text{Re}(\text{OTOC}) \simeq \cos\left(\frac{12\pi h_W h_V}{\epsilon_W \epsilon_V c} (t - |x|)^2\right) e^{-\frac{36\pi^2 h_W^2 h_V}{\epsilon_W^2 \epsilon_V^2 c^2} (t - |x|)^4}. \tag{A.15}$$

The same time scales can be identified,

$$t_s \simeq |x| + \sqrt{\frac{\epsilon_W \epsilon_V c}{24 h_W h_V}}, \tag{A.16}$$

$$t_d \simeq |x| + \sqrt{\frac{\epsilon_W \epsilon_V c}{6\pi h_W \sqrt{h_V}}}, \tag{A.17}$$

$$t_{QN} \simeq |x| + \sqrt{\frac{\epsilon_W \epsilon_V c}{6\pi h_W}}, \tag{A.18}$$

where, once again, the weight h_V controls the time separation between the different regimes.

⁹This is a natural choice from the CFT point of view, because the ordering of the operators inside the four-point function is fixed by the euclidean time ordering of the operators.

B Center-of-mass energy in generic BTZ

In this appendix, we show that the center-of-mass energy of two colliding geodesics in a non-extremal BTZ black hole already contains an initial period of power law growth, followed by an exponential growth set by the temperature. As the angular momentum of the black hole is tuned towards extremality, this region of power law growth extends to larger separation times until the exponential behaviour disappears completely at extremality.

The metric of a rotating BTZ black hole is given by

$$ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} + r^2 \left(d\varphi - \frac{r_+ r_-}{r^2} dt \right)^2, \quad f(r) = \frac{(r^2 - r_+^2)(r^2 - r_-^2)}{r^2}, \quad (\text{B.1})$$

where the angular coordinate φ is periodically identified, $\varphi \sim \varphi + 2\pi$. The angular velocity of the black hole is given by $\Omega = r_-/r_+$ and extremal BTZ corresponds to setting $r_+ = r_-$.

As explained in the main text, we consider a collision between radially infalling null geodesics. One geodesic falls in at time t_1 and $\varphi = 0$ and the other moves outwards and reaches the boundary at t_2 and the same $\varphi = 0$. The two cross at a radius r_* and we will compute their center-of-mass energy at this point

$$s = -2m_V m_W k_V \cdot k_W|_{r=r_*}, \quad (\text{B.2})$$

where k_V^μ and k_W^μ are the velocities associated to the two geodesics.

This geometry has two Killing vectors, ∂_t and ∂_φ , with associated conserved quantities

$$E = -(\partial_t)^\mu k_\mu = \left(f(r) - \frac{r_+^2 r_-^2}{r^2} \right) \dot{t} + r_+ r_- \dot{\varphi}, \quad (\text{B.3})$$

$$L = (\partial_\varphi)^\mu k_\mu = r^2 \dot{\varphi} - r_+ r_- \dot{t}. \quad (\text{B.4})$$

Setting $L = 0$ and using the null condition $k^2 = 0$, the final coordinate can be fixed to be

$$\dot{r}^2 = E^2, \quad (\text{B.5})$$

so that the center-of-mass energy of two geodesics with $L_i = 0$ and $E_V = E_W = E$, at the collision, can be written in terms of only the energy and the position of the collision,

$$s = \frac{4m_V m_W E^2}{f(r_*)}. \quad (\text{B.6})$$

The horizon is located at the outermost zero of $f(r)$. For non-extremal BTZ, this is a simple zero, whereas for extremal BTZ it becomes a double zero. For $r_* \sim r_+$, the center-of-mass energy can be approximated by

$$s \sim \frac{2m_V m_W r_+ E^2}{(r_+^2 - r_-^2)(r_* - r_+)}, \quad r_*^2 - r_+^2 \ll r_+^2 - r_-^2, \quad (\text{B.7})$$

$$\sim \frac{m_V m_W E^2}{(r_* - r_+)^2}, \quad r_+^2 - r_-^2 \ll r_*^2 - r_+^2 \ll r_+^2. \quad (\text{B.8})$$

The remaining task is to relate the position of the collision to the location at which the geodesics meet the boundary,

$$t_\infty - t_* = \int_{r_*}^{\infty} \frac{dt}{dr} dr = \int_{r_*}^{\infty} \frac{\dot{t}}{\dot{r}} dr = \pm \int_{r_*}^{\infty} \frac{dr}{f(r)}. \quad (\text{B.9})$$

Once again, we distinguish two regimes, depending on the value of the ratio of the distance between the two horizons and the distance between the collision and the outer horizon,

$$\int_{r_*}^{\infty} \frac{dr}{f(r)} \sim \frac{r_+}{2(r_+^2 - r_-^2)} \int_{r_*}^{\infty} \frac{dr}{r - r_+} = -\frac{r_+ \log(r_* - r_+)}{2(r_+^2 - r_-^2)}, \quad r_*^2 - r_+^2 \ll r_+^2 - r_-^2, \quad (\text{B.10})$$

$$\sim \frac{1}{4} \int_{r_*}^{\infty} \frac{dr}{(r - r_+)^2} = \frac{1}{4(r_* - r_+)}, \quad r_+^2 - r_-^2 \ll r_*^2 - r_+^2 \ll r_+^2. \quad (\text{B.11})$$

In other words, for non-extremal black holes we find that the depth inside the geometry explored by probes separated by a distance Δt on the boundary scales like

$$r_* - r_+ \sim e^{-\frac{r_+^2 - r_-^2}{r_+} \Delta t}, \quad r_*^2 - r_+^2 \ll r_+^2 - r_-^2, \quad (\text{B.12})$$

$$\sim \frac{1}{2\Delta t}, \quad r_+^2 - r_-^2 \ll r_*^2 - r_+^2 \ll r_+^2. \quad (\text{B.13})$$

This leads to

$$s \sim \frac{2m_V m_W r_+ E^2}{(r_+^2 - r_-^2)} e^{\frac{r_+^2 - r_-^2}{r_+} \Delta t}, \quad r_*^2 - r_+^2 \ll r_+^2 - r_-^2, \quad (\text{B.14})$$

$$\sim 4m_V m_W E^2 \Delta t^2, \quad r_+^2 - r_-^2 \ll r_*^2 - r_+^2 \ll r_+^2. \quad (\text{B.15})$$

Note that for a non-rotating black hole, $r_- = 0$, and the second regime never applies. In that case, r_* approaches the horizon exponentially. As the spin of the black hole increases, a region of power law approach to the horizon appears before the exponential approach begins. As the extremal limit is approached this power law regime persists for longer until at extremality, $r_- = r_+$, the exponential regime disappears completely and only the power law regime remains.

C Shock wave in extremal BTZ

Following the method presented in [29], we construct the shock wave solutions used in the main text, which are associated to geodesics with zero angular momentum in extremal BTZ. We make use of the fact that extremal BTZ is just a patch of pure AdS₃, where the latter may be viewed as a hyperboloid in four-dimensional flat space through the constraint

$$\eta_{MN} X^M X^N = -1, \quad \eta_{MN} = \text{diag}(-1, 1, 1, -1). \quad (\text{C.1})$$

We refer to X^M as ‘embedding coordinates’. We then choose the following set of independent lightcone coordinates,

$$\mathcal{V} = X^0 + X^1, \quad \mathcal{U} = X^0 - X^1, \quad \mathcal{Z} = X^2, \quad (\text{C.2})$$

while the remaining embedding coordinate X^3 is determined from either one of the two branches

$$X^3 = \pm\sqrt{1 - \mathcal{UV} + \mathcal{Z}^2}. \tag{C.3}$$

A choice of branch corresponds to a choice of either one of the two ‘hemispheres’ of the AdS hyperboloid.

A highly energetic particle following a null trajectory along $\mathcal{V} = \mathcal{Z} = 0$ in the lower hemisphere ($X^3 = -1$) has a stress tensor given by

$$T_{\mathcal{V}\mathcal{V}} = -mk_{\mathcal{V}} \delta(\mathcal{V})\delta(\mathcal{Z})\Theta(-X^3), \tag{C.4}$$

where its velocity $k_{\mathcal{V}}$ is a constant of motion. The Heaviside step function $\Theta(-X^3)$ explicitly restricts the source to lie in the lower hemisphere of the AdS hyperboloid. It has the effect of discarding a second null geodesic at $\mathcal{V} = \mathcal{Z} = 0$, but lying in the upper hemisphere ($X^3 = 1$) instead. When going to the extremal BTZ patch, this second geodesic simply coincides with the ‘reflected’ continuation at the AdS conformal boundary of the geodesic of interest. This will be made explicit later on. Here, we are interested in null geodesics either created or absorbed at the AdS conformal boundary such that we don’t consider such boundary ‘reflections’. The associated shock wave geometry is found by solving Einstein’s equations sourced by the above stress tensor. It takes the form

$$ds^2 = ds_{\text{AdS}}^2 + ds_{\text{SW}}^2, \quad ds_{\text{SW}}^2 = -16\pi G_{\text{NM}} k_{\mathcal{V}} \Pi(\mathcal{Z})\delta(\mathcal{V})\Theta(-X^3)d\mathcal{V}^2, \tag{C.5}$$

where $\Pi(\mathcal{Z})$ solves

$$\left[(1 + \mathcal{Z}^2) \partial_{\mathcal{Z}}^2 + \mathcal{Z} \partial_{\mathcal{Z}} - 1 \right] \Pi(\mathcal{Z}) = -\delta(\mathcal{Z}). \tag{C.6}$$

Before solving this equation, we first need to determine the appropriate boundary conditions.

The shock wave sourced by a highly energetic particle in any locally AdS₃ spacetime can be mapped to the solution (C.5) written in embedding coordinates X^M . In particular, shock waves in maximally rotating BTZ black hole backgrounds may be found by appropriate coordinate transformation. To achieve this, we first give the map¹⁰ between some other *intermediate* embedding coordinate system \bar{X}^M and retarded BTZ coordinates (v, r, ϕ) ,

$$\bar{X}^0 = \frac{1}{2}e^{-r+\phi}(1 + (r + r_+)(2v + \phi)) - \frac{(r - r_+)e^{r+\phi}}{4r_+}, \tag{C.7a}$$

$$\bar{X}^1 = \frac{1}{2}e^{-r+\phi}(1 + (r + r_+)(2v + \phi)) + \frac{(r - r_+)e^{r+\phi}}{4r_+}, \tag{C.7b}$$

$$\bar{X}^2 = \frac{e^{r+\phi}(1 + (r - r_+)(2v + \phi))}{4r_+} - \frac{1}{2}(r + r_+)e^{-r+\phi}, \tag{C.7c}$$

$$\bar{X}^3 = \frac{e^{r+\phi}(1 + (r - r_+)(2v + \phi))}{4r_+} + \frac{1}{2}(r + r_+)e^{-r+\phi}. \tag{C.7d}$$

¹⁰It may be found by performing the following chain of coordinate transformations: $\bar{X}^M \rightarrow$ Poincaré patch of AdS $\rightarrow (t, r, \varphi) \rightarrow (v, r, \phi)$; see [36].

Any null geodesic in extremal BTZ then maps to a null ray in the intermediate coordinate system \bar{X}^M . Depending on the null geodesic of interest, as a final step we need to find the isometry relating these intermediate coordinates \bar{X}^M to the coordinates X^M described above, in such a way that the null geodesic lies at $\mathcal{V} = \mathcal{Z} = 0$ in the lower hemisphere of the AdS hyperboloid ($X^3 = -1$).

Outgoing shock wave. The trajectory of an outgoing geodesic with zero angular momentum has been described in section 3.1. It can be mapped to the null ray

$$\mathcal{V} = \mathcal{Z} = 0, \quad (X^3 = -1), \quad (\text{C.8})$$

through the following AdS isometry,

$$\begin{pmatrix} X^0 \\ X^1 \\ X^2 \\ X^3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \cosh c_2 & \sinh c_2 \\ 0 & 0 & \sinh c_2 & \cosh c_2 \end{pmatrix} \begin{pmatrix} a & 0 & 0 & -b \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ b & 0 & 0 & a \end{pmatrix} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \cosh c_1 & \sinh c_1 \\ 0 & 0 & \sinh c_1 & \cosh c_1 \end{pmatrix} \begin{pmatrix} \bar{X}^0 \\ \bar{X}^1 \\ \bar{X}^2 \\ \bar{X}^3 \end{pmatrix}, \quad (\text{C.9})$$

with parameters

$$a = \frac{e^{2r_+ \phi_{\text{out}}} - 2r_+(2v_{\text{out}} + \phi_{\text{out}})}{e^{2r_+ \phi_{\text{out}}} + 2r_+(2v_{\text{out}} + \phi_{\text{out}})}, \quad b = \frac{e^{r_+ \phi_{\text{out}}} \sqrt{8r_+(2v_{\text{out}} + \phi_{\text{out}})}}{e^{2r_+ \phi_{\text{out}}} + 2r_+(2v_{\text{out}} + \phi_{\text{out}})}, \quad (\text{C.10a})$$

$$c_1 = -r_+ \phi_{\text{out}} - \frac{1}{2} \log \frac{2v_{\text{out}} + \phi_{\text{out}}}{2r_+}, \quad c_2 = \frac{1}{2} \log 2r_+(2v_{\text{out}} + \phi_{\text{out}}). \quad (\text{C.10b})$$

One may check that $a^2 + b^2 = 1$ such that the associated isometry is a rotation in the X^0 - X^3 plane. Using (C.7) and (C.9), we get a final expression for the null coordinate \mathcal{V} ,

$$\mathcal{V} = \frac{e^{-r_+ \Delta \phi} [1 + (r - r_+)(2\Delta v + \Delta \phi)] - e^{r_+ \Delta \phi} [1 + (r + r_+)(2\Delta v + \Delta \phi)]}{e^{r_+ \phi_{\text{out}}} + 2r_+(2v_{\text{out}} + \phi_{\text{out}})e^{-r_+ \phi_{\text{out}}}}, \quad (\text{C.11})$$

with $\Delta \phi \equiv \phi_{\text{out}} - \phi$ and $\Delta v \equiv v_{\text{out}} - v$. We can now explicitly check that the null ray lying at $\mathcal{V} = \mathcal{Z} = 0$ in the upper hemisphere ($X^3 = 1$) maps to a ‘reflected’ ingoing null geodesic with zero angular momentum and trajectory $v(r) = v_{\text{out}}$, $\phi(r) = \phi_{\text{out}}$.

In the main text, we only need the rr -component of the shock wave created by the outgoing geodesic. It is found from (C.5) by use of the coordinate transformation (C.11), and by plugging the relation between one component of the velocity (3.15) and the conserved energy E defined in (3.8),

$$k_r = \frac{2r^2}{(r^2 - r_+^2)^2} E, \quad (\text{C.12})$$

yielding

$$h_{rr} = \frac{8\pi G_N m E}{r_+} (2\Delta v + \Delta \phi) \sinh(r_+ \Delta \phi) \Pi(\mathcal{Z}) \delta(r - r_0(v, \phi)) \Theta(-X^3), \quad (\text{C.13})$$

with

$$r_0(v, \phi) = \frac{1}{2\Delta v + \Delta \phi} - r_+ \coth r_+ \Delta \phi, \quad (\text{C.14})$$

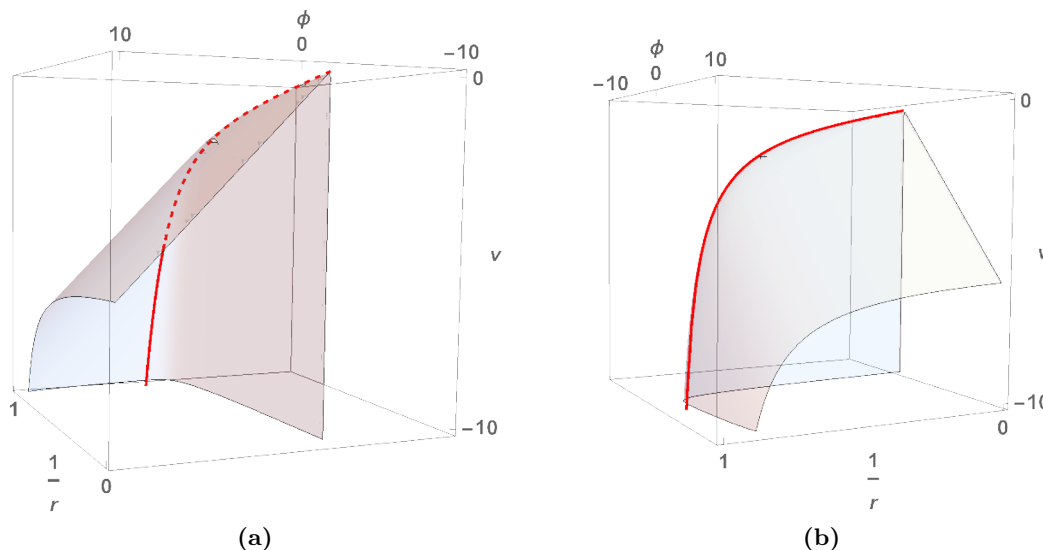

Figure 9. Support of the shock wave (C.13) emitted by a null outgoing geodesic with boundary insertion point $v_{\text{out}} = 0$, $\phi_{\text{out}} = -2$, viewed in retarded coordinates (v, r, ϕ) from two different perspectives. The horizon radius has been set to $r_+ = 1$ and the outgoing geodesic is indicated by the red line. The shock wave is emitted from the geodesic towards the conformal boundary. The shock wave (C.17) associated with a conformal boundary with cylinder topology used in the main text, is found by adding images in order to implement the periodic identification $\phi \sim \phi + 2\pi$.

and

$$\mathcal{Z}(v, r_0(v, \phi), \phi) = -\frac{\sinh^2(r_+ \Delta\phi) - r_+^2 (2\Delta v + \Delta\phi)^2}{2r_+ \sinh(r_+ \Delta\phi) (2\Delta v + \Delta\phi)}, \quad (\text{C.15a})$$

$$X^3(v, r_0(v, \phi), \phi) = \frac{\sinh^2(r_+ \Delta\phi) + r_+^2 (2\Delta v + \Delta\phi)^2}{2r_+ \sinh(r_+ \Delta\phi) (2\Delta v + \Delta\phi)}. \quad (\text{C.15b})$$

The restriction $X^3 < 0$ in (C.13) is equivalent to $\Delta\phi(2\Delta v + \Delta\phi) < 0$. From (C.14), we find that only $-2\Delta v < \Delta\phi < 0$ yields a positive value for r_0 . Since the BTZ radial coordinate r ranges over positive values, only a positive r_0 can contribute to the support of the shock wave (C.13). The support of this outgoing shock wave is depicted in figure 9.

Let us now come back to the boundary conditions that one needs to impose on (C.6). The support of the shock wave stretches out from the outgoing geodesic towards the boundary and reaches the boundary when $\Delta\phi = 0$ or $\Delta\phi = -2\Delta v$, as may be seen from (C.14). Those values correspond to $\mathcal{Z} \rightarrow \pm\infty$ in embedding space. We therefore impose that $\Pi(\mathcal{Z})$ should decay at infinity. Together with a continuity constraint on $\Pi(\mathcal{Z})$ at $\mathcal{Z} = 0$, one finds the following solution

$$\Pi(\mathcal{Z}(v, r_0(v, \phi), \phi)) = \begin{cases} \frac{1}{2} \left(\sqrt{1 + \mathcal{Z}^2} + \mathcal{Z} \right) = -\frac{\sinh r_+ \Delta\phi}{2r_+ (2\Delta v + \Delta\phi)} & \text{for } \mathcal{Z} \leq 0 \\ \frac{1}{2} \left(\sqrt{1 + \mathcal{Z}^2} - \mathcal{Z} \right) = -\frac{r_+ (2\Delta v + \Delta\phi)}{2 \sinh r_+ \Delta\phi} & \text{for } \mathcal{Z} > 0, \end{cases} \quad (\text{C.16})$$

where we assumed $-2\Delta v < \Delta\phi < 0$ in the last equality.

Equation (C.13) represents the rr -component of the shock wave of an outgoing null geodesic in the decompactified limit. When the coordinate ϕ is periodic with period 2π , one should sum over images,

$$h_{rr}^{(2\pi)} = \sum_{n \in \mathbb{Z}} h_{rr}(r, \Delta v, \Delta \phi_n), \quad \Delta \phi_n \equiv \phi_{\text{out}} - \phi + 2\pi n. \quad (\text{C.17})$$

The shock wave of a single image of the geodesic only has support at bulk points $(v, r_0(v, \phi), \phi)$ satisfying $-2\Delta v < \Delta \phi < 0$, such that only finitely many images will contribute to the shock wave considered at any given bulk point.

Ingoing shock wave. The derivation of the shock wave sourced by an ingoing particle with zero angular momentum is identical, provided that one uses advanced coordinates (3.17). The relevant rr -component is thus obtained from (C.17) by making the replacements

$$\Delta v \rightarrow \Delta u \equiv u - u_{\text{in}}, \quad \Delta \phi_n \rightarrow \Delta \phi'_n \equiv \phi' - \phi'_{\text{in}} + 2\pi n. \quad (\text{C.18})$$

Comparison with earlier literature. It is worth contrasting the shock wave expression (C.17) to the one obtained in the case of non-extremal BTZ in [23]; see also [22]. These authors considered the shock waves sourced by geodesics lying on the past and future horizons of a non-maximally rotating BTZ black hole, respectively. As already mentioned, this allows one to compute the leading contribution to the OTOC in the regime $\Delta t \gg \beta$ but precludes the study of zero temperature states which include vacuum AdS and extremal BTZ. For these, it is crucial that one considers shock waves sourced by geodesics away from horizons instead. In particular, (C.17) cannot be straightforwardly obtained as the zero-temperature limit of the shock wave presented in [22, 23], which simply diverges. A similar qualitative feature, however, is the appearance of a sum over images due to the angular periodicity. Each image may be thought of as being associated to an additional winding of the shock wave around the black hole. More images are being generated as the time separation Δv with the source particle increases. In particular, an infinite number of images contribute to (C.17) in the limit $\Delta v \rightarrow \infty$. The shock wave described in [23] may be similarly expressed as an infinite sum over images, although it has been explicitly resummed in that case. We refer the reader to section 3.2 for further comments on the relation between shock waves in maximally and non-maximally rotating BTZ black holes.

ABSTRACT: We illustrate scenarios in which Hawking radiation collected in finite regions of a reservoir provides temporary access to the interior of black holes through transient entanglement “islands.” Whether these islands appear and the amount of time for which they dominate — sometimes giving way to a thermalization transition — is controlled by the amount of radiation we probe. In the first scenario, two reservoirs are coupled to an eternal black hole. The second scenario involves two holographic quantum gravitating systems at different temperatures interacting through a Rindler-like reservoir, which acts as a heat engine maintaining thermal equilibrium. The latter situation, which has an intricate phase structure, describes two eternal black holes radiating into each other through a shared reservoir.

1 Introduction

The fine-grained entropy of any quantum system A entangled with its complement \bar{A} satisfies the unitarity bound $S(A) \leq \min\{\log \dim \mathcal{H}_A, \log \dim \mathcal{H}_{\bar{A}}\}$ in terms of the dimensions of the corresponding Hilbert spaces. In a holographic theory, the entropy may be geometrized in terms of the areas of extremal surfaces in spacetime [1–6]. As the system evolves, entanglement structure can change dynamically, and be reflected in exchange of dominance between different extremal surfaces. Beautiful work has shown that this exchange can be necessary for the satisfaction of the bound on $S(A)$ as time evolves [4–17].

One example [13] involves holographic CFTs entangled in a thermofield double state dual to eternal black holes connected behind their horizons by a wormhole. The entropy of a pair of subregions in these theories is initially associated to an extremal surface passing through the wormhole. The area of this surface grows in time, threatening violation of the entropy bound, a fate avoided by a thermalization transition after which the two regions no longer share mutual information. After this time, their entropy is geometrized by a pair of disconnected extremal surfaces of constant area outside the horizons. A second example occurs in the same setup of eternal black holes, this time coupled to reservoirs collecting the Hawking radiation escaping the black holes [4–6, 8, 11]. In this case, at early times the entropy of the radiation increases in time exactly as computed by Hawking. At the Page time,

a nontrivial quantum extremal surface (QES) [1–3, 18] appears in the spacetime. This leads to a saturation of the entropy by requiring us to include the interior Hawking modes in the computation of the entropy. The nontrivial QES occurs due to the replica wormhole saddle points in the quantum gravity path integral [8, 11]. It bounds an “island” and is responsible for information recovery from Hawking radiation via access to the black hole interior.

In this paper, we study what occurs when one considers finite-sized portions of the radiation. For sufficiently small portions, the radiation may thermalize before or after it has a chance to encode the black hole interior. We will probe this competition between thermalization and the island mechanism — realizing both examples discussed above in the same physical system — by examining the time-dependence of entanglement entropy. The various transitions can be predicted by a careful application of the unitarity bound described above. In short, island regions will appear when the entropy of quantum fields on the black hole background threatens the unitarity bound set by its Bekenstein-Hawking entropy, whereas thermalization will occur when the entropy of the radiation approaches the maximal amount dictated by the size of the radiation region’s Hilbert space. We will exhibit a nontrivial phase structure transitioning between these possibilities in two scenarios, which we now summarize.

Summary of results. Our first scenario, studied in section 2, involves finite regions in two reservoirs coupled to a thermofield double black hole in AdS_2 , see figure 1 (the entropy of infinite radiation regions in this model was studied in [7, 8]). The entropy initially grows linearly as time evolves, then (depending on the region size and boundary conditions) there may be a transition to half the initial rate, and finally the growth stabilizes; see figure 3. If we treat the radiation as holographic in its own right, the transition between the initial and the final phase involves an exchange between an extremal surface passing between the reservoirs through the induced dimension, and a pair of disconnected extremal surfaces of constant area, as in [13]; see figure 2. However the “island formula” (reviewed below) dictates a new intermediate phase, which includes an island, although the entropy does not stabilize but instead grows with only half the initial slope. The eventual stabilization of entanglement entropy of finite intervals then happens not because of entanglement islands, but because of the thermalization of the segments. When the entanglement entropy saturates, the island is no longer accessible.

Our second scenario involves two holographic quantum dots at different temperatures, each dual to an eternal AdS_2 black hole, in local equilibrium with a finite radiation reservoir. The reservoir is modeled by Rindler space, which acts as a heat engine maintaining local equilibrium by redshifting warmer modes approaching the cooler black hole and vice versa; see the beginning of section 3 and figure 4. The radiation theory will itself be holographic. The phase structure includes transitions between an asymmetric wormhole (the “confined” phase; see section 3.2 and figure 7) and two black holes of different temperature (the “deconfined” phase; see section 3.1 and figure 5). In the deconfined phase, many extremal surfaces vie to dominate the entropy of reservoir regions in this model. This is studied in section 4; see figure 9, 10, 11 for the case where we include one pair of thermofield double quantum dots in the region whose entropy we are computing and figure 12, 13, 14 for the case where

we do not. As time evolves, these surfaces exchange dominance to maintain the unitary upper bound on entropy. In particular, unlike the single black hole case, in this model it is possible to have both temporary island configurations and permanent island configurations.

2 An eternal black hole coupled to a reservoir

Consider an AdS₂ eternal black hole with flat, non-gravitating radiation reservoirs glued to the two boundaries (figure 1) [7, 8]. In the AdS₂ region we have Jackiw-Teitelboim (JT) gravity, along with transparent boundary conditions for conformal matter in the black hole and reservoirs. The action is:

$$I = -\frac{\phi_0}{4\pi} \left[\int_{\Sigma_2} R + 2 \int_{\partial\Sigma_2} K \right] - \frac{1}{4\pi} \left[\int_{\Sigma_2} \phi(R+2) + 2\phi_b \int_{\partial\Sigma_2} (K-1) \right] + I_{\text{CFT}}, \quad (2.1)$$

where the first term is topological, the last term is a Conformal Field Theory (CFT) with central charge c , ϕ_0 gives the Bekenstein-Hawking entropy of the extremal black hole (we have set $4G_N = 1$), and ϕ_b is the asymptotic value of the dilaton on Σ_2 , the region of spacetime where gravity is dynamical. Varying (2.1) with respect to the dilaton fixes the metric to be locally AdS₂. Globally we consider the eternal black hole (figure 1), with each of the two exterior regions described by

$$ds_{\text{grav}}^2 = \frac{4\pi^2}{\beta^2} \frac{-dt^2 + d\sigma^2}{\sinh^2 \frac{2\pi\sigma}{\beta}}, \quad t \in \mathbb{R}, \quad \sigma \in (-\infty, -\epsilon]. \quad (2.2)$$

We glue the surface $\sigma = -\epsilon$ continuously to the reservoir [7], so the latter's metric is:

$$ds_{\text{bath}}^2 = \frac{-dt^2 + d\sigma^2}{\epsilon^2}, \quad t \in \mathbb{R}, \quad \sigma \in [-\epsilon, +\infty). \quad (2.3)$$

Varying with respect to the metric yields the dilaton equation of motion:

$$D_\mu D_\nu \phi - g_{\mu\nu} \square \phi + g_{\mu\nu} \phi + 2\pi T_{\mu\nu} = 0. \quad (2.4)$$

With the stress tensor given by $T_{\mu\nu} = \frac{c}{24\pi} g_{\mu\nu}$, the dilaton in the gravitational region (2.2) is

$$\phi(\sigma) = \frac{2\pi\phi_r}{\beta} \coth \frac{2\pi\sigma}{\beta}, \quad (2.5)$$

where ϕ_r is an integration constant.

2.1 Radiation entropy

The island formula [4–6, 8, 11] says that the entanglement entropy of reservoir region A is

$$\mathcal{S}(A) = \min_{\mathcal{I}} \text{ext} [S_{\text{CFT}}(A \cup \mathcal{I}) + \text{Area}(\partial\mathcal{I})], \quad (2.6)$$

where \mathcal{I} is an “island” in the gravitating region. In JT gravity the area term equals the dilaton value on the corresponding surface plus the constant ϕ_0 , while, for a general 2d CFT, the entropy on $A \cup \mathcal{I}$ is related to the (generically non-universal) correlator of twist

Figure 1. Penrose diagram of an eternal AdS₂ black hole with flat reservoirs glued to the boundaries, and identical equal-time segments $[p_1, p_2]$ and $[p_3, p_4]$. We compute the entanglement entropy of the union of these segments.

operators. We take the CFT to be holographic following [6],¹ and compute $S_{\text{CFT}}(A \cup \mathcal{I})$ through the Ryu-Takayanagi formula [1, 2] in a 3d gravity theory dual to this CFT on a fixed curved background.

In Euclidean signature, the CFT on the 2d boundary of the 3d gravity theory is defined on a Euclidean black hole attached to reservoirs with fixed metrics. The dynamical part of the 2d boundary is referred to as a “Planck brane”, which corresponds to a cut-off boundary of the 3d geometry. Given a specific dynamical 2d metric ds_2^2 and stress tensor, it is convenient to introduce a complex coordinate w on the 2d boundary so that $T_{ww} = 0$ in the flat Weyl-transformed metric $dwd\bar{w}$ [6]. Since the stress tensor vanishes, the dual 3d spacetime can be described by Poincaré coordinates in Euclidean AdS₃:

$$ds^2 = \frac{dwd\bar{w} + dz^2}{z^2}. \tag{2.7}$$

Writing the original boundary metric (before Weyl transformation) as

$$ds_2^2 = \Omega^{-2}(w, \bar{w})dwd\bar{w}, \tag{2.8}$$

the holographic relation

$$g_{\mu\nu}^{(3)}|_{\text{bdy}} = \frac{1}{\varepsilon^2}g_{\mu\nu}^{(2)} \tag{2.9}$$

leads to

$$\frac{dwd\bar{w}}{z(w)^2} = \frac{1}{\varepsilon^2}\Omega^{-2}(w, \bar{w})dwd\bar{w} \Rightarrow z(w) = \varepsilon\Omega(w, \bar{w}), \tag{2.10}$$

which determines the embedding of the Planck brane in the 3d geometry [6]. Note that the regulator ε is distinct from the 2d cutoff ϵ where the reservoir is glued to the AdS₂ black hole.

Following [1, 2] the CFT entropies $S_{\text{CFT}}(A \cup \mathcal{I})$ are computed by lengths of geodesics in (2.7) ending on boundary points of $A \cup \mathcal{I}$, with $z(w)$ treated as a cutoff. Physical quantities will depend nontrivially on Ω , e.g., the entropy of a single interval between w_1 and w_2 is [27, 28]:

$$S(w_1, w_2) = \frac{c}{6} \log \left(\frac{|w_1 - w_2|^2}{\varepsilon_1 \varepsilon_2 \Omega(w_1, \bar{w}_1) \Omega(w_2, \bar{w}_2)} \right), \tag{2.11}$$

¹For further developments of the doubly holographic approach to the entanglement entropy of radiation, see e.g. [14, 19–26], especially [20] for a pedagogical treatment.

Figure 2. Extremal surfaces that extend into the 3d bulk from the Penrose diagram in figure 1 playing the role of the 2D boundary. (a) \rightarrow (c) is a thermalization transition, which can be interrupted by the island configuration (b). Surface (d) is always subleading.

To return to Lorentzian coordinates (2.2), we write $w = e^{\frac{2\pi}{\beta}(\sigma+i\tau)}$ and Wick rotate $\tau = it$. The single interval entropy is universal for 2d CFTs [27] but we consider a union of intervals. Typically, several combinations of geodesics end on such unions, with each geodesic length given by (2.11). For fixed $A \cup \mathcal{I}$ the minimal total geodesic length gives the entropy. Thus, we identify possible 3d geodesic configurations computing $S_{\text{CFT}}(A \cup \mathcal{I})$, extremize the functional in (2.6) for each choice, and select the minimizing choice.

2.2 The entanglement entropy of finite segments

To compute the entropy of the region $A = [p_1, p_2] \cup [p_3, p_4]$ in figure 1, we will use a time that continuously glues global AdS₂ to the reservoirs, reversing Schwarzschild time t (2.2) in one of the exterior regions of the black hole. Thus we choose endpoint coordinates

$$p_1 = (b, -t + i\pi); \quad p_2 = (a, -t + i\pi); \quad p_3 = (a, t); \quad p_4 = (b, t). \quad (2.12)$$

Figure 2 shows 3d geodesics between interval endpoints $p_{1,2,3,4}$ and a possible island in the black hole region.² The green curves are Ryu-Takayanagi surfaces, while red regions inside the black hole are islands whose endpoints are the quantum extremal surfaces found by extremizing (2.6).

Configuration (a): linear growth. Two 3d geodesics connect $p_1 \leftrightarrow p_4$ and $p_2 \leftrightarrow p_3$, respectively. There are no islands and the entropy is given by

$$\mathcal{S}_a = S_{\text{connected}}^{\text{no island}}(p_1, p_2; p_3, p_4) = 2 \frac{c}{3} \log \left[\frac{\pi}{\beta} \cosh \frac{2\pi t}{\beta} \right]. \quad (2.13)$$

This expression grows approximately linearly in time.

²UV divergences are associated with endpoints of $p_{1,2,3,4}$ and possible islands. The first kind are the same for any choice of geodesic, so we omit them. The second kind renormalize ϕ_0 .

Configuration (b): island. This fully connected configuration includes an island in the black hole region between $[q_1, q_2]$. The location is obtained by extremizing (2.6) with respect to $q_{1,2} = (x, t_x)$ in their respective black hole exterior patches. The entropy is

$$S_{\text{connected}}^{\text{island}} = 2 \left(\phi_0 + \frac{2\pi\phi_r}{\beta} \coth \left(-\frac{2\pi}{\beta} x \right) \right) + \frac{c}{3} \log \left(\frac{\beta \left(\cosh \left[\frac{\pi}{\beta} (x-a) \right] - \cosh \left[\frac{2\pi}{\beta} (t-t_x) \right] \right)}{\pi \sinh \left(-\frac{2\pi x}{\beta} \right)} \right) + \frac{c}{3} \log \left[\frac{\pi}{\beta} \cosh \frac{2\pi t}{\beta} \right]. \quad (2.14)$$

The extrema for the time and space decouple, and the time equation yields $t_x = t$. The solution for x is cumbersome, but in the regime $\frac{\phi_r}{c\beta} \gg 1$ there is a simplified expression

$$x \approx a + \frac{\beta}{2\pi} \log \left[24\pi \frac{\phi_r}{c\beta} \right], \quad \frac{\phi_r}{c\beta} \gg 1. \quad (2.15)$$

The first line in (2.14) determines the time-independent island contribution. The second line, which grows linearly with half the slope compared to the configuration (a), comes from the long geodesic that goes across the Einstein-Rosen bridge.

Configuration (c): thermalization. This configuration gives the sum of thermalized CFT entanglement entropies for the thermofield double copies of the reservoir segment:

$$S_{\text{thermalized}} = 2 \frac{c}{3} \log \left(\frac{\beta}{\pi} \sinh \frac{\pi|a-b|}{\beta} \right). \quad (2.16)$$

Configurations (d): disconnected islands. Here two islands lie in exterior regions of the black hole, connected with the RT geodesics to their respective copies of the radiation segment. One can show that this configuration is always subleading compared to (c) while also being time independent.

Summary. Varying the size of the reservoir regions with other parameters fixed, we see in figure 3 that for large regions we have transitions (a) \rightarrow (b) \rightarrow (c), accessing an island region for a finite period of time before losing it. For smaller regions we directly make the thermalization transition (a) \rightarrow (c) as in [13]. Thus, finite radiation segments give temporary access to the black hole interior, unlike infinite segments which give permanent access at late times [7–9, 11]. This happens because during the entanglement evolution any finite segment will eventually thermalize, scrambling information from the island. From the path integral point of view the transition (a) \rightarrow (b) arises by including replica wormholes [7, 11], and will be smoothed by also summing over replica non-symmetric manifolds [11, 29, 30].

By utilizing the unitarity bound discussed in section 1, the qualitative nature of these transitions can be predicted without much computation. In particular, (a) and (b) will eventually threaten the unitarity bound set by the size of the Hilbert space of our radiation region, so must eventually transition. What about the transition (a) \rightarrow (b)? Clearly this need not come close to saturating the unitarity bound of our radiation region, since the entropy continues to increase in phase (b) due to interior Hawking modes being captured by the island while their exterior partners escape away into the infinite region of the bath.

Figure 3. **A.** The entanglement entropy curves for the configurations (a), (b), (c) and (d) for region size much larger than the distance from the interface and comparable to ϕ_r/c . **B.** The Page curve of a finite segment, obtained by minimizing between the saddles shown in plot A.

However, the structure of the geodesics in figure 2(a) indicates that the mutual information vanishes between (i) the gravitational region and the adjoining baths up to the radiation region, and (ii) the rest of the complement of the radiation region A . In particular, this means that each region of the complement is subject to its own unitarity bound. The relevant bound here is the one set by the gravitational region (plus some of the adjoining baths, which we take to be a small correction): once the entropy of this region comes close to $2S_{\text{BH}}$, a transition must occur.

3 Two holographic quantum dots connected by a reservoir

The quantum-mechanical setup we consider next involves two thermofield double pairs of a holographic quantum mechanical system (which we refer to as the quantum dot) interacting through a common reservoir. The quantum dots are dual to JT gravity described by the action (2.1). They are coupled to a CFT₂ of central charge c , which lives in the reservoir. We will not specify the exact Hamiltonian of the quantum dots; however a common example of a quantum mechanical system holographically dual to JT gravity (in an appropriate limit) is the SYK model [31–33].

The temperatures of the quantum dots are treated as independent parameters, and so for this setup to be in the equilibrium, we have the reservoir working as a heat engine which cools the matter CFT quanta being emitted from the hotter quantum dot and going into the cooler one. The action of the heat engine is caused by the nontrivial metric in the reservoir. Such a reservoir in Euclidean signature has a boundary consisting of two thermal circles of different lengths (figure 4). One can write down a metric for such a reservoir as follows:³

$$ds^2 = \frac{dr^2 + f(r)^2 d\tau^2}{\epsilon^2}, \quad \tau \sim \tau + 2\pi\alpha, \quad r \in (r_1, r_2). \quad (3.1)$$

Notice that the thermal periodicity changes from $2\pi f(r_1)\alpha/\epsilon$ to $2\pi f(r_2)\alpha/\epsilon$. So, as advertised, such a spacetime acts as a heat engine which equilibrates the radiation between the

³We include the regulator ϵ so that the metric in the gravity dual is manifestly continuous throughout the spacetime, similarly to the discussion in section 2.

Figure 4. Euclidean picture of the two quantum dots living on the thermal circles of different lengths coupled by the conical reservoir.

two systems with different temperature. This is similar to considering different radial positions in a black hole in thermal equilibrium: the physical temperature for static observers at each location is different, yet the entire system is in thermal equilibrium.

In the present paper we consider the simplest case and assume that $f(r) = r$ and the reservoir has the metric of a cone:

$$ds_R^2 = \frac{dr^2 + r^2 d\tau^2}{\epsilon^2}, \quad \tau \sim \tau + 2\pi\alpha. \quad (3.2)$$

The results in this model can be extended to a general $f(r)$ in a straightforward manner. The position-dependent temperature is precisely that of Rindler space, obtained by continuing to Lorentzian signature $\tau \rightarrow it$.

By choosing an interval of size L_R and inverse temperatures β_1 and β_2 , we fix the radial coordinates of boundaries in figure 4 and the solid angle of the cone. Choosing $\beta_2 > \beta_1$, this yields the relations

$$r_1 = \frac{L_R \beta_1}{\beta_2 - \beta_1}, \quad r_2 = \frac{L_R \beta_2}{\beta_2 - \beta_1}, \quad \alpha = \frac{\beta_2 - \beta_1}{2\pi L_R}. \quad (3.3)$$

For $\alpha \neq 1$ there is a conical singularity, although it is excised from the region we are considering. The parameter α has a physical interpretation as the strength of the heat engine which equilibrates the two sides, and it must be tuned as we vary the temperatures or the distance over which we want to equilibrate the temperatures. Some formulas will be simpler to write in terms of α , but fixing α and $\beta_{1,2}$ fixes L_R . The equal-temperature limit can be realized by taking $\alpha \rightarrow 0$ while keeping L_R fixed, in which case $r_{1,2} \rightarrow \infty$. Physically we are taking the strength of the equilibrator to zero (equal temperatures are already equilibrated), but to keep finite-sized circles we need to scale the coordinates to infinity.

We can rewrite the cone metric as conformally flat:

$$ds_R^2 = \Omega_R(\xi)^{-2} \frac{d\xi^2 + d\theta^2}{\epsilon^2}, \quad \xi \in [0, L], \quad \theta \sim \theta + 2\pi. \quad (3.4)$$

Note that the dimensionless coordinate ξ plays the role of the spatial coordinate, and θ plays the role of Euclidean time. The Weyl factor is given by the formula

$$\Omega_R(\xi) = \frac{1}{\alpha r} = \frac{2\pi}{\beta_1} e^{-\alpha\xi}, \quad r = r_1 e^{\alpha\xi}, \quad L = \alpha^{-1} \log \frac{\beta_2}{\beta_1}. \quad (3.5)$$

There are two possible two-dimensional gravitational duals for our Rindler reservoir coupled to holographic quantum dots living on thermal circles at each end. We can either complete the circular boundaries of the reservoir into a torus, or we can have independent disks at the two boundaries. The first possibility represents a confined phase, described by a wormhole, shown schematically in figure 7. The second possibility represents a deconfined phase, described by independent thermofield double black holes, shown schematically in figure 4.

The partition sum of the theory will undergo transitions between these confined and deconfined phases as the parameters change. We expect that the phase structure will be similar to the one in [34]. The wormhole solution should be global AdS₂ as in [34], except that the dilaton profile will be a one-parameter generalization of the usual one: the solution has a free constant that is usually fixed by the \mathbb{Z}_2 symmetry, but in our case this constant will be fixed by the choice of temperatures. This allows us to cut the solution off at slightly different coordinate values on either side of the wormhole, which leads to equal values of ϕ_r , but with different temperatures. In other words, the boundary conditions from the bulk perspective are given by

$$ds_{1,2}^2 = \frac{du^2}{\epsilon^2}, \quad u \sim u + \beta_{1,2}, \quad \phi_{1,2} = \frac{\phi_r}{\epsilon} \tag{3.6}$$

at leading order in ϵ . The other novelty is the Rindler region. As we reviewed above, a Weyl transformation maps this to the usual case of a finite cylinder with constant thermal periodicity. The Weyl anomaly then makes a contribution to the partition sum, but since the transformation is the same in both solutions, the anomaly does not affect the phase structure.

3.1 Black hole phase

The action is given in (2.1) and the solution that describes the geometry (figure 4) involves two Euclidean copies of the gravitational solution in (2.2)–(2.5), with different temperatures:

$$ds_1^2 = \frac{4\pi^2}{\beta_1^2} \frac{d\tau_1^2 + d\sigma^2}{\sinh^2 \frac{2\pi\sigma}{\beta_1}}; \quad \sigma \in (-\infty, -\epsilon], \quad \tau_1 \sim \tau_1 + \beta_1, \tag{3.7}$$

$$ds_2^2 = \frac{4\pi^2}{\beta_2^2} \frac{d\tau_2^2 + d\sigma^2}{\sinh^2 \left[\frac{2\pi\sigma}{\beta_2} - L \right]}; \quad \sigma \in \left[\frac{\beta_2}{2\pi} L + \epsilon, +\infty \right), \quad \tau_2 \sim \tau_2 + \beta_2. \tag{3.8}$$

The reservoir metric is given by (3.4), with $L = \alpha^{-1} \log \frac{\beta_2}{\beta_1}$ being the size of the reservoir in the cylinder coordinates. The reservoir coordinate ξ is dimensionless, hence the extra conversion factor of $\frac{\beta_2}{2\pi}$. The dilaton profile in the disk regions is given by the equations

$$\phi(\sigma)_1 = -\frac{2\pi}{\beta_1} \phi_r \coth \frac{2\pi\sigma}{\beta_1}; \tag{3.9}$$

$$\phi(\sigma)_2 = \frac{2\pi}{\beta_2} \phi_r \coth \left(\frac{2\pi\sigma}{\beta_2} - L \right). \tag{3.10}$$

Figure 5. The schematic picture of the black hole phase in the Euclidean signature. The spacetime is two hyperbolic disks connected by the conical reservoir.

We can break up the on-shell partition function for this solution into two main pieces. The first is the gravitational contribution on the disks; it is obtained by directly evaluating the pure JT gravity part of the action on the solution, and reads

$$Z_{\text{disks,grav}} = e^{2\phi_0 + \pi\phi_r \left(\frac{1}{\beta_1} + \frac{1}{\beta_2} \right)}. \quad (3.11)$$

The second piece of the on-shell partition function comes from the matter CFT living on the curved background. The spacetime metric can be written as $ds^2 = e^{2\omega} d\hat{s}_{\text{flat}}^2$ everywhere in the spacetime, and so the nontrivial Weyl factor ω gives a Weyl anomaly contribution [35]:

$$Z_{\text{anomaly}} = \exp \left[\frac{c}{24\pi} \int \sqrt{\hat{g}} (\partial\omega)^2 \right]. \quad (3.12)$$

The computation of this partition function involves a step which will also be used in the computations of entanglement entropy in this model, so we discuss it in detail.

Our spacetime is a closed manifold, so there are no physical boundaries to generate boundary terms. We perform the conformal transformation from the disks and the conical reservoir shown in figure 4 to the plane with metric of the form $ds^2 = e^{2\omega} d\hat{s}_{\text{flat}}^2$. We write the flat reference metric in polar coordinates:

$$d\hat{s}_{\text{flat}}^2 = dw d\bar{w} = d\rho^2 + \rho^2 d\varphi^2, \quad (3.13)$$

where $w = \rho e^{i\varphi}$ is the complex coordinate, $\rho \in [0, +\infty)$ and $\varphi \sim \varphi + 2\pi$. The explicit form of the conformal transformation is given by

$$\text{Disk 1 : } w = e^{\frac{2\pi}{\beta_1}(\sigma + i\tau_1)}; \quad (3.14)$$

$$\text{Reservoir : } w = e^{\xi + i\theta}; \quad (3.15)$$

$$\text{Disk 2 : } w = e^{\frac{2\pi}{\beta_2}(\sigma + i\tau_2)}. \quad (3.16)$$

As shown in figure 6, the plane is divided into three regions where the Weyl factor ω is

Figure 6. Euclidean geometry of two black holes coupled via a reservoir conformally mapped to a plane. The shaded region is the reservoir.

given by different functions:

$$\text{Disk 1: } e^{\omega_1} = \Omega_1^{-1} = \frac{2}{1-\rho^2}, \quad \rho \in \left[0, 1 - \frac{2\pi\epsilon}{\beta_1}\right]; \quad (3.17)$$

$$\text{Reservoir: } e^{\omega_{\text{bath}}} = \Omega_{\text{bath}}^{-1} = \frac{\beta_1}{2\pi\epsilon} \rho^{\alpha-1}, \quad \rho \in \left(1 - \frac{2\pi\epsilon}{\beta_1}\epsilon, \left(\frac{\beta_2}{\beta_1}\right)^{\frac{1}{\alpha}} \left(1 + \frac{2\pi\epsilon}{\beta_2}\right)\right); \quad (3.18)$$

$$\text{Disk 2: } e^{\omega_2} = \Omega_2^{-1} = \frac{2\left(\frac{\beta_2}{\beta_1}\right)^{\frac{1}{\alpha}}}{\rho^2 - \left(\frac{\beta_2}{\beta_1}\right)^{\frac{2}{\alpha}}}, \quad \rho \in \left[\left(\frac{\beta_2}{\beta_1}\right)^{\frac{1}{\alpha}} \left(1 + \frac{2\pi\epsilon}{\beta_2}\right), \left(\frac{\beta_2}{\beta_1}\right)^{\frac{1}{\alpha}} \Lambda\right], \quad (3.19)$$

where the bottom line includes the Weyl factor from the Rindler geometry in the reservoir defined in (3.5) written in terms of $w = e^{\xi+i\theta}$, and $\Lambda \gg 1$ is the cutoff. The cutoff is defined with the $(\beta_2/\beta_1)^{1/\alpha}$ prefactor to ensure the ratio of radii defining disk 2 is independent of β_1 , which means the contribution of disk 2 to the partition function will be independent of β_1 (see (3.21) below). We now compute the contributions from the three regions to (3.12) separately.

Disk 1. We integrate from $\rho = 0$ to $\rho = 1 - \frac{2\pi\epsilon}{\beta_1}$ and get

$$Z_1 = \exp \left[\frac{c\beta_1}{24\pi\epsilon} + \frac{c}{6} \log \frac{4\pi\epsilon}{\beta_1} - \frac{c}{8} \right] \tilde{Z}_1, \quad (3.20)$$

where \tilde{Z}_1 is the partition function of the theory on the portion $\rho \in [0, 1 - 2\pi\epsilon/\beta_1]$ of flat space.

Disk 2. We integrate from $\rho = \left(\frac{\beta_2}{\beta_1}\right)^{\frac{1}{\alpha}} \left(1 + \frac{2\pi\epsilon}{\beta_2}\right)$ to $\rho = \Lambda \gg 1$ and get

$$Z_2 = \exp \left[\frac{c\beta_2}{24\pi\epsilon} - \frac{c}{6} \log \frac{4\pi\epsilon}{\beta_2} - \frac{c}{24} + \frac{c}{3} \log \Lambda \right] \tilde{Z}_2, \quad (3.21)$$

where \tilde{Z}_2 is the partition function of the theory on the portion $\rho \in \left[\left(\frac{\beta_2}{\beta_1} \right)^{\frac{1}{\alpha}} \left(1 + \frac{2\pi\epsilon}{\beta_2} \right), \left(\frac{\beta_2}{\beta_1} \right)^{\frac{1}{\alpha}} \Lambda \right]$ of flat space.

Reservoir region. Here we integrate from $\rho = 1 - \frac{2\pi\epsilon}{\beta_1}$ to $\rho = \left(\frac{\beta_2}{\beta_1} \right)^{\frac{1}{\alpha}} \left(1 + \frac{2\pi\epsilon}{\beta_2} \right)$ and get

$$Z_{\text{reservoir}} = \exp \left[\frac{c(\alpha - 1)^2}{12\alpha} \log \frac{\beta_2}{\beta_1} \right] \tilde{Z}_{\text{reservoir}}, \quad (3.22)$$

where $\tilde{Z}_{\text{reservoir}}$ is the partition function of the theory on the portion $\rho \in \left[1 - 2\pi\epsilon/\beta_1, \left(\frac{\beta_2}{\beta_1} \right)^{\frac{1}{\alpha}} \left(1 + 2\pi\epsilon/\beta_2 \right) \right]$ of flat space. Combining (3.20)–(3.22) and using the normalization $\tilde{Z}_1 \tilde{Z}_2 \tilde{Z}_{\text{reservoir}} = 1$, we get the total result for the CFT anomaly contribution:

$$Z_{\text{anomaly}} = \exp \left[-\frac{c}{6} + \frac{c}{12} \left(\alpha + \frac{1}{\alpha} \right) \log \frac{\beta_2}{\beta_1} + \frac{c(\beta_1 + \beta_2)}{24\epsilon} + \frac{c}{3} \log \Lambda \right]. \quad (3.23)$$

Next we combine this result with the gravitational partition function (3.11):

$$Z = \exp \left(2\phi_0 - \frac{c}{6} + \pi\phi_r \left(\frac{1}{\beta_1} + \frac{1}{\beta_2} \right) + \frac{c}{12} \left(\alpha + \frac{1}{\alpha} \right) \log \frac{\beta_2}{\beta_1} \right). \quad (3.24)$$

This is the final result for the partition function of the disconnected black hole phase. We removed two terms from (3.23): a $1/\epsilon$ divergence proportional to the sum of lengths of the boundary of the hyperbolic disk which was removed by a local counterterm, and a divergence in Λ that is expected to renormalize ϕ_0 .⁴

3.2 Asymmetric wormhole phase

The asymmetric wormhole solution is a quotient of Euclidean AdS₂ spacetime with the metric [34, 36]

$$ds^2 = \frac{d\chi^2 + d\sigma^2}{\sin^2 \sigma}, \quad \phi = -2\pi T_{\sigma\sigma}^{\text{traceless; bulk}} \left(\frac{\gamma - \sigma}{\tan \sigma} + 1 \right), \quad (3.25)$$

where $\chi \sim \chi + b$ is a periodic coordinate which plays the role of Euclidean time direction and $\sigma \in [\epsilon_1, \pi - \epsilon_2]$ is the spatial coordinate with $\epsilon_{1,2}$ being small cutoffs to be determined below. The two boundaries of AdS₂ are glued to the Rindler reservoir with the metric (3.4). The spacetime is thus a conformally flat manifold with the topology of a torus, as shown in figure 7.

It remains to compute $T_{\sigma\sigma}^{\text{traceless; bulk}}$ and fix γ . Ignoring the curved metric for a moment, the torus has circumferences b and $d = \pi + (2\pi\alpha)^{-1} b \log \frac{\beta_2}{\beta_1}$ along the χ and σ directions of the AdS₂ bulk, and along the θ and ξ directions of the reservoir, respectively. For the wormhole solution to exist, we take $b > d$. If we consider a holographic CFT on this

⁴Note that if we chose the cutoff in the plane as Λ instead of $(\beta_2/\beta_1)^{1/\alpha} \Lambda$, it would modify the coefficient of the term $\alpha^{-1} \log \frac{\beta_2}{\beta_1}$ and give the wrong answer in the equal-temperature limit where $\alpha \rightarrow 0$ and $\alpha^{-1} \log \frac{\beta_2}{\beta_1} \rightarrow 2\pi L_R/\beta$, where we denote the limiting value of β_1 and β_2 as β .

Figure 7. Schematic of the wormhole phase. The asymmetry of the wormhole is caused by the different sizes of the thermal circles which are glued to the regulated AdS₂ boundaries. Correspondingly, the two boundary regulators are different.

background, and quantize along the χ direction of the AdS₂ (θ direction of the reservoir), we are in the vacuum. The vacuum stress tensor on such a cylinder of circumference d , evaluated for a torus with the flat metric $\hat{g}_{\mu\nu}$ is therefore:

$$T_{\sigma\sigma}^{\hat{g}} = -T_{\chi\chi}^{\hat{g}} = -\frac{\pi c}{6d^2} = -\frac{c}{6\pi} \frac{1}{\left(1 + \frac{b \log \frac{\beta_2}{\beta_1}}{2\pi^2\alpha}\right)^2}. \quad (3.26)$$

Now recall that the gravitational part of the manifold has a curved metric (3.25) of the form $g_{\mu\nu} = e^{2\omega} \hat{g}_{\mu\nu}$, where $\hat{g}_{\mu\nu}$ is the flat metric. This gives an anomalous contribution to the stress tensor which has a traceless piece and a piece proportional to the metric. The traceless piece coming from the combination of the flat torus and the anomaly is what enters in the dilaton solution above and is given as

$$T_{\sigma\sigma}^{\text{traceless; bulk}} = -T_{\chi\chi}^{\text{traceless; bulk}} = -\frac{c}{6\pi} \frac{1}{\left(1 + \frac{b \log \frac{\beta_2}{\beta_1}}{2\pi^2\alpha}\right)^2} + \frac{c}{24\pi}. \quad (3.27)$$

Unlike previous works we have a free parameter γ in the solution for the dilaton; without this free parameter the solution would only exist for equal temperatures on the two sides. We want to match the lengths of the different thermal circles at the interfaces between the wormhole and the Rindler bath while maintaining equal ϕ_r values (see eq. (3.6)). This requires asymmetric cutoffs $\sigma_1 = \epsilon_1 \ll 1$, $\pi - \sigma_2 = \epsilon_2 \ll 1$:

$$\frac{b}{\epsilon_{1,2}} = \frac{\beta_{1,2}}{\epsilon} \implies \epsilon_{1,2} = \frac{b}{\beta_{1,2}} \epsilon, \quad \phi|_{\sigma_1} = \phi|_{\sigma_2} \implies \gamma = \frac{\pi\beta_2}{\beta_1 + \beta_2}. \quad (3.28)$$

So the choice of temperatures β_1, β_2 dictates the cutoffs σ_1, σ_2 and the dilaton solution. In the symmetric case $\beta_1 = \beta_2$ we would find $\gamma = \pi/2$. The dilaton boundary condition fixes b through

$$\phi|_{\sigma_1} = \frac{\phi_r}{\epsilon} \implies \left(\frac{c}{3 \left(1 + \frac{b \log \frac{\beta_2}{\beta_1}}{2\pi^2\alpha}\right)^2} - \frac{c}{12} \right) = \frac{\phi_r b (\beta_1 + \beta_2)}{\pi \beta_1 \beta_2}. \quad (3.29)$$

Having established the dilaton solution, we are now ready to discuss the full partition function of the wormhole phase. We can break up the partition function in this phase into three pieces:

- (i) The gravitational contribution from the AdS₂ wormhole, computed using the action (2.1) evaluated on the solution (3.25).
- (ii) The CFT anomaly from the Weyl transform from cylinder $\chi \in [0, b)$, $\sigma \in [\epsilon_1, \pi - \epsilon_2]$ to the AdS₂ metric in the gravitational region. It is computed using equation (3.12) with $e^\omega = \frac{1}{\sin \sigma}$.
- (iiia) The contribution of the CFT on a torus of lengths d and b . Recall that we assume $b > d$ to project onto the vacuum for a holographic CFT. Under this assumption the partition function is the thermal partition function of a CFT on the circle of size $d = \pi + (2\pi\alpha)^{-1}b \log \frac{\beta_2}{\beta_1}$.
- (iiib) The CFT anomaly from Weyl transforming from the cylinder to the cone in the reservoir region with the Weyl factor given by (3.5).

Altogether we get

$$Z = Z_{(i)}Z_{(ii)}Z_{(iii)} = \exp \left(\underbrace{-\frac{\phi_r b^2}{4\pi} \left(\frac{1}{\beta_1} + \frac{1}{\beta_2} \right)}_{(i)} - \underbrace{\frac{cb}{24}}_{(ii)} + \underbrace{\frac{c}{6} \frac{b}{1 + \frac{b \log \frac{\beta_2}{\beta_1}}{2\pi^2 \alpha}}}_{(iiia)} + \underbrace{\frac{c\alpha}{12} \log \frac{\beta_2}{\beta_1}}_{(iiib)} \right). \quad (3.30)$$

Note that the contribution (i) is accompanied by a $1/\epsilon$ -divergence proportional to the length of AdS boundaries, which is identical to the $1/\epsilon$ -divergence that appeared in (3.23) in the disconnected phase and is removed in the same way. Note that the equation (3.29) can be reproduced by extremizing (3.30) over b .

The contribution (iiib) is the same between the two phases, and can hence be ignored in determining which phase is dominant. The phases are easy to compare in two limits for which the equation (3.29) has a simple solution. In the first limit we have (trading α for L_R)

$$L_R \ll \phi_r/c: \quad b \approx \frac{\beta_1 \beta_2 c \pi}{4\phi_r(\beta_1 + \beta_2)} \quad (3.31)$$

$$\implies Z_{WH} \approx \exp \left(\frac{\beta_1 \beta_2 c^2 \pi}{64\phi_r(\beta_1 + \beta_2)} + I_R \right), \quad Z_{BH} \approx \exp \left(2\phi_0 + \left(\frac{1}{\beta_1} + \frac{1}{\beta_2} \right) \pi \phi_r + I_R \right), \quad (3.32)$$

where $I_R = \frac{c}{24\pi} \frac{\beta_2 - \beta_1}{L_R} \log \frac{\beta_2}{\beta_1}$ is the contribution from the reservoir which is common for the two phases. Equating the two expressions, we find that the wormhole dominates for

$$\frac{\beta_1 \beta_2}{\beta_1 + \beta_2} \gtrsim \frac{128\phi_r \phi_0}{c^2 \pi}. \quad (3.33)$$

In the second limit we have

$$L_R \gg \phi_r/c: \quad b \approx \frac{\pi(\beta_2 - \beta_1)}{L_R \log \frac{\beta_2}{\beta_1}} \quad (3.34)$$

$$\implies Z_{WH} \approx \exp\left(\frac{c\pi(\beta_2 - \beta_1)}{24L_R \log \frac{\beta_2}{\beta_1}} + I_R\right), \quad Z_{BH} \approx \exp\left(2\phi_0 - \frac{\pi c L_R \log \frac{\beta_2}{\beta_1}}{6(\beta_2 - \beta_1)} + I_R\right). \quad (3.35)$$

Equating the two expressions, we find that the wormhole dominates for

$$\frac{\beta_2 - \beta_1}{\log \frac{\beta_2}{\beta_1}} \gtrsim \frac{48L_R \phi_0}{c\pi}. \quad (3.36)$$

Notice that in this limit it is sufficient to take β_2 large at any value of β_1 for the wormhole to dominate.

4 Page curves of two connected black holes

We can now analyze the structure of entanglement entropy in our model to ask when island configurations appear, and whether and how they compete with other quantum extremal surfaces to saturate the entropy.

A priori, we can study this question in either of the two phases discussed in the previous section. However, we will argue that the wormhole phase does not have any island saddles. First we show that, for a holographic theory, we have to be in the vacuum channel, i.e. in the doubly holographic picture the three-dimensional bulk filling in the torus is thermal AdS₃. To see this, if we were instead in the vacuum in the dual channel, i.e. the three-dimensional bulk filling in the torus being the BTZ black hole, this would imply a positive stress-energy tensor. Such a stress tensor would not consistently solve the equation of motion (2.4) with the boundary conditions needed for the dilaton. This is the familiar statement that we need a negative stress-energy to support the wormhole [36, 37].⁵ To complete the argument, note that in the vacuum channel the 2d entanglement entropy is $O(c)$ and constant for intervals in the bath and their thermofield double partners. Any nontrivial QES will come with a cost of ϕ_0 , which we assume to be much larger than the CFT central charge c . Hence the nontrivial QES will never dominate. In the rest of this section we therefore focus on the phase with two black holes.

4.1 The two black hole setup

We are interested in the temporal behavior of the entanglement entropy of the two thermofield double copies of a segment that includes some portion of radiation in the reservoir and may or may not include one of the quantum dots dual to black holes. The metric of the exterior regions of the black hole is given by the Lorentzian version of the solution (3.7)–(3.8). We rescale the coordinates in such a way that they are dimensionless and continuous

⁵The spacetime wormhole can be converted into an (eternally) traversable spatial wormhole by analytic continuation, e.g. in equation (3.25) continue $\chi \rightarrow it$.

Figure 8. The Penrose diagram for two eternal black holes with different inverse temperatures β_1, β_2 connected by two copies of the reservoir (shown by the shaded regions) with the conical metric (3.4). The arrows show the direction of the coordinate time in the external regions of the black holes. The diagram is identified across the dashed line which goes through the bifurcation surface of the second black hole.

across the pairs of exterior regions connected to their corresponding reservoirs. The metric in the external black hole region then reads:

$$ds_1^2 = \frac{-dt^2 + d\xi^2}{\sinh^2 \xi}; \quad \xi \in \left(-\infty, -\frac{2\pi}{\beta_1}\epsilon\right] \quad (4.1)$$

$$ds_2^2 = \frac{-dt^2 + d\xi^2}{\sinh^2(\xi - L)}; \quad \xi \in \left[L + \frac{2\pi}{\beta_2}\epsilon, +\infty\right), \quad (4.2)$$

and the reservoir metric is the Lorentzian continuation of the metric (3.4):

$$ds_R^2 = \frac{\beta_1^2}{4\pi^2} e^{\alpha\xi} \frac{-dt^2 + d\xi^2}{\epsilon^2}, \quad \xi \in \left[-\frac{2\pi}{\beta_1}\epsilon, L + \frac{2\pi}{\beta_2}\epsilon\right]. \quad (4.3)$$

Note that temperature dependence is now contained in the cutoffs for ξ . Thus the lengths of thermal circles on the boundaries in the Euclidean continuation of the metric are the same and are equal to $\beta_{1,2}/\epsilon$. The dilaton solution in these rescaled coordinates reads

$$\phi(\sigma)_1 = -\frac{2\pi}{\beta_1} \phi_r \coth(-\xi); \quad (4.4)$$

$$\phi(\sigma)_2 = \frac{2\pi}{\beta_2} \phi_r \coth(\xi - L). \quad (4.5)$$

In terms of the Schwarzschild-like coordinate t , the right side of the TFD evolves forward and the left side evolves backward, as indicated by arrows in figure 8. This setup generalizes the eternal black hole version of the information paradox discussed in [7, 8, 11] and in section 2 of the present paper to the case of two eternal black holes instead of one. Correspondingly, at late times we can expect islands to appear in both black hole regions. Similar models were considered in [11, 25, 26]. See [38, 39] for a discussion of entanglement between disjoint gravitating universes.

To compute the generalized entropy functional, we again assume that the matter CFT is holographic and dual to some asymptotically AdS₃ geometry, and we follow the approach explained in section 2.1. The CFT entanglement entropy can be computed by (2.11) using

Figure 9. We collect the radiation in the bold blue segments of radiation that include the boundary duals (quantum dots) of the second eternal black hole.

the conformal transformation to the plane from section 3.1. This transformation maps a pair of black hole exterior regions connected by a reservoir on the same side of the thermofield double (in Euclidean signature) to the complex w -plane with the conformally flat metric $\Omega^{-2}(w, \bar{w})dw d\bar{w}$, with the Weyl factor Ω in the three regions given by (3.17)–(3.18):

$$\text{Black hole 1 : } \quad \Omega_1 = \frac{1 - |w|^2}{2}; \quad (4.6)$$

$$\text{Black hole 2 : } \quad \Omega_2 = \frac{|w|^2 - \left(\frac{\beta_2}{\beta_1}\right)^{\frac{2}{\alpha}}}{2 \left(\frac{\beta_2}{\beta_1}\right)^{\frac{1}{\alpha}}}; \quad (4.7)$$

$$\text{Reservoir : } \quad \Omega_{\text{bath}} = \frac{2\pi}{\beta_1} |w|^{1-\alpha}. \quad (4.8)$$

Finally, to compute the area terms in the island formula (2.6) we need also the dilaton profile, which is given by equations (3.9)–(3.10).

4.2 Entanglement entropy of segments including the second black hole

We begin by treating the second black hole as a detector which collects the radiation from the first black hole. This detector also radiates back into the reservoir, at a rate which creates an equilibrium with the reservoir heat engine. The Hilbert space available to the black hole detector is finite, but nevertheless it is large enough to be comparable to the Hilbert space of the first black hole. This means that it should be able to gain access to the island.

In the microscopic description, we want to compute the entanglement entropy of a quantum dot and its thermofield double partner, plus some of their adjoining baths (figure 9). The coordinates of the reservoir endpoints in terms of the ξ, t variable are chosen as

$$p_2 = (a, -t + i\pi); \quad p_3 = (a, t). \quad (4.9)$$

In the two-dimensional effective gravitational description we need to search for QESs which extend the regions into the bulk, plus possible QESs in the other gravitational region which

Figure 10. Configurations of the RT geodesics extending into the 3d bulk which determine the competing generalized entropy channels with the second black hole included in the region being probed. The drawings are identified across the dashed line which goes through the bifurcation surface of the second black hole. Multiple-island configurations, which turn out to be always subleading, are not shown. For the connected configurations (a) and (b) the blue segments join across the bifurcation surface and the QES is empty surface.

bound islands. Three configurations⁶ can dominate the Page curve; they are shown in figure 10 (other configurations are subleading). As we assume the CFT is holographic, it is straightforward to identify the channels in the CFT entanglement entropy which define the competing generalized entropy functionals and quantum extremal island configurations.

Configuration (a): linear growth. This is a fully connected no-island configuration, with a trivial (empty) QES in the second black hole region. The endpoints $p_2 = (a, -t + i\pi)$ and $p_3 = (a, t)$ are connected by a geodesic in the 3D bulk. With this in mind, the entanglement entropy of the configuration (a) is given just by one geodesic shown in figure 10(a), and reads

$$\mathcal{S}_a = S_{\text{conn.}}^{\text{no island}}(p_2, p_3) = \frac{c}{3} \log \left(\frac{\beta_1 e^{\alpha a}}{\pi} \cosh t \right). \quad (4.10)$$

Configuration (b): the island. This is a fully connected configuration that includes an island in the first black hole region and an empty QES in the second black hole region. The location of the island $[q_1, q_2]$ is again defined by the QESs. Since the points p_2 and p_3 are located symmetrically with respect to the bifurcation surface of the first black hole, that means that the QES points will have the same coordinates $q_{1,2} = (x, t_x)$. The generalized entropy is

$$\mathcal{S}_b = \text{Ext}_{q_1} S_{\text{gen}}^{\text{island}}(q_1, p_2) + \text{Ext}_{q_2} S_{\text{gen}}^{\text{island}}(q_2, p_3), \quad (4.11)$$

where the generalized entropy functional reads

$$\begin{aligned} S_{\text{gen}}^{\text{island}}(q_2, p_3) &= \phi_0 + \frac{2\pi\phi_r}{\beta_1} \coth(-x) \\ &+ \frac{c}{6} \log \left(\frac{\beta_1 e^{\alpha a} (\cosh(x-a) - \cosh(t-t_x))}{\pi \sinh(-x)} \right). \end{aligned} \quad (4.12)$$

Extremizing t_x gives $t_x = t$, and so the island contribution is time-independent.

⁶We omit the usual UV divergences in the generalized entropy functionals and other formulae for the entanglement entropy as we did in section 2.

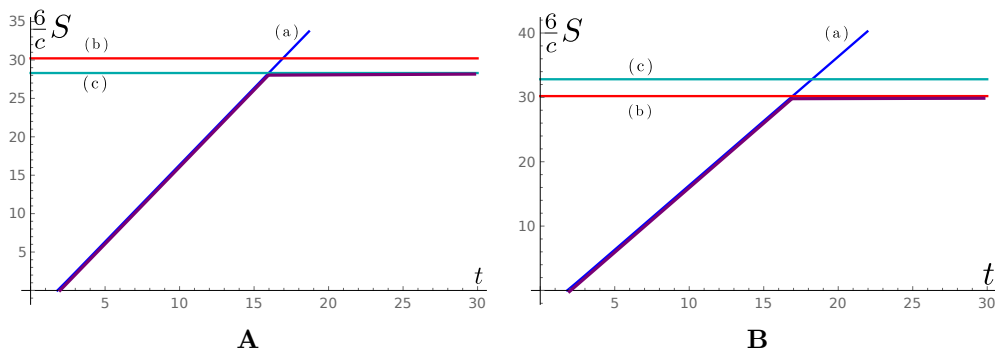

Figure 11. Page curves for the radiation segments plus the second black hole. We fix the physical reservoir size $L_R = 0.5$, physical location of $p_{2,3}$ endpoints $r = r_1 + 0.01L_R$, $\beta_1 = 1$, $\phi_0 = 10\frac{c}{6}$ and $\phi_r = \frac{c}{6}$. (A) $\beta_2 = 2$. The no-island phase dominates at late times. (B) $\beta_2 = 1.3$. The island phase dominates at late times.

Configuration (c): disconnected QES configuration. This configuration corresponds to two times the entropy of the segment. The corresponding generalized entropy functional reads

$$S_{\text{gen}}(p_3, p_4) = \phi_0 + \frac{2\pi\phi_r}{\beta_2} \coth\left(y - \alpha^{-1} \log \frac{\beta_2}{\beta_1}\right) + \frac{c}{6} \log\left(\frac{2\beta_1 e^{\alpha a + y} \frac{\beta_2^{1/\alpha}}{\beta_1} [\cosh(y - a) - \cosh(t - t_y)]}{\pi \left(e^{2y} - \left(\frac{\beta_2}{\beta_1}\right)^{2/\alpha}\right)}\right), \quad (4.13)$$

where (y, t_y) are the coordinates of the QES p_4 . The total entropy in this configuration reads

$$\mathcal{S}_c = 2 \times \underset{p_4}{\text{Ext}} S_{\text{gen}}(p_3, p_4). \quad (4.14)$$

It is worth noting that for this configuration the QES points $p_{1,4}$ end up at finite distance between the AdS_2 boundary and the horizon in the corresponding external regions of the second black hole. This quantity is also time-independent.

4.2.1 Page curves

The possible behaviors in the case of the black hole detector involve a competition between the two phases of constant entanglement entropy at late times — namely, between configurations (b) and (c). Let us fix the physical size of the reservoir L_R . Then we can have a transition between (b) and (c) at late times if we vary the temperature ratio β_2/β_1 or the physical position of the points $p_{2,3}$ at the Rindler coordinate $r = \frac{\beta_1}{2\pi\alpha} e^{\alpha a}$. We show this transition in figure 11 for the case when we vary the temperature of the “detector” β_2 while keeping r fixed. We see that adjusting this temperature can reveal the island of the first black hole. A similar results were obtained in [23, 26].

This transition has a simple interpretation, if we think of the island configuration (b) as the entanglement entropy of the first black hole plus the segments $[0, a]$. It competes against configuration (c), which is the entropy of the second black hole plus segments $[a, L]$.

Figure 12. We consider the radiation in the bold blue segments of the reservoir.

Then the island of the first black hole reveals itself if the entropy of the first black hole becomes smaller than the entanglement entropy of the probed system (which includes the second black hole and the radiation segment $[a, L]$). This means that this system, which we can think of as a detector, has enough room to effectively accommodate all states of the radiation. If the detector’s entropy is not large enough, however, it effectively thermalizes before gaining access to the island, which is expressed by the phase (c). In other words, the no-island phase 9(c) and the island phase 9(b) can be interpreted, respectively, as the island phase and the no-island phase of the computation of entanglement entropy of the complementary subsystem. Note that the key property in the evolution of the entanglement entropy of radiation regions which include one of the black holes is that the Hilbert space of the radiation is large. Because of this, there are no finite size effects that would introduce an intermediate phase into the Page curve for any choice of parameters, as we saw in the case of a single black hole in section 2. Below, we exclude both black holes from the radiation region, so that the radiation segment belongs to the interior of the reservoir only. We will then see that the Page curve structure becomes richer.

4.3 Entanglement entropy of segments in reservoir

We compute the entanglement entropy of the union of two identical segments $A = [p_1, p_2] \cup [p_3, p_4]$ positioned inside corresponding copies of the reservoir, as shown in figure 12. The coordinates of these endpoints are chosen as:

$$p_1 = (b, -t + i\pi); \quad p_2 = (a, -t + i\pi); \quad p_3 = (a, t); \quad p_4 = (b, t). \quad (4.15)$$

We now have 5 possible generalized entropy configurations which can dominate, shown in figure 13.

Configuration (a): linear growth. This is a fully connected no-island configuration, where two RT geodesics connect the endpoints $p_1 \leftrightarrow p_4$ and $p_2 \leftrightarrow p_3$, respectively. The entanglement entropy of this configuration is given by the formula

$$\mathcal{S}_a = S_{\text{conn.}}^{\text{no island}}(p_1, p_2; p_3, p_4) = 2\frac{c}{3} \log \left(\frac{\beta_1 e^{\frac{\alpha(a+b)}{2}}}{\pi} \cosh t \right). \quad (4.16)$$

This expression grows in time approximately linearly, and in the general case the entropy depends on the segment location when $\alpha \neq 0$.

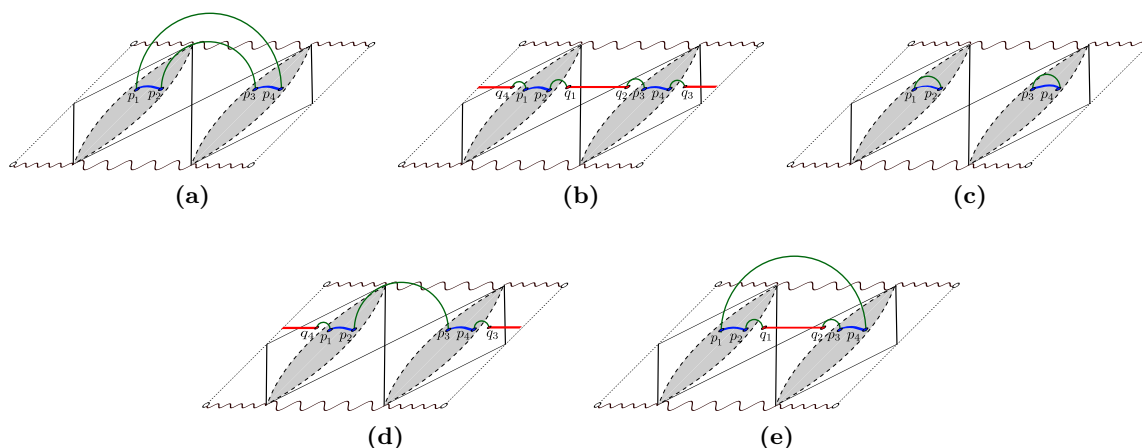

Figure 13. Configurations of the RT geodesics extending into the 3d bulk which determine the competing generalized entropy channels. The drawings are identified across the dashed line which goes through the bifurcation surface of the second black hole. Multiple-island configurations that are always subleading are not shown.

Configuration (b): two islands. This is a fully connected configuration that includes an island in every black hole region. The location of the islands $[q_{1,3}, q_{2,4}]$ is defined by the QESs, obtained by extremizing the generalized entropy functionals. These generalized entropy functionals are exactly the same ones as (4.12) for the island in the first black hole and (4.13) for the island in the second black hole. We write down the corresponding formulae for the QESs on the right side of the thermofield double, the points $q_2 = (x, t_x)$ and $q_3 = (y, t_y)$. The QESs q_1 and q_4 on the left are determined analogously.

$$S_{\text{gen}}^{\text{island}}(q_2, p_3) = \phi_0 + \frac{2\pi\phi_r}{\beta_1} \coth(-x) + \frac{c}{6} \log \left(\frac{\beta_1 e^{\alpha a} (\cosh(x-a) - \cosh(t-t_x))}{\pi \sinh(-x)} \right); \quad (4.17)$$

$$S_{\text{gen}}^{\text{island}}(q_3, p_4) = \phi_0 + \frac{2\pi\phi_r}{\beta_2} \coth \left(y - \alpha^{-1} \log \frac{\beta_2}{\beta_1} \right) + \frac{c}{6} \log \left(\frac{2\beta_1 e^{\alpha b + y} \frac{\beta_2}{\beta_1}^{1/\alpha} [\cosh(y-b) - \cosh(t-t_y)]}{\pi \left(e^y - \left(\frac{\beta_2}{\beta_1} \right)^{2/\alpha} \right)} \right). \quad (4.18)$$

The total entropy in this configuration is given by the sum of the two island contributions, or four quantum extremal surfaces:

$$\mathcal{S}_b = \text{Ext}_{q_2} S_{\text{gen}}^{\text{island}}(q_2, p_3) + \text{Ext}_{q_3} S_{\text{gen}}^{\text{island}}(q_3, p_4) + \text{Ext}_{q_4} S_{\text{gen}}^{\text{island}}(q_4, p_1) + \text{Ext}_{q_1} S_{\text{gen}}^{\text{island}}(q_1, p_2). \quad (4.19)$$

The two-island contribution is time-independent, and $t_x = t_y = t$.

Configuration (c): generalized thermalization. This is a disconnected configuration, which is the sum of the CFT entanglement entropy for the two thermofield double

copies of the reservoir segment. The entanglement entropy of a copy is given by the formula

$$S_{\text{disc.}}(p_1, p_2) = \frac{c}{3} \log \left(\frac{\beta_1 e^{\alpha(a+b)}}{\pi} \sinh \frac{|a-b|}{2} \right). \quad (4.20)$$

This configuration can be interpreted as describing the extension of the notion of thermalization to the case of the varying temperature. The entropy of the segment on the left of TFD $[p_3, p_4]$ is given by an analogous formula, and the total entropy in this configuration is given by

$$\mathcal{S}_c = S_{\text{disc.}}(p_1, p_2) + S_{\text{disc.}}(p_3, p_4). \quad (4.21)$$

Configurations (d) and (e): single island. In these configurations we have an island in one of the black holes while the other black hole still produces linear growth:

$$\mathcal{S}_d = \text{E}_{q_4}^{\text{Ext}} S_{\text{gen}}^{\text{island}}(q_4, p_1) + \text{E}_{q_3}^{\text{Ext}} S_{\text{gen}}^{\text{island}}(q_3, p_4) + \frac{c}{3} \log \left(\frac{\beta_1 e^{a\alpha}}{\pi} \cosh t \right); \quad (4.22)$$

$$\mathcal{S}_e = \text{E}_{q_1}^{\text{Ext}} S_{\text{gen}}^{\text{island}}(q_1, p_2) + \text{E}_{q_2}^{\text{Ext}} S_{\text{gen}}^{\text{island}}(q_2, p_3) + \frac{c}{3} \log \left(\frac{\beta_1 e^{ab}}{\pi} \cosh t \right). \quad (4.23)$$

These expressions grow linearly with half the slope of configuration (a).

Let us note that there are also configurations that have two islands in black hole regions, similarly to the case (d) in section 2 (see figure 2). Just as in that case of a single eternal black hole, such configurations are always subleading, so we do not consider them.

4.3.1 Page curves

We have four qualitatively different possibilities for the Page curve, which are determined by the competition between the two-island phase (b) and the disconnected phase (c) at very late times, and by the possibility of one of the two single-island phases (d) or (e) dominating for a finite time between the early and very late times.

First, let us consider the equal-temperature case, which is achieved in the limit $\alpha \rightarrow 0$, $\frac{\beta_2}{\beta_1} \rightarrow 1$ with $L = 2\pi L_R/\beta$ fixed. The four qualitatively different Page curves are shown in figure 14. More specifically, we plot the contributions of the five phases (a)–(e) described above.

- In figure 14A the linear growth generated by the connected no-island phase (a) transitions into the two-island phase (b), which keeps the entanglement entropy constant. The segment is large enough so that the island phase saturates the entanglement entropy before the disconnected phase (c) has a chance to become relevant.
- In figure 14B the connected phase (a) also dominates at early time, but because of the de-centered position of the segment in the reservoir, at some time the transition to the mixed phase (e) happens. This phase has an island in the first black hole but continues to grow linearly with halved slope due to the active remaining ER bridge across the second black hole. At later times, another transition happens, where the entanglement entropy is completely saturated by the two-island phase. Thus, the single-island phase persists only for finite time.

Figure 14. Page curves for the radiation segments in the reservoir in the equal temperature case with $\beta_1 = \beta_2 = 1$. (A) $a = 0.12L$, $b = 0.88L$. (B) $a = 0.02L$, $b = 0.78L$. (C) $a = 0.24L$, $b = 0.76L$. (D) $a = 0.04L$, $b = 0.52L$. We have set $\frac{c}{6}\phi_0 = 20$ and $\frac{\pi\phi_r}{3} = 10$.

- In figure 14C, the segment is small enough so that the entanglement entropy is saturated by the disconnected phase (c) before any islands get involved.
- In figure 14D, the early-time growth (a) transitions into the mixed phase (e) with slower growth and an island in one of the black holes. However, later the entanglement entropy is saturated by the disconnected phase (c) again, so the island is no longer accessible. Thus, this behavior only allows for temporary access to an island.

When the temperatures are different, $\beta_1 \neq \beta_2$, the qualitative behavior is the same. The main difference is that now temporary single-island phases are possible even for segments centered in the reservoir, because there is an additional non-uniform contribution in the entanglement entropy arising from the heat engine, which is represented, e.g., by the second term in (4.20). Because of this, a Page curve for any fixed pair of segments can include a temporary single island phase if we adjust the temperature difference and/or the reservoir size and positions of endpoints of A .

By utilizing the unitarity bound $S(A) \leq \min\{\log \dim \mathcal{H}_A, \log \dim \mathcal{H}_{\bar{A}}\}$ discussed in section 1 and applied at the end of section 2, the qualitative nature of these transitions can be predicted. In our setting, both $\dim \mathcal{H}_A$ and $\dim \mathcal{H}_{\bar{A}}$ are finite, and so these Hilbert spaces enforce distinct unitarity bounds. When the former is threatened, there is a thermalization transition (c), whereas when the latter is threatened, we are led to the two-island phase (b). There is also the possibility of transition to one-island phases (d) or (e), which have growing entropy and therefore are not explained by the simple unitarity bound. As in section 2,

this case can be explained by a unitarity bound applied to the two gravitational regions (plus the adjoining baths up to the radiation region A) separately. When the entropy of this region approaches the entropy of the two black holes in the given gravitational region $2S_{BH}$, a transition must occur.

5 Discussion

We have investigated the effects of competition between the thermalization mechanism and the island information recovery mechanism in the time evolution of entanglement entropy of Hawking radiation. We considered finite radiation regions in the classic example of a thermofield double black hole coupled to two semi-infinite baths. We also introduced a new model, where we have two pairs of thermofield double black holes at different temperatures radiating into a finite shared bath (and its thermofield double). To maintain equilibrium this required a Rindler-like bath which operated as a heat engine equilibrating the two sides. A summary of our results can be found in section 1.

The two-temperature system provides a tunable parameter which models thermal loss from engineered quantum dots in the lab, such as the SYK system. In relation to this, it should also be possible to write down an explicit coupling between two SYK systems at different temperatures leading to asymmetric wormholes, generalizing the Maldacena-Qi solution [36].⁷

It would be interesting to study the generalization of our two-temperature model to higher dimensions. In two dimensions we saw that we can have transitions from the asymmetric wormhole (the “confined” phase) to two thermofield double black holes (the “deconfined” phase). In higher dimensions, by picking the bath and boundary CFTs appropriately, one can more cleanly probe the confining structure of the model as the temperatures are varied through an order parameter like center symmetry [43], which does not have much meaning in $(0+1)$ dimensions. In the two-temperature model considered in this paper, the fate of one of the thermofield double quantum dots was tied to the other one, since the confining phase was a gravitational solution which linked the two systems. In higher dimensions, however, the confining phase of a single thermofield double boundary pair is two copies of thermal AdS, and it need not link to the other thermofield double. Thus we can have one of the thermofield double boundary pairs in the confined phase while the other pair is in the deconfined phase. It would be interesting to work out whether this actually occurs, and, if so, what the doubly holographic solution looks like; it would need to have nontrivial topology to accommodate the change from confined to deconfined phases.

The computations of entanglement entropy in the black hole phase would also take on a different structure in higher dimensions. The closest analogy to our results would be obtained by taking the bath CFT $_d$ to be placed on \mathbb{R}^d and considering infinite strips,

⁷There are avatars of the asymmetric wormhole in contexts where it is not the leading saddle of a path integral; for example in the matrix model description of JT gravity [40, 41] it is an off-shell configuration captured by $\langle Z(\beta_1)Z(\beta_2) \rangle$, while in systems with multiple uncoupled SYK dots there may exist subleading saddles which link the various systems (such subleading saddles have been exhibited for the case of equal temperatures in [42]).

which would allow the “halfway” surfaces seen in two dimensions, as in figure 2(b). Such surfaces would not appear for compact regions. One way to see this is to note that in figure 2(b) the two endpoints of an interval are treated differently, which would not work for the boundary of a higher-dimensional ball, which is connected.

ABSTRACT: We construct integrable deformations of the λ -type for asymmetrically gauged WZW models. This is achieved by a modification of the Sfetsos gauging procedure to account for a possible automorphism that is allowed in G/G models. We verify classical integrability, derive the one-loop beta function for the deformation parameter and give the construction of integrable D-brane configurations in these models. As an application, we detail the case of the λ -deformation of the cigar geometry corresponding to the axial gauged $SL(2, R)/U(1)$ theory at large k . Here we also exhibit a range of both A-type and B-type integrability preserving D-brane configurations.

1 Introduction

Since the observation of worldsheet integrability in the $AdS_5 \times S^5$ superstring [1], integrable two-dimensional non-linear sigma-models have played a prominent role in the gauge-gravity correspondence. In the planar limit in particular, the simplicity offered by integrability allows one to go beyond perturbation theory and interpolate at finite 't Hooft coupling between known results at both sides of the correspondence (for a review see [2, 3]).

For the purpose of the present paper, we are interested in the application of bosonic integrable sigma models as building blocks of worldsheet theories¹ describing strings propagating in curved backgrounds. Well known examples in this context are the Wess-Zumino-Witten (WZW) model [4], which has an exact worldsheet CFT formulation, and the Principal Chiral Model (PCM) [5], which has worldsheet integrability, on a non-Abelian group manifold. Closely related are the gauged WZW model and the Symmetric Space Sigma Model (SSSM) which can be obtained by gauging an appropriate subgroup of the global symmetry group. These gauged theories retain some desirable properties; the gauged WZW model gives a Lagrangian description of coset CFT's [6, 7] and the SSSM retains integrability [8]. Both provide highly symmetrical target spaces which have been key in the construction of amenable string duals.

¹When supplemented with a fermionic field content, as in a Green-Schwarz formulation for instance, they should describe consistent string configurations.

An interesting question in recent years has been to deform known holographic theories while maintaining worldsheet integrability.² Prominent examples include the η - [10–12], β - [9, 13, 14]³ and λ -deformations [16–18]. Our focus will be on the λ -deformation which is an integrable two-dimensional QFT for all values $\lambda \in [0, 1]$. For $\lambda \rightarrow 0$ the model traces back to the WZW model (or gauged WZW model) while for $\lambda \rightarrow 1$ one finds the non-Abelian T-dual of the PCM (or SSSM). There has been significant evidence from both a worldsheet [18, 19] and target space [20–22] perspective that, when applied to supercoset geometries, the λ -model is a marginal deformation introducing no Weyl anomaly. In [23, 24] it was also shown one can promote bosonic coset λ -models to type IIB supergravity backgrounds when a suitable ansatz is made for the RR fields.

We will focus our attention here on bosonic coset λ -deformations of G/H gauged WZW models. A limitation to the standard construction so far is that it is deforming WZW models where only the vector subgroup is gauged [16, 17]. When the subgroup H is Abelian, however, gauging an axial action in the WZW leads to a topologically distinct target space [25, 26]. For H non-Abelian, particular asymmetrical gaugings can be of interest in the case of higher rank groups [25, 27]. The present note will fill this gap by deforming spacetimes obtained from asymmetrically gauged WZW models on a general footing.⁴

A physical motivation of this line of study is the two-dimensional Euclidean black hole in string theory [31–33] corresponding to the $SL(2, R)/U(1)_k$ WZW model [31, 34]. When the gauged $U(1)$ is compact and vector one obtains the so-called trumpet geometry, while for an axial gauging one finds the so-called cigar.⁵ Analytical continuation of the Euclidean time gives the Minkowskian black hole where the trumpet corresponds to the region within the singularity and the cigar to the region outside the horizon [31, 37]. In particular the cigar approaches asymptotically a flat space cylinder while the tip describes the horizon itself. These regions are known to be T-dual [37–40] to the \mathbb{Z}_k orbifold of one another and are indeed described by an equivalent coset CFT [37].

The stringy origin of a black hole horizon has been an attractive asset for the study of the axial $SL(2, R)/U(1)_k$ WZW. In two target space dimensions the only low energy closed string modes are tachyons winding around the periodic direction of the cigar. However, when these states enter the region of the horizon at the tip, winding number conservation breaks, leading to the existence of a tachyonic condensate in that region. This has been understood in [41] using the (bosonic) FZZ duality [41–43] between the cigar geometry and Sine-Liouville theory where the latter is an interacting theory in a flat space cylinder geometry. Here it is an exponentially growing potential that breaks winding conservation explicitly and only allows high momentum tachyon modes to penetrate through the dual

²One ambition here is to have gravity duals that reduce the amount of (super)symmetries on the gauge theory side as in e.g. [9].

³See also the recent [15] and references therein.

⁴Similar ideas of an asymmetric deformation have been developed in [28, 29] where a tensor product of coset manifolds is considered with either different levels or an asymmetrical gauging between the tensor product terms (see also the recently appeared [30]). The novelty of our approach includes deforming an asymmetric gauging of one factor in the tensor product.

⁵These backgrounds are only valid for large k , receiving (quantum) corrections for finite k [35, 36].

of the region behind the horizon [44]. The machinery developed in this note allows one to study the effects of the λ -deformation to the cigar geometry and the Sine-Liouville potential explicitly. At this point the interested reader might be enticed by the success of integrability in going beyond perturbation theory to study quantum gravity effects associated to the horizon. Moreover, using the large N matrix model description of the cigar through Sine-Liouville theory [41], this particular application opens the route to a tractable interpretation of the integrable λ -deformations in holography.

In section 2 we develop the λ -deformation of the asymmetrically gauged WZW model. We show that the model is classically integrable and that, when the asymmetrical gauging respects the symmetric space decomposition,⁶ the one-loop beta function of the λ -parameter match those obtained in the case of symmetric gaugings. We conclude this section by describing integrable boundary conditions of the worldsheet theory where we develop the method of [45] to accommodate for coset spaces and asymmetric gaugings.

We then briefly introduce the $SL(2, R)/U(1)_k$ WZW and apply the λ -deformation to the cigar geometry⁷ in section 3. To first order we will see the deformation to explicitly break the axial-vector duality of the undeformed case. The analysis of our method for the integrable boundary conditions, however, shows the D-brane configurations of [46–50] to persist the deformation albeit with isometries being lost. We find D1-branes extending to asymptotic infinity, but allowed only at particular angles in the deformed cigar, D0-branes at the tip and D2-branes covering the whole or part of the space. In the undeformed case these branes are distinguished, in the nomenclature of [51], as the former being of A-type, while the latter two being of B-type. Finally, after a small review on FZZ duality, we give the starting point to the study of a deformed Sine-Liouville theory by extracting the first order perturbation.

We conclude in section 4 with a short summary and outlook of our results.

2 Left-right asymmetrical λ -deformations

In this section we generalise the construction of λ -deformations of symmetric coset manifolds G/H developed in [16–18] to incorporate the possibility of deforming the left-right asymmetrical gauged WZW model [25, 27].

This *asymmetric* coset λ -deformation is constructed in a number of steps based on the Sfetsos gauging procedure [16]. First one combines⁸ the Wess-Zumino-Witten (WZW) model [4] on a group manifold G ,

$$S_{\text{WZW},k}(g) = -\frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau \langle g^{-1} \partial_+ g, g^{-1} \partial_- g \rangle - \frac{k}{24\pi} \int_{M_3} \langle \bar{g}^{-1} d\bar{g}, [\bar{g}^{-1} d\bar{g}, \bar{g}^{-1} d\bar{g}] \rangle, \quad (2.1)$$

⁶It seems only a technical issue to relax this requirement.

⁷Although the region of the deformed cigar geometry was captured globally in [23] and can be obtained from analytical continuations of the $SU(2)/U(1)$ case of [16], the methodology developed here is more fundamental and, moreover, applicable to a wide range of models.

⁸For a summary of our conventions and more details on the WZW and SSSM we refer the reader to the appendix A.

with the Symmetric Space Sigma Model (SSSM) on G/H ,

$$S_{\text{SSSM}, \kappa^2}(\hat{g}, B_{\pm}) = -\frac{\kappa^2}{\pi} \int d\sigma d\tau \langle (\hat{g}^{-1} \partial_+ \hat{g} - B_+), (\hat{g}^{-1} \partial_- \hat{g} - B_-) \rangle, \quad (2.2)$$

where the latter is invariant under an $H_R \subset G$ action $\hat{g} \rightarrow \hat{g}h$ with $h \in H$ when the gauge fields $B_{\pm} \in \mathfrak{h}$ transform as $B_{\pm} \rightarrow h^{-1}(B_{\pm} + \partial_{\pm})h$. Note that these models are realised through distinct group elements $g \in G$ and $\hat{g} \in G$ respectively which we assume to be connected to the identity. Next, we reduce back to $\dim G - \dim H$ degrees of freedom by gauging simultaneously the left-right asymmetric G -action in the WZW model (generalising the usual λ -model construction [16–18] where the vector action is gauged) and the G_L -action in the SSSM given by,

$$\begin{aligned} g &\rightarrow g_0^{-1} g \tilde{g}_0, \\ \hat{g} &\rightarrow g_0^{-1} \hat{g}. \end{aligned} \quad (2.3)$$

Here $g_0 = \exp(G^A T_A) \in G$ and $\tilde{g}_0 = \exp(G^A \tilde{T}_A) \in G$ have the same parameters G^A but are generated by different embeddings T_A and \tilde{T}_A of a representation of the Lie algebra \mathfrak{g} of G . Their relation can be packaged into an object W as $\tilde{T}_A = W(T_A) = W^B{}_A T_B$. To find a gauge-invariant action we introduce the gauge fields $A_{\pm} = A_{\pm}^A T_A$ transforming as,

$$A_{\pm} \rightarrow g_0^{-1} (A_{\pm} - \partial_{\pm}) g_0, \quad W(A_{\pm}) \rightarrow \tilde{g}_0^{-1} (W(A_{\pm}) - \partial_{\pm}) \tilde{g}_0, \quad (2.4)$$

and we perform the usual minimal substitution (i.e. replacing derivatives by $\partial_{\pm} \cdot - A_{\pm} \cdot$) in the SSSM term and replace the WZW term by the left-right asymmetrical gauged WZW model⁹ [25, 27] on the coset G/G_{AS} given by,

$$\begin{aligned} S_{\text{WZW}, k}(g, A_{\pm}^A, W) &= S_{\text{WZW}, k}(g) + \frac{k}{\pi} \int_{\Sigma} d\sigma d\tau \langle A_-, \partial_+ g g^{-1} \rangle - \langle W(A_+), g^{-1} \partial_- g \rangle \\ &+ \langle A_-, g W(A_+) g^{-1} \rangle - \frac{1}{2} \langle A_-, A_+ \rangle - \frac{1}{2} \langle W(A_-), W(A_+) \rangle. \end{aligned} \quad (2.5)$$

The latter is gauge-invariant¹⁰ provided that $W : \mathfrak{g} \rightarrow \mathfrak{g}$ is a metric-preserving automorphism of the Lie algebra \mathfrak{g} [25, 27] i.e.,

$$W([T_A, T_B]) = [W(T_A), W(T_B)] \quad \text{and} \quad \langle W(T_A), W(T_B) \rangle = \langle T_A, T_B \rangle. \quad (2.6)$$

Finally, one can fix the gauge symmetry by setting $\hat{g} = \mathbf{1}$, which allows one to integrate out the gauge fields B_{\pm} easily. The result is a generalised version¹¹ of the λ -deformed gauged

⁹In the following, we will abbreviate the left-right asymmetrical gauged WZW model with G/H_{AS} WZW when the subgroup $H \subset G$ is gauged.

¹⁰The invariance under the gauge transformations (2.3) can be easily checked when rewriting the action (2.5) using the Polyakov-Wiegmann identity [52], which in our conventions takes the form,

$$S_{\text{WZW}, k}(g_1 g_2) = S_{\text{WZW}, k}(g_1) + S_{\text{WZW}, k}(g_2) - \frac{k}{\pi} \int d\sigma d\tau \langle g_1^{-1} \partial_- g_1, \partial_+ g_2 g_2^{-1} \rangle,$$

for $g_1, g_2 \in G$. One obtains $S_{\text{WZW}, k}(g, A_{\pm}^A, W) = S_{\text{WZW}, k}(g_L^{-1} g \tilde{g}_R) - S_{\text{WZW}, k}(g_L^{-1} g_R)$, where $g_{L,R} \in G$ and one identifies $A_+ = \partial_+ g_R g_R^{-1}$ and $A_- = \partial_- g_L g_L^{-1}$. The gauge transformations are given by $g \rightarrow g_0^{-1} g \tilde{g}_0$ and $g_{L,R} \rightarrow g_0^{-1} g_{L,R}$.

¹¹When the automorphism $W = \mathbf{1}$ one finds the usual λ -model on the G/H coset [16, 17] which is deforming the *vectorially* gauged G/H_V WZW model.

WZW given by,

$$S_\lambda(g, A_\pm^A, W) = S_{\text{wzw},k}(g) + \frac{k}{\pi} \int d\sigma d\tau \langle A_-, \partial_+ g g^{-1} \rangle - \langle W(A_+), g^{-1} \partial_- g \rangle + \langle A_-, g W(A_+) g^{-1} \rangle - \langle A_+, \Omega(A_-) \rangle, \quad (2.7)$$

where we introduced the operator $\Omega(\mathfrak{g}) = \mathfrak{g}^{(0)} \oplus \frac{1}{\lambda} \mathfrak{g}^{(1)}$ with $\mathfrak{g}^{(0)} \equiv \mathfrak{h}$. The deformation parameter λ is defined as $\lambda = \frac{k}{\kappa^2 + k}$.

The action (2.7) still has a residual $\dim H$ left-right asymmetrical gauge symmetry inherited from the G/G_{AS} WZW model (2.5) which acts as,

$$g \rightarrow h^{-1} g \tilde{h}, \quad A_\pm^{(0)} \rightarrow h^{-1} \left(A_\pm^{(0)} - \partial_\pm \right) h, \quad A_\pm^{(1)} \rightarrow h^{-1} A_\pm^{(1)} h, \quad (2.8)$$

with $h = \exp(X)$, $\tilde{h} = \exp(W(X))$ connected to the identity and where $X \in \mathfrak{g}^{(0)}$. Consequently under the gauge transformation we have $W(A_\pm^{(0)}) \rightarrow \tilde{h}^{-1} (W(A_\pm^{(0)}) - \partial_\pm) \tilde{h}$ and $W(A_\pm^{(1)}) \rightarrow \tilde{h}^{-1} W(A_\pm^{(1)}) \tilde{h}$. This shows that the fields $A_\pm^{(0)}$ are still genuine (but non-propagating) gauge fields while the fields $A_\pm^{(1)}$ are auxiliary. Both can be integrated out, yielding the constraints,

$$A_+ = - (D_g W - \Omega)^{-1} \partial_+ g g^{-1}, \quad A_- = (D_{g^{-1}} - W \Omega)^{-1} g^{-1} \partial_- g. \quad (2.9)$$

Once the gauge fields are eliminated in favour of these equations, the resulting action is given by,

$$S_\lambda(g, W) = S_{\text{wzw},k}(g) + \frac{k}{\pi} \int d\sigma d\tau \langle \partial_+ g g^{-1}, (\mathbf{1} - D_g W \Omega)^{-1} \partial_- g g^{-1} \rangle, \quad (2.10)$$

accompanied with a non-constant dilaton profile, coming from the Gaussian integral over gauge fields, given by,

$$e^{-2\Phi} = e^{-2\Phi_0} \det(D_g W - \Omega), \quad (2.11)$$

with Φ_0 constant.

In the $\lambda \rightarrow 0$ limit one reproduces the G/H_{AS} WZW (i.e. the action (2.5) but with $A_\pm^{(1)} = 0$) which can be seen directly from the constraint equations. For small λ one finds, by integrating out the auxiliary fields $A_\pm^{(1)}$ in (2.7), the first order correction to the G/H_{AS} WZW to be,

$$S_\lambda(g, A_\pm^{(0)}, W) = S_{\text{wzw},k}(g, A_\pm^{(0)}, W) + \frac{\lambda}{\pi k} \int d\sigma d\tau \langle \mathcal{J}_+^{(1)}, W^{-1} \mathcal{J}_- \rangle + \mathcal{O}(\lambda^2), \quad (2.12)$$

where we introduced the Kac-Moody currents \mathcal{J}_\pm of the G/H_{AS} WZW¹² defined as

$$\mathcal{J}_+ = -k(\partial_+ g g^{-1} + g W(A_+^{(0)}) g^{-1} - A_-^{(0)}), \quad \mathcal{J}_- = k(g^{-1} \partial_- g - g^{-1} A_-^{(0)} g + W(A_+^{(0)})), \quad (2.13)$$

¹²Although we are not aware of an occurrence in the literature of these currents in the case of the G/H_{AS} WZW, they can be derived analogously to [53] showing that their Poisson brackets satisfy two commuting classical versions of a Kac-Moody algebra.

Hence, the perturbation term away from the CFT point is a particular coupling between these currents. Under the residual gauge transformation (2.8) the currents transform as,¹³

$$\mathcal{J}_+ \rightarrow h^{-1}\mathcal{J}_+h + kh^{-1}\partial_\sigma h, \quad \mathcal{J}_- \rightarrow \tilde{h}^{-1}\mathcal{J}_-\tilde{h} - kW(h^{-1}\partial_\sigma h), \quad (2.14)$$

so that the perturbation term is gauge invariant as is indeed required for consistency.

Another interesting limit to consider is the $\lambda \rightarrow 1$ scaling limit (sending $k \rightarrow \infty$) for which in the usual vectorial gauged case of [16] one reproduces the non-Abelian T-dual of the SSSM. This fact can be traced back to the property that the G/G_V WZW under the scaling limit reduces to a Langrange multiplier term. For the G/G_{AS} WZW (2.5) this is not true for general W which strongly suggests there is no interpretation of this limit as a non-Abelian T-dual.

The novelty of the constructed coset λ -model (2.7) is that it deforms the left-right asymmetrically gauged G/H_{AS} WZW model (2.5) instead of solely the vectorial gauged G/H_V WZW. As advertised, this will allow us to deform also target spaces obtained by an axial gauging when the subgroup H is abelian. However, even in the undeformed case, as noted in [27], not all W that satisfy the conditions (2.6) will produce interesting and novel spacetimes. Indeed, if W is an inner automorphism of the Lie algebra, where one can always find a constant $w \in G$ so that $W(T_A) = wT_Aw^{-1}$, the action (2.7) can be rewritten as,

$$S_\lambda(g, A_\pm^A, W) = S_\lambda(gw, A_\pm^A, \mathbf{1}), \quad (2.15)$$

where we used the $G_L \times G_R$ invariance of the WZW term. Hence, in this case only a trivial redefinition of the fields $g \in G$ to $gw \in G$ has been performed. Nevertheless, if $w \in G^{\mathbb{C}}$ or a different outer automorphism of the Lie algebra the generalisation is non-trivial as we will see later in section 3.

To conclude this section, we note that the construction as described above is also applicable to the group manifold and super-coset case. For the former one can perform the gauging procedure starting with a combination of a WZW and an ordinary PCM model on a Lie group G . The formulae in this section then continue to persist upon the redefinition $\Omega = \lambda^{-1}$. We believe this asymmetrical λ -model can have an interest for higher rank group manifolds allowing Dynkin outer automorphisms such as for instance when $G = \text{SU}(N)$, $N > 2$. Moreover, one can view this λ -model as one with a single but anisotropic coupling matrix $\lambda^{AB} = \lambda W^{AB}$ as discussed for instance in [29, 54]. In the super-coset case, where G is a Lie supergroup, the Sfetsos gauging procedure is not applicable anymore, but one can follow straightforwardly the construction of [18] and replace the G/G_V WZW with the G/G_{AS} WZW. The conditions on the automorphism W are analogous to (2.6) but here the inner product on the Lie supergroup will be taken to be the supertrace STr instead of an ordinary trace. When, moreover, the Lie superalgebra has a semi-symmetric space decomposition defined by a \mathbb{Z}_4 grading $\mathfrak{g} = \oplus_{i=0}^3 \mathfrak{g}^{(i)}$ where $\mathfrak{g}^{(0)} \equiv \mathfrak{h}$ and $[\mathfrak{g}^{(i)}, \mathfrak{g}^{(j)}] \subset \mathfrak{g}^{(i+j \bmod 4)}$, the formulae in this section are again similar upon the redefinition $\Omega(\mathfrak{g}) = \mathfrak{g}^{(0)} \oplus \lambda^{-1}\mathfrak{g}^{(1)} \oplus \lambda^{-2}\mathfrak{g}^{(2)} \oplus \lambda\mathfrak{g}^{(3)}$ and upon the usage of the supertrace. Note

¹³Note that the Kac-Moody currents \mathcal{J}_\pm are not Lorentz invariant by definition.

that, with respect to the supertrace, Ω is not symmetric anymore, so that the constraint equations (2.9) are however altered as,

$$\begin{aligned} A_+ &= -(D_g W - \Omega^T)^{-1} \partial_+ g g^{-1}, \\ A_- &= (D_{g^{-1}} - W \Omega)^{-1} g^{-1} \partial_- g, \end{aligned} \quad (2.16)$$

with $\Omega^T(\mathfrak{g}) = \mathfrak{g}^{(0)} \oplus \lambda \mathfrak{g}^{(1)} \oplus \lambda^{-2} \mathfrak{g}^{(2)} \oplus \lambda^{-1} \mathfrak{g}^{(3)}$.

2.1 Classical integrability

To check the integrability of the asymmetrical λ -model we follow the method of [17]¹⁴ starting from the action (2.7). As in the SSSM it is necessary here to assume the Lie algebra to have a symmetric space decomposition defined by $\mathfrak{g} = \mathfrak{g}^{(0)} \oplus \mathfrak{g}^{(1)}$, with $\mathfrak{g}^{(0)} \equiv \mathfrak{h}$, and a \mathbb{Z}_2 grading $[\mathfrak{g}^{(i)}, \mathfrak{g}^{(j)}] \subset \mathfrak{g}^{(i+j \bmod 2)}$.

The equations of motion of the group fields g can be written as,

$$[\partial_+ - W(A_+), \partial_- + g^{-1} \partial_- g - g^{-1} A_-] = 0, \quad (2.17)$$

or equivalently,

$$[\partial_+ - \partial_+ g g^{-1} - g W(A_+) g^{-1}, \partial_- - A_-] = 0. \quad (2.18)$$

Using the constraints (2.9) and W being a constant Lie algebra automorphism these can be rewritten as,

$$\begin{aligned} [\partial_+ - A_+, \partial_- - \Omega(A_-)] &= 0, \\ [\partial_+ - \Omega(A_+), \partial_- - A_-] &= 0. \end{aligned} \quad (2.19)$$

The above equations of motion can be represented through a $\mathfrak{g}^{\mathbb{C}}$ -valued Lax connection depending on a spectral parameter $z \in \mathbb{C}$ that satisfies a zero-curvature condition,

$$[\partial_+ + \mathcal{L}_+(z), \partial_- + \mathcal{L}_-(z)] = 0, \quad \forall z \in \mathbb{C}, \quad (2.20)$$

when it is given by,

$$\mathcal{L}_{\pm}(z) = -A_{\pm}^{(0)} - z^{\pm 1} \lambda^{-1/2} A_{\pm}^{(1)}. \quad (2.21)$$

This fact shows the left-right asymmetrical λ -theories on G/H manifolds to be classically integrable models [55] for general automorphisms W . These λ -models therefore supplement the list of [29] of integrable λ -models with a general single coupling matrix for $\lambda^{\alpha\beta} = \lambda W^{\alpha\beta}$ with W satisfying (2.6). Additionally, along similar lines, one can show integrability for the asymmetrical λ -model on group and super-coset manifolds for which the Lax connection will take the form,

$$\mathcal{L}_{\pm}(z) = -\frac{2}{1+\lambda} \frac{1}{1 \mp z} A_{\pm}, \quad (2.22)$$

and,

$$\mathcal{L}_{\pm}(z) = -A_{\pm}^{(0)} - z^{-1} \lambda^{\pm 1/2} A_{\pm}^{(1)} - z^{\pm 2} \lambda^{-1} A_{\pm}^{(2)} - z \lambda^{\mp 1/2} A_{\pm}^{(3)}, \quad (2.23)$$

respectively.

¹⁴Note that to translate to [17] one should identify the group fields as $g = \mathcal{F}^{-1}$. The method of [17] consists of relating the equations of motions of the fields in the λ -model to the equations of motions of the SSSM for which the Lax pair is known.

2.2 One-loop beta functions

To compute the one-loop beta functions of the λ -parameter of the above asymmetrically deformed theories, we follow the method of [19], but see also [56, 57] for possibly different approaches. The authors of [19] consider fluctuations around a background field for the currents rather than the fundamental field g and applied the background field approach to the PCM and the SSSM. They efficiently generalise their results to the usual λ -deformed theories on group or (super)-coset manifolds by identifying the appropriate fields such that the classical equations of motion take an identical form to those of the PCM or SSSM models respectively. With minor adjustments we can follow the same path here.

To begin we choose for the group valued field g the same background as [19], namely,

$$g = \exp(\sigma^+ \Lambda_+ + \sigma^- \Lambda_-), \quad (2.24)$$

with Λ_{\pm} constant commuting elements of $\mathfrak{g}^{(1)}$. Hence, on the background we have $\partial_{\pm} g g^{-1} = g^{-1} \partial_{\pm} g = \Lambda_{\pm}$. Through the constraints (2.9) the background of the gauge fields A_{\pm} then becomes,

$$A_+^{bg} = (\Omega - W)^{-1} \Lambda_+, \quad A_-^{bg} = (\mathbf{1} - W\Omega)^{-1} \Lambda_-, \quad (2.25)$$

and, after passing to Euclidean signature, the tree-level contribution of the asymmetrical λ -model Lagrangian (2.7) on the background (2.24), (2.25) evaluates simply to,

$$L^0(\lambda) = \frac{k}{2\pi} \langle \Lambda_+, (W\Omega + \mathbf{1})(W\Omega - \mathbf{1})^{-1} \Lambda_- \rangle. \quad (2.26)$$

To compute the one-loop contribution one introduces a fluctuation around the background and integrates it out in the path integral by a saddle point approximation. Doing so, one needs to calculate the functional determinant of the operator that describes the equations of motion of the fluctuation. Rather than carrying this out directly on the λ -model it is useful to observe that their equations of motion can be identified with those of the SSSM (2.2) where the computation is easier and described in detail in [19].

To see this, let us consider the SSSM (2.2) and define for now $\widehat{L}_{\pm} = \widehat{g}^{-1} \partial_{\pm} \widehat{g} - B_{\pm}$. The equations of motion of the gauge field B_{\pm} take the form of a constraint equation,

$$\widehat{L}_{\pm}^{(0)} = 0. \quad (2.27)$$

Subjected to this constraint, the equations of motion and the Maurer-Cartan identity of the group-valued field $\widehat{g} \in G$ become, projected onto $\mathfrak{g}^{(0)}$ and $\mathfrak{g}^{(1)}$,

$$\begin{aligned} \partial_{\pm} \widehat{L}_{\mp}^{(1)} + [B_{\pm}, \widehat{L}_{\mp}^{(1)}] &= 0, \\ \partial_+ B_- - \partial_- B_+ + [B_+, B_-] + [\widehat{L}_+^{(1)}, \widehat{L}_-^{(1)}] &= 0. \end{aligned} \quad (2.28)$$

One can, moreover, fix the gauge by a covariant gauge choice,

$$\partial_+ B_- + \partial_- B_+ = 0. \quad (2.29)$$

The equations of motion (2.28) can be recast in terms of a flat Lax connection $\mathcal{L}(z)$,

$$\mathcal{L}_{\pm}(z) = B_{\pm} + z^{\pm 1} \widehat{L}_{\pm}^{(1)}, \quad (2.30)$$

satisfying $[\partial_+ + \mathcal{L}_+(z), \partial_- + \mathcal{L}_-(z)] = 0$ for all $z \in \mathbb{C}$ and ensuring the classical integrability of the SSSM. The SSSM Lax connection then indeed takes an identical form to the Lax (2.21) of the λ -deformed theory if we identify,

$$B_{\pm} = -A_{\pm}^{(0)}, \quad \widehat{L}_{\pm}^{(1)} = -\lambda^{-1/2} A_{\pm}^{(1)}, \quad (2.31)$$

where the fields A_{\pm} satisfy the constraints (2.9).

For the one-loop contribution we can now proceed with the SSSM as in section 2.2 of [19] and subject the result to the identification (2.31). Let us denote the background fields for the gauge field B_{\pm} and the current $\widehat{L}_{\pm}^{(1)}$ by B_{\pm}^{bg} and Θ_{\pm} respectively, so that,

$$\begin{aligned} B_{\pm}^{bg} &= 0, \\ \Theta_+ &= -\lambda^{-1/2}(\Omega - W)^{-1}\Lambda_+, \quad \Theta_- = -\lambda^{-1/2}(\mathbf{1} - W\Omega)^{-1}\Lambda_-, \end{aligned} \quad (2.32)$$

where we assumed that W respects the \mathbb{Z}_2 -grading of $\mathfrak{g} = \mathfrak{g}^{(0)} \oplus \mathfrak{g}^{(1)}$ (as will be the case for the vector or axial deformed cases of section 3).¹⁵ Varying the equations of motion (2.28) and the covariant gauge fixing (2.29) the operator that governs the fluctuations can be found, after Fourier transforming to momentum space, to be,

$$\mathcal{D} = \begin{pmatrix} p_- & 0 & 0 & -\Theta_+^{\text{adj}} \\ 0 & p_+ & -\Theta_-^{\text{adj}} & 0 \\ -\Theta_-^{\text{adj}} & \Theta_+^{\text{adj}} & -p_- & p_+ \\ 0 & 0 & p_- & p_+ \end{pmatrix}, \quad (2.33)$$

acting on the fluctuations in the order $(\delta\widehat{L}_+^{(1)}, \delta\widehat{L}_-^{(1)}, \delta B_+, \delta B_-)$. Here we have $(\Theta_{\pm}^{\text{adj}})_B{}^C = \Theta_{\pm}^A (T_A^{\text{adj}})_B{}^C = i\Theta_{\pm}^A F_{AB}{}^C$. The one-loop contribution to the Lagrangian,

$$L^1(\lambda) = \frac{1}{2} \int^{\mu} \frac{d^2 p}{(2\pi)^2} \text{Tr} \log \mathcal{D}, \quad (2.34)$$

will have a logarithmic divergence given by [19],

$$L^1(\lambda) = -\frac{c_2(G)}{2\pi} \langle \Theta_+, \Theta_- \rangle \log \mu + \dots \quad (2.35)$$

where $c_2(G) \equiv x_{\text{adj}}$ is the index of the adjoint representation. Substituting (2.32) and using the property (2.6) that W preserves the Lie algebra metric we find,

$$L^1(\lambda) = \frac{c_2(G)}{2\pi} \frac{1}{\lambda} \langle \Lambda_+, (W\Omega - \mathbf{1})^{-1} W (W\Omega - \mathbf{1})^{-1} \Lambda_- \rangle \log \mu + \dots \quad (2.36)$$

The one-loop beta function of the λ -parameter then follows from demanding that the one-loop effective Lagrangian $L(\lambda) = L^0(\lambda) + L^1(\lambda)$ is independent of the scale μ ,

$$\mu \partial_{\mu} \left[k \langle \Lambda_+, \left(\frac{W\Omega + 1}{W\Omega - 1} \right) \Lambda_- \rangle + \frac{c_2(G)}{\lambda} \langle \Lambda_+, (W\Omega - 1)^{-1} W (W\Omega - 1)^{-1} \Lambda_- \rangle \log \mu \right] = 0, \quad (2.37)$$

¹⁵When W does not respect the \mathbb{Z}_2 -grading one will generate non-zero background fields for the gauge fields B_{\pm} and the calculation of [19] is not directly applicable anymore. In this case it seems that one needs to choose a different but appropriate background field for the group elements $g \in G$ than the one chosen in (2.24). We will not consider this technical issue here further.

This yields (recall that $\Omega(\mathfrak{g}^{(1)}) = \lambda^{-1}$) to first order in $1/k$,

$$\mu \partial_\mu \lambda = -\frac{c_2(G)}{2k} \lambda + \mathcal{O}\left(\frac{1}{k^2}\right). \quad (2.38)$$

We find agreement with [19] and with [56] for the case $G = \text{SU}(2)$, $H = \text{U}(1)$. We conclude that including an automorphism W of the Lie algebra $\mathfrak{g} = \mathfrak{g}^{(0)} \oplus \mathfrak{g}^{(1)}$ which respects the \mathbb{Z}_2 -grading does not affect the one-loop beta function of the asymmetrical λ -model. As with the conventional symmetric λ -model, the deformation for compact groups is marginally relevant driving the model away from the CFT point and marginally irrelevant for non-compact groups (as then one should send $k \rightarrow -k$, see appendix A).

2.3 Integrable boundary conditions

In this section we derive the (open string) boundary conditions that preserve integrability for the asymmetrical coset λ -model from the boundary monodromy method of [45, 58–60] to interpret them later as integrable D-brane configurations in the deformed background.

We define the generalised transport matrix,

$$T^{\mathcal{W}}(b, a; z) = \overleftarrow{P} \exp \left(- \int_a^b d\sigma \mathcal{W}[\mathcal{L}_\sigma(\tau, \sigma; z)] \right), \quad (2.39)$$

with an explicit dependence on the worldsheet coordinates (τ, σ) included and where \mathcal{W} is a constant metric-preserving Lie algebra automorphism (\mathcal{W} is not to be confused with the automorphism W used in the asymmetric gauging). Generally speaking, under periodic boundary conditions (when $\partial\Sigma = 0$) and with a flat Lax connection, one finds classical integrability by generating a tower of conserved charges from the *monodromy matrix* $T^{\mathcal{W}}(2\pi, 0; z)$ as $\partial_\tau \text{Tr} T^{\mathcal{W}}(2\pi, 0; z)^n = 0$ with $n \in \mathbb{Z}$, see e.g. [61]. This is not the case under open boundary conditions. Instead, we build the *boundary monodromy matrix* $T_b(z)$ by gluing the usual ($\mathcal{W} = \mathbf{1}$) transport matrix $T(\pi, 0; z)$ (from the $\sigma = 0$ to the $\sigma = \pi$ end) to the generalised transport matrix $T_R^{\mathcal{W}}(2\pi, \pi; z)$ in the reflected region:

$$T_b(z) = T_R^{\mathcal{W}}(2\pi, \pi; z) T(\pi, 0; z), \quad (2.40)$$

where $T_R^{\mathcal{W}}(2\pi, \pi; z)$ is constructed from the Lax (2.21) under the reflection $\sigma \rightarrow 2\pi - \sigma$ so that,

$$T_R^{\mathcal{W}}(2\pi, \pi; z) = T^{\mathcal{W}}(0, \pi; z^{-1}). \quad (2.41)$$

One finds an infinite set of conserved charges given by $\text{Tr} T_b(z)^n = 0$ with $n \in \mathbb{Z}$ when $\partial_\tau T_b(z) = [T_b(z), N(z)]$ for some $N(z)$. This is satisfied sufficiently when $N(z) = \mathcal{L}_\tau(0; z)$ and when we impose the boundary conditions [45, 60]:

$$\mathcal{L}_\tau(z)|_{\partial\Sigma} = \mathcal{W}[\mathcal{L}_\tau(z^{-1})]|_{\partial\Sigma}, \quad (2.42)$$

on both the open string ends. Explicitly, for the Lax connection (2.21) of the λ -coset model, we find by expanding order by order in the arbitrary parameter z the conditions,

$$\mathcal{O}(z) : \quad A_+^{(1)} \Big|_{\partial\Sigma} = \mathcal{W}[A_-^{(1)}] \Big|_{\partial\Sigma}, \quad (2.43a)$$

$$\mathcal{O}(z^0) : \quad A_\tau^{(0)} \Big|_{\partial\Sigma} = \mathcal{W}[A_\tau^{(0)}] \Big|_{\partial\Sigma}, \quad (2.43b)$$

$$\mathcal{O}(z^{-1}) : \quad A_-^{(1)} \Big|_{\partial\Sigma} = \mathcal{W}[A_+^{(1)}] \Big|_{\partial\Sigma}. \quad (2.43c)$$

Note from the above that the automorphism \mathcal{W} should respect the \mathbb{Z}_2 grading. Moreover, from (2.43b) one deduces that $\mathcal{W}(\mathfrak{g}^{(0)}) = \mathbf{1}$ unless $A_\tau^{(0)}|_{\partial\Sigma} = 0$ and using (2.43c) in (2.43a) that $\mathcal{W}^2(\mathfrak{g}^{(1)}) = \mathbf{1}$. Taking these restrictions on \mathcal{W} into account we continue with (2.43a) as describing the *integrable* boundary conditions. In components, and using the constraint equations (2.9), it translates to conditions on the local coordinates X^μ as,

$$[(D_g W - \Omega)^{-1}]^\alpha \, {}_B R^B{}_\mu \partial_+ X^\mu|_{\partial\Sigma} = -\mathcal{W}^\alpha{}_\beta [(D_{g^{-1}} - W\Omega)^{-1}]^\beta \, {}_C L^C{}_\mu \partial_- X^\mu|_{\partial\Sigma}. \quad (2.44)$$

Given a G/H model one can now continue by studying the eigensystem and derive the corresponding D-brane configurations in the target space background. This will be illustrated in section 3.3 for $G = \text{SL}(2, R)$ and $H = \text{U}(1)$.

In [45] we described also the possibility to glue $T(\pi, 0; z)$ to a gauge transformed reflected transport matrix $T_R^{\mathcal{W}g}(2\pi, \pi; z)$. Here we have the residual gauge symmetry (2.8) under which the Lax (2.21) transforms as $\mathcal{L}(z) \rightarrow h^{-1}\mathcal{L}h + h^{-1}dh$ with $h \in H$. The integrable boundary conditions then read,

$$\mathcal{L}_\tau(z)|_{\partial\Sigma} = \mathcal{W} [h^{-1}\mathcal{L}_\tau(z^{-1})h + h^{-1}\partial_\tau h]|_{\partial\Sigma}, \quad (2.45)$$

which allows a gluing of the gauge fields that is field-dependent. We will see in the explicit example of section 3 that this possibility will prove to be of significant importance to exhibit distinct D-brane configurations.

3 Deforming the Euclidean black hole and Sine-Liouville

We now illustrate the general story above with a simple example. The simplest example one could consider is the $\text{SU}(2)/\text{U}(1)$ case, however, there are no non-trivial outer automorphisms here and all that is achieved is simply a coordinate redefinition as seen from (2.15). One could go on to look at compact theories based on e.g. $\text{SU}(3)$ which does have such a symmetry however we choose here instead to pursue directly the $\text{SL}(2, R)/\text{U}(1)$ theories given their interest towards black hole physics.

For $G = \text{SL}(2, R)$ we take our generators T_A , $A = \{1, 2, 3\}$ to be,

$$T_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad T_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad T_3 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad (3.1)$$

such that $\text{Tr}(T_A T_B) = \text{diag}(+1, +1, -1)$ and adopt the following parameterisation of a group element $g \in \text{SL}(2, R)$ connected to the identity,

$$g = e^{\frac{\tau-\theta}{\sqrt{2}} T_3} e^{\sqrt{2}\rho T_1} e^{\frac{\tau+\theta}{\sqrt{2}} T_3} = \cosh \rho \begin{pmatrix} \cos \tau & \sin \tau \\ -\sin \tau & \cos \tau \end{pmatrix} + \sinh \rho \begin{pmatrix} \cos \theta & \sin \theta \\ \sin \theta & -\cos \theta \end{pmatrix}, \quad (3.2)$$

with $\rho \in [0, +\infty)$, $\theta, \tau \in [0, 2\pi]$. We take the subgroup $H = \text{U}(1)$ to be generated by T_3 .

3.1 The parafermionic $SL(2, R)/U(1)$ WZW theory

Let us first consider gauging the $U(1)_k$ subgroup in the WZW model on (a single cover of) $SL(2, R)_k$. As a coset CFT this model can be understood as being generated by a set of non-compact *parafermionic* currents introduced in [62] which are semi-local chiral fields with fractional spin (see also [63] and for the compact analogues [64]). In terms of these [63] showed the symmetry algebra to be the non-linear infinite W-algebra $\hat{W}_\infty(k)$. Although obscured as a non-rational CFT it is expected that, as in the compact $SU(2)/U(1)$ theory [51, 64], the level k parafermion theory and its \mathbb{Z}_k orbifold are equivalent for k integral [37, 65].

For large k we can view these theories as sigma models for strings propagating in a two-dimensional target space equipped with a non-constant dilaton originating from the action (2.5). If we perform an axial gauging $g \rightarrow hgh$ with $h \in H$ the τ -coordinate is gauge and we obtain, up to finite $1/k$ corrections, the *cigar* geometry,

$$ds_A^2 = k (d\rho^2 + \tanh^2 \rho d\theta^2), \quad e^{-2\Phi_A} = e^{-2\Phi_0} \cosh^2 \rho, \quad (3.3)$$

and zero B-field. The geometry is semi-infinite and terminates at $\rho = 0$ where the dilaton field is of maximum but finite value. The Ricci scalar computed from this metric is $R = \frac{4}{k \cosh^2 \rho}$ so that $\rho = 0$ is only a coordinate singularity.

If instead we perform the vector gauging $g \rightarrow h^{-1}gh$ the coordinate θ is gauge and we find at large k the *trumpet* geometry,

$$ds_V^2 = k (d\rho^2 + \coth^2 \rho d\tau^2), \quad e^{-2\Phi_A} = e^{-2\Phi_0} \sinh^2 \rho, \quad (3.4)$$

and zero B-field. The Ricci scalar is now $R = -\frac{4}{k \sinh^2 \rho}$ and, therefore, $\rho = 0$ is a true curvature singularity where the dilaton field reaches $+\infty$. Notice that both solutions (3.3) and (3.4) are related by the transformation,

$$\rho \rightarrow \rho + \frac{i\pi}{2}, \quad \theta \rightarrow \tau. \quad (3.5)$$

which, because it involves a complexification, is obviously not a standard field redefinition. Below we will understand it as originating from an outer automorphism. When performing an analytical continuation to Lorentzian signature the above solutions can be interpreted as a two-dimensional black hole for which the global Kruskal coordinates were written down in [31]. The cigar and trumpet solutions correspond to the region outside the horizon and inside the singularity respectively and are described by an equivalent coset CFT [37] with a central charge,

$$c = \frac{3k}{k-2} - 1. \quad (3.6)$$

As we will see shortly, the cigar is known to be T-dual to the \mathbb{Z}_k orbifold of the trumpet solution, and vice versa, where in the Euclidean picture the orbifolding can be understood as changing the temperature of the black hole [37–40].

The axial gauged $SL(2, R)/U(1)$ WZW (3.3) has a $U(1)_\theta$ isometry shrinking to zero size at $\rho = 0$ breaking the conservation of winding number. Nevertheless one can associate

a classically conserved current J_{\pm}^{θ} to $U(1)_{\theta}$ given by,

$$J_{\pm}^{\theta} = k \tanh^2 \rho \partial_{\pm} \theta, \quad \partial_+ J_-^{\theta} + \partial_- J_+^{\theta} = 0. \quad (3.7)$$

Using the conservation equation together with the equations of motion for ρ, θ , one can give semi-classical analogues of the non-compact parafermions which furnish chiral algebra's,

$$\partial_- \Psi_{(\pm)}^A = \partial_+ \bar{\Psi}_{(\pm)}^A = 0, \quad (3.8)$$

in terms of phase space variables [66, 67],

$$\Psi_{(\pm)}^A = (\partial_+ \rho \mp i \tanh \rho \partial_+ \theta) e^{\mp i \left(\theta + \frac{\tilde{\theta}}{k} \right)}, \quad \bar{\Psi}_{(\pm)}^A = (\partial_- \rho \pm i \tanh \rho \partial_- \theta) e^{\pm i \left(\theta - \frac{\tilde{\theta}}{k} \right)}, \quad (3.9)$$

where $\tilde{\theta}$ is a non-local expression in terms of ρ and θ defined by,

$$\partial_{\pm} \tilde{\theta} = \pm J_{\pm}^{\theta}. \quad (3.10)$$

This relation corresponds precisely to the canonical T-duality rule found when performing a standard Buscher procedure [68–70] on the $U(1)_{\theta}$ isometry. In the dual picture $\tilde{\theta}$ becomes a local coordinate with a periodicity of 2π [40]. The T-dual background is,

$$ds_{\mathcal{O}}^2 = k \left(d\rho^2 + \frac{1}{k^2} \coth^2 \rho d\tilde{\theta} \right), \quad e^{-2\Phi_{\mathcal{O}}} = e^{-2\Phi_0} \sinh^2 \rho, \quad (3.11)$$

and thus corresponds to the \mathbb{Z}_k orbifold of the vectorial gauged theory (3.4). Acting with the T-duality action (3.10) the non-compact parafermions of the dual background become,

$$\begin{aligned} \Psi_{(\pm)}^A &\rightarrow \Psi_{(\pm)}^{\mathcal{O}} = \left(\partial_+ \rho \mp i \coth \rho \frac{\partial_+ \tilde{\theta}}{k} \right) e^{\mp i \left(\frac{\tilde{\theta}}{k} + \theta \right)}, \\ \bar{\Psi}_{(\pm)}^A &\rightarrow \bar{\Psi}_{(\pm)}^{\mathcal{O}} = \left(\partial_- \rho \pm i \coth \rho \frac{\partial_- \tilde{\theta}}{k} \right) e^{\pm i \left(\frac{\tilde{\theta}}{k} - \theta \right)}, \end{aligned} \quad (3.12)$$

in which now θ is a non-local expression in the fields ρ and $\tilde{\theta}$ satisfying,

$$\partial_{\pm} \theta = \pm J_{\pm}^{\tilde{\theta}}, \quad J_{\pm}^{\tilde{\theta}} = \coth^2 \rho \frac{\partial_{\pm} \tilde{\theta}}{k}, \quad (3.13)$$

with $J_{\pm}^{\tilde{\theta}}$ the $U(1)_{\tilde{\theta}}$ classically conserved current of the background (3.11). Together with the classical equations of motions, this ensures again the dual parafermions to be holomorphically conserved, $\partial_- \Psi_{(\pm)}^{\mathcal{O}} = \partial_+ \bar{\Psi}_{(\pm)}^{\mathcal{O}} = 0$.

3.2 Asymmetrical λ -deformed $SL(2, \mathbf{R})/U(1)$

Let us now consider the asymmetrically deformed λ -theories. The metric preserving automorphisms W satisfying (2.6) are elements of $SO(2, 1)$ (including elements disconnected from the identity). They can for instance act as,

$$W : \{T_1, T_2, T_3\} \mapsto \{T_1, \cosh \alpha T_2 + \sinh \alpha T_3, \sinh \alpha T_2 + \cosh \alpha T_3\}, \quad (3.14)$$

induced from the action on $g \in \text{SL}(2, R)$ by $g \mapsto wgw^{-1}$ with,

$$w = \exp\left(\frac{\alpha}{\sqrt{2}}T_1\right). \quad (3.15)$$

When the parameter $\alpha \in \mathbb{R}$ the asymmetric gauging involves an inner automorphism which from (2.15) can clearly be absorbed by a trivial field redefinition. When instead we take for instance $\alpha = i\pi$ we have $w \in \text{SL}(2, \mathbb{C})$ and hence the automorphism W is outer. It is an element of $\text{SO}(2, 1)$ corresponding to a reflection of the T_2 and T_3 directions (i.e. $W = \text{diag}(+1, -1, -1)$) and is thus disconnected from the identity. The corresponding asymmetrical λ -theory then defines a background that deforms the axial gauged $\text{SL}(2, R)/\text{U}(1)$ WZW (since $W(T_3) = -T_3$) or *cigar* geometry of (3.3). Under the residual gauge symmetry (2.8) the τ -coordinate is then indeed gauge so that we can adopt the gauge fixing choice $\tau = 0$. Introducing the complex coordinates $\zeta = \sinh \rho e^{i\theta}$ and $\bar{\zeta} = \sinh \rho e^{-i\theta}$ the group element can then be written as,

$$\begin{aligned} g &= \begin{pmatrix} \cosh \rho + \cos \theta \sinh \rho & \sin \theta \sinh \rho \\ \sin \theta \sinh \rho & \cosh \rho - \cos \theta \sinh \rho \end{pmatrix}, \\ &= \frac{1}{2} \begin{pmatrix} \zeta + \bar{\zeta} - 2\sqrt{\zeta\bar{\zeta} + 1} & -i(\zeta - \bar{\zeta}) \\ -i(\zeta - \bar{\zeta}) & -\zeta - \bar{\zeta} - 2\sqrt{\zeta\bar{\zeta} + 1} \end{pmatrix}. \end{aligned} \quad (3.16)$$

The gauge field equations of motion (2.9) are,

$$\begin{aligned} (1 - \lambda)A_+^1 + i(1 + \lambda)A_+^2 &= -\frac{\sqrt{2}\lambda}{\sqrt{1 + \zeta\bar{\zeta}}}\partial_+\zeta, \\ (1 - \lambda)A_-^1 + i(1 + \lambda)A_-^2 &= \frac{\sqrt{2}\lambda}{\sqrt{1 + \zeta\bar{\zeta}}}\partial_-\bar{\zeta}, \end{aligned} \quad (3.17)$$

with A_\pm^3 determined in terms of A_\pm^1 and A_\pm^2 . The deformed background can be computed from (2.10) and (2.11) to be,

$$\begin{aligned} ds_{A,\lambda}^2 &= k \left(\frac{1 - \lambda}{1 + \lambda} (d\rho^2 + \tanh^2 \rho d\theta^2) + \frac{4\lambda}{1 - \lambda^2} (\cos \theta d\rho - \sin \theta \tanh \rho d\theta)^2 \right), \\ &= \frac{k}{1 - \lambda^2} \frac{(\lambda (d\zeta^2 + d\bar{\zeta}^2) + (1 + \lambda^2)d\zeta d\bar{\zeta})}{1 + |\zeta|^2}, \\ e^{-2\Phi} &= e^{-2\Phi_0} \cosh^2 \rho = e^{-2\Phi_0} (1 + |\zeta|^2), \end{aligned} \quad (3.18)$$

and zero B-field. Notice that the deformation has broken the $\text{U}(1)_\theta$ isometry to a \mathbb{Z}_2 . As before, $\rho = 0$ is only a coordinate singularity where the dilaton is constant.

Note that for $\lambda = 0$ we have that the metric is of the form $ds_A^2 = k\partial\bar{\partial}V(\zeta\bar{\zeta})d\zeta d\bar{\zeta}$ with $V(x) = -\text{Li}_2(-x) = \int_0^x ds s^{-1} \log(1 + s)$ and the geometry is indeed Kähler [34] allowing $\mathcal{N} = (2, 2)$ worldsheet supersymmetry. Let us see if we can find a similar form in the deformation, i.e. as $ds_{A,\lambda}^2 = k\partial\bar{\partial}V^\lambda(\zeta, \bar{\zeta})d\zeta d\bar{\zeta}$, with an eye on future applications to extended worldsheet supersymmetry. First, let us bring the metric into canonical form by defining $\zeta = Z - \lambda\bar{Z}$ such that,

$$ds_{A,\lambda}^2 = k \frac{(1 - \lambda^2)dZ d\bar{Z}}{1 - \lambda(Z^2 + \bar{Z}^2) + (1 + \lambda^2)Z\bar{Z}}, \quad (3.19)$$

Although performing directly a double integral of the function $(1 + \lambda^2)(1 - \lambda(Z^2 + \bar{Z}^2) + (1 + \lambda^2)Z\bar{Z})^{-1}$ appears to be inaccessible one can however do an expansion in λ and integrate each term in this evolution. To first order we find,

$$V^\lambda(Z, \bar{Z}) = -\text{Li}_2(-Z\bar{Z}) + \lambda \left(\frac{1}{Z^2} + \frac{1}{\bar{Z}^2} \right) \log(1 + Z\bar{Z}) - \lambda \left(\frac{Z}{\bar{Z}} + \frac{\bar{Z}}{Z} \right) + \mathcal{O}(\lambda^2). \quad (3.20)$$

Whilst a series expansion can doubtless be found, the resummation of such a result is not evident. However, this first-order perturbed potential can be the starting point for the development of the notion of integrability in an $\mathcal{N} = (2, 2)$ superspace setting, a totally uncharted topic. We hope to come back to this in a future publication.

For the remains of the paper we will see it to be more useful to reformulate the deformation in terms of the axial parafermions (3.9). The Lagrangian L_A of the sigma model corresponding to the deformed geometry (3.18) is a perturbation of the CFT point $L_{A,\text{wzw}}$ by a bilinear in the axial parafermions (as in [16]) given to all orders by,

$$L_A = k \left(\frac{1 + \lambda^2}{1 - \lambda^2} L_{A,\text{wzw}} + \frac{\lambda}{1 - \lambda^2} (\Psi_{(+)}^A \bar{\Psi}_{(-)}^A + \Psi_{(-)}^A \bar{\Psi}_{(+)}^A) \right). \quad (3.21)$$

Notice that the non-local phases $\tilde{\theta}$ of the parafermions drop out of this bilinear combination. Furthermore, this perturbation is clearly a non-compact analogue of the one considered in [71].

When instead we take $\alpha = 0$ in (3.15) and thus W the identity (that is trivially inner) one obtains the background known from [23], or from an analytical continuation of the $\text{SU}(2)/\text{U}(1)$ case of [16],

$$ds_{V,\lambda}^2 = k \left(\frac{1 - \lambda}{1 + \lambda} (d\rho^2 + \coth^2 \rho d\tau^2) + \frac{4\lambda}{1 - \lambda^2} (\cos \tau d\rho - \sin \tau \coth \rho d\tau)^2 \right), \quad (3.22)$$

$$e^{-2\Phi} = e^{-2\Phi_0} \sinh^2 \rho,$$

and zero B-field, deforming the vectorial gauged *trumpet* geometry of (3.4). Here $\rho = 0$ is again representing the curvature singularity.¹⁶ After taking the \mathbb{Z}_k orbifold, where the coordinate τ is replaced by the $2\pi/k$ periodic coordinate $\tilde{\theta}/k$, the first order correction to the corresponding Lagrangian L_O becomes a bilinear in terms of the orbifold parafermions Ψ_{\pm}^O of (3.12) as [16],

$$L_O = k \left(\frac{1 + \lambda^2}{1 - \lambda^2} L_{O,\text{wzw}} + \frac{\lambda}{1 - \lambda^2} (\Psi_{(+)}^O \bar{\Psi}_{(+)}^O + \Psi_{(-)}^O \bar{\Psi}_{(-)}^O) \right), \quad (3.23)$$

in which again the non-local phases drop out. One might at first sight think this indicates the axial-vector duality of the CFT point ($\lambda = 0$) [37–40] to persist in the deformation. However, one needs to be more careful here: when performing the T-duality transformation (3.12) on (3.21) the $\Psi_{(\pm)}^O$ enter in a combination where the non-local θ does not drop out and so the deformation term (3.23) is not recovered. Indeed this can be expected as the deformation destroys the isometries of the background.

¹⁶After analytical continuation, reference [23] derived the global Kruskal coordinates of the vectorially deformed theory to interpret the background as a deformed two-dimensional black hole capturing therefore also the region outside the horizon. However, a systematic analysis to obtain this region from an axial gauged deformation was lacking there.

3.3 Integrable branes in the λ -cigar

Let us now consider integrable boundary conditions defined in the λ -cigar geometry. Even in the undeformed case, this is a challenging question because of the well known difficulties with non-rational CFT. However, the expectation is (and based on a semi-classical analysis of the DBI action) that the cigar geometry allows D0-, D1- and D2-brane configurations [46–50]. Except for the D0, these branes can be understood as descending from the ungauged $SL(2, R)$ WZW model [72]. Geometrically, the D0 is located at the tip of the cigar, the D1 covers a so-called *hairpin* and the D2 is either space-filling or extends from the circle at some value $\rho_\star > 0$ to infinity. The D1-branes are understood to be non-compact analogues of the A-branes of [51] in the $SU(2)/U(1)$ WZW while the D0 and D2 are analogues of the B-branes. The latter are an interesting type as they provide a way to derive symmetry breaking branes in the parent theory which are non-obvious to obtain from first principles, see for instance [73] and references therein. Here we will find the above D-brane configurations by employing the classical integrability technique outlined in section 2.3.

We start with analysing the simplest case given in equations (2.42), (2.44) for the cigar, i.e. taking $W = \text{diag}(1, -1, -1)$, and for $\mathcal{W} = \mathbf{1}_3$ (which is trivially satisfying the restrictions given below (2.43)). After a straightforward computation this leads to the integrable boundary conditions,

$$\begin{aligned} \cos \theta \partial_\tau \rho - \sin \theta \tanh \rho \partial_\tau \theta &= 0, \\ \sin \theta \partial_\sigma \rho + \cos \theta \tanh \rho \partial_\sigma \theta &= 0, \end{aligned} \tag{3.24}$$

which describe static D1-branes. These boundary conditions notably do not depend on the deformation parameter and indeed match precisely those of the CFT point [46–48]. In terms of the complex coordinates $\zeta = \sinh \rho e^{i\theta}$, $\bar{\zeta} = \sinh \rho e^{-i\theta}$ they simplify to,

$$\partial_\tau (\zeta + \bar{\zeta}) = 0, \quad \partial_\sigma (\zeta - \bar{\zeta}) = 0. \tag{3.25}$$

The Dirichlet condition gives the embedding equation in the two-dimensional (ρ, θ) space such that the D1-branes cover so-called *hairpins* on the cigar as visualised in figure 1 in the undeformed case. In the limit $\rho \rightarrow \infty$ the branes reach the asymptotic circle at two opposite positions, $\theta = \pi/2, 3\pi/2$. Another possibility in the λ -cigar is taking the gluing automorphism $\mathcal{W} = \text{diag}(-1, -1, 1)$. In this case the integrable boundary conditions (2.44) are an exchange of the Dirichlet and Neumann direction,

$$\partial_\tau (\zeta - \bar{\zeta}) = 0, \quad \partial_\sigma (\zeta + \bar{\zeta}) = 0, \tag{3.26}$$

corresponding to a rotation along the circle of the static D1-branes over an angle $\pi/2$. In contrast to the undeformed case, the extra restrictions on the automorphism \mathcal{W} prevents the branes to be rotated smoothly into each other while preserving the integrability properties, essentially since the deformation destroys such isometry of the background.

Figure 1. The D1-brane configurations in the undeformed cigar manifold embedded in \mathbb{R}^3 . Heuristically, one can think of the deformation as to convert the $U(1)_\theta$ circle into an ellipse. However, visualising this exactly is surprisingly challenging.¹⁷

Let us consider the D1-branes found above also from the semi-classical perspective. If we let y be the spatial coordinate of the D1-brane¹⁸ and introduce $u = |\zeta| = \sinh(\rho)$ then the DBI action reads,

$$S_{\text{DBI}} = T_1 \int dy e^{-\Phi} \sqrt{\det \hat{G}}, \quad (3.27)$$

where,

$$e^{-2\Phi} \det \hat{G} \propto u'(y)^2 (1 + \lambda^2 + 2\lambda \cos(2\theta(y))) - 4\lambda u(y)u'(y)\theta'(y) \sin(2\theta(y)) + u(y)^2 \theta'(y)^2 (1 + \lambda^2 - 2\lambda \cos(2\theta(y))). \quad (3.28)$$

Although the action evidently depends on the deformation parameter, this drops out in the classical Euler-Lagrange equations, which have a solution,

$$u(y) = v \csc(\theta_0 + \theta(y)), \quad (3.29)$$

with v, θ_0 integration constants. Hence, the D1-branes are semi-infinite with $u \in (v, \infty)$. Plugging this solution back into the DBI action yields,

$$S_{\text{DBI}} \propto \lim_{u \rightarrow \infty} \sqrt{u^2 - v^2} \sqrt{1 + \lambda^2 + 2\lambda \cos(2\theta_0)}. \quad (3.30)$$

Whilst this is clearly diverging, for any UV cut-off the action is minimised by $\theta_0 = \frac{\pi}{2}, \frac{3\pi}{2}$. Asymptotically as $\rho \rightarrow \infty$ these special configurations match precisely to the integrable D-branes described in (3.25).

As is the case in the undeformed cigar we anticipate¹⁹ here also $D0$ -branes localised at the tip. The corresponding worldsheet boundary conditions read,

$$\partial_\tau \theta = \partial_\tau \rho = 0, \quad \rho = 0. \quad (3.31)$$

To ascertain if these constitute integrable boundary conditions we shall reverse the logic compared to the $D1$ case described above; we shall start with these boundary conditions on the field and from this infer a boundary condition on the Lax connection. A first step is

¹⁷Whilst it is easy to find an explicit isometric embedding in \mathbb{R}^3 for the undeformed cigar geometry, finding the same for the deformed cigar proved to be an engrossing, deceptively challenging, and ultimately frustrating activity, at least for the present authors. Solutions to this problem would be welcomed.

¹⁸As is commonplace in the topic we assume that there is an auxiliary time direction and assume some static gauge.

¹⁹Inspired by [45] where a generic geometrical approach was taken for group manifolds, we anticipate the brane configurations of the CFT to persist in the deformed theory.

to use the gauge field equations eq. (3.17) of motion evaluated with the gauge fixing choice eq. (3.16). Then the D0 boundary condition reads simply,

$$A_+^1 = A_-^1, \quad A_+^2 = -A_-^2, \quad A_+^3 = A_-^3 = 0, \quad (3.32)$$

where the latter equality follows on $\rho = 0$. In terms of the Lax connection (2.21),

$$\mathcal{L}_\tau(z) = \frac{1}{\sqrt{2\lambda}z} \begin{pmatrix} -(1+z^2)A_+^1 & (1-z^2)A_+^2 \\ (1-z^2)A_+^2 & (1+z^2)A_+^1 \end{pmatrix} \quad (3.33)$$

we find that this satisfies the condition $\mathcal{L}_\tau(z)| = \mathcal{W}[\mathcal{L}_\tau(z^{-1})]$ of (2.42) when $\mathcal{W} = \text{diag}(1, -1, -1)$. In this case \mathcal{W} satisfies all necessary requirements when $\rho = 0$ (since then $A_+^3 = 0$): it is a constant metric-preserving automorphism of $\mathfrak{sl}(2, R)$ and $\mathcal{W}^2(\mathfrak{g}^{(1)}) = \mathbf{1}$.

In [46, 47] it was shown that there is also a D2-brane configuration supported by a worldvolume gauge field \mathcal{A} with field strength $F_{\rho\theta} \equiv f = \partial_\rho \mathcal{A}_\theta$ (in which the gauge $\mathcal{A}_\rho = 0$ is adopted). In the deformed scenario we might again anticipate finding such a configuration. Indeed from the DBI action,

$$S_{\text{DBI}} \propto \int d\rho d\sigma e^{-\Phi} \sqrt{\det(G + F)}, \quad (3.34)$$

we find that the λ -dependence drops from the equation of motion for the gauge field which is solved with,

$$f^2 = \frac{\beta^2 \tanh^2 \rho}{-\beta^2 + \cosh^2 \rho}. \quad (3.35)$$

Here we see that when the constant $\beta > 1$, the field strength f is critical outside the region $\cosh \rho \geq \beta$ so that the D2-brane extends from the asymptotic circle to a minimum value in ρ given by $\cosh \rho_* = \beta$. When $\beta < 1$, however, the D2 is space-filling.

The question now comes if this corresponds to an integrable boundary condition. Recall that a volume-filling brane should consist of generalised Neumann type boundary conditions that incorporate the gauge field F :

$$G_{ab} \partial_\sigma X^a = F_{ab} \partial_\tau X^b. \quad (3.36)$$

In terms of the coordinates $X = (\rho, \theta)$ these are quite inelegant and have explicit dependence on λ . However, we may recast this result in terms of the gauge fields $A_\pm^{(1)}$ using the on-shell equations of motion (3.17). We find that upon doing so the λ -dependence is again removed and yields,

$$(1 + f^2 \coth^2 \rho) \{A_-^1, A_-^2\} = (1 - f^2 \coth^2 \rho) \{-A_+^1, A_+^2\} - 2f \coth \rho \{A_+^2, A_+^1\}. \quad (3.37)$$

This tells us the gluing between the gauge fields should be field-dependent and therefore hints towards a boundary condition of the form (2.45) where one includes a gauge transformation in the boundary monodromy matrix. Indeed, after a tedious but straightforward computation we find that gauge transforming the Lax (2.21),

$$\mathcal{L}(z) \rightarrow h^{-1} \mathcal{L}(z) h + h^{-1} dh, \quad (3.38)$$

by,

$$h = \exp(v(\rho, \beta)T_3) \in H, \quad v(\rho, \beta) = \sqrt{2} \arcsin(\coth^2 \rho f^2 + 1)^{-1/2}, \quad (3.39)$$

the integrable boundary condition (2.45) agrees with the D2 boundary conditions (3.37) when $\mathcal{W} = \text{diag}(1, -1, -1)$.

Concluding, we see here integrable D-branes corresponding to D0-, D1- and D2-configurations which are all obtained differently from a boundary condition on the Lax connection. We see also that not all of the D1-branes of the undeformed theory preserve integrability: instead of having the continuous $U(1)_\theta$ isometry, only two configurations at specific angles survive the integrable deformation.

3.4 Connection to Sine-Liouville theory

We are now in a position to discuss the deformation to the dual Sine-Liouville (SL) background, which in the undeformed case has the action (see for instance [41, 74]),

$$S_{\text{SL},k}(x, \phi) = \frac{1}{\pi} \int_{\Sigma} d\tau d\sigma \partial_+ \phi \partial_- \phi + \partial_+ x \partial_- x + QR^{(2)}\phi + \mu e^{b\phi} \cos(R\tilde{x}), \quad (3.40)$$

with $R^{(2)}$ the worldsheet Ricci scalar. The target space has the topology of cylinder with $\phi \in (-\infty, +\infty)$ the radial coordinate and x a 2π periodic coordinate with radius R and a dual \tilde{x} . The parameters Q , b and R are related as $Q = -1/b$ and $R^2 - b^2 = 2$ ensuring Sine-Liouville is an exact CFT with central charge,

$$c = 2 + 6Q^2, \quad (3.41)$$

and a potential $V(\phi, \tilde{x}) = \mu e^{b\phi} \cos(R\tilde{x})$ with scaling dimension 1. The central charge of the Euclidean cigar (3.6) matches with that of SL when $Q^2 = \frac{1}{k-2}$, hence (taking the positive root of Q) we have $b = -\sqrt{k-2}$ and $R = \sqrt{k}$.

A dictionary between the (undeformed) Euclidean cigar black hole and Sine-Liouville theory can be made in the asymptotic flat space limit $\rho \rightarrow \infty$ where the cigar approaches the topology of a cylinder and its dilaton falls off linearly, $\Phi_A - \Phi_0 \rightarrow -\rho$. On the SL side, this limit corresponds to the region $\phi \rightarrow \infty$ in which the potential $V(\phi, \tilde{x})$ as well as the string coupling constant go to zero given the dilaton $\Phi_{\text{SL}} = Q\phi$. The identification is therefore at large k given by,

$$\rho \sim -Q\phi, \quad \theta \sim \frac{x}{\sqrt{k}}, \quad \tilde{\chi} \sim \sqrt{k}\tilde{x}. \quad (3.42)$$

At finite ρ and ϕ , the duality between both theories can be demonstrated as an exact match between the symmetry algebra's, vertex operators and n -point functions [41–43] (see also [74]) where they look both topologically and dynamically very different. Indeed, it can be understood that the dynamics is governed by the geometry in the cigar picture and by the potential $V(\phi, \tilde{x})$ in the SL picture. Additionally, the tip of the cigar is the end of space corresponding to the horizon of the Euclidean black hole and hence cutting off the strong string coupling region, while on the SL side this region is protected by the potential $V(\phi, \tilde{x})$. On the worldsheet the duality can be viewed as a strong-weak coupling

duality. However, the sigma model point of view taken here forces us in the small coupling (large k) regime on the cigar side.

For us the power of the duality lies in the observation that the semi-classical cigar parafermions (3.9) in the flat space limit under the identification (3.42),

$$\Psi_{(\pm)}^{\text{SL}} = \left(-\frac{\partial_+\phi}{\sqrt{k-2}} \mp i\frac{\partial_+x}{\sqrt{k}} \right) e^{\mp \frac{2ix_L}{\sqrt{k}}}, \quad \bar{\Psi}_{(\pm)}^{\text{SL}} = \left(-\frac{\partial_-\phi}{\sqrt{k-2}} \pm i\frac{\partial_-x}{\sqrt{k}} \right) e^{\pm \frac{2ix_R}{\sqrt{k}}}, \quad (3.43)$$

commute²⁰ with the SL potential $V(\phi, \tilde{x})$ [74]. Here $x(\sigma^+, \sigma^-) = x_L(\sigma^+) + x_R(\sigma^-)$ and $\tilde{x}(\sigma^+, \sigma^-) = x_L(\sigma^+) - x_R(\sigma^-)$. Therefore, one can rely on the expression (3.43) for all values of ϕ . Since the parafermion fields induce the deformation (3.21) we can now easily extract the perturbation on the SL theory side. To first order in λ the deforming term in the large k regime becomes,

$$\begin{aligned} \delta L_{\text{SL}} = \lambda & \left(2 \cos\left(\frac{2x}{R}\right) \partial_+\phi \partial_-\phi - 2 \cos\left(\frac{2x}{R}\right) \partial_+x \partial_-x \right. \\ & \left. + 2 \sin\left(\frac{2x}{R}\right) (\partial_+x \partial_-\phi + \partial_-x \partial_+\phi) \right) + \mathcal{O}(\lambda^2). \end{aligned} \quad (3.44)$$

A similar structure is expected for finite λ , as (3.21) is exact in λ , so that one deforms the flat space SL theory to a curved background. We anticipate this is the starting point of an integrable deformation of the SL theory. Moreover, it appears to be in a different class to the integrable deformations studied in [74]. We will leave this as an open problem to be fully understood.

4 Conclusion

The Sfetsos procedure [16] to construct the λ -deformation of a G/H coset realised as a gauged WZW model actually requires the G/G model as a starting point. To date, even when H is abelian, attention has been restricted to the case in which in the G/G model the G symmetry, and consequently that of H , acts vectorially. Here we explore the asymmetric gauging of G in which the left and right actions differ by the application of an algebra automorphism. When this is an outer automorphism what results can not be trivially removed via field redefinitions. In this way, we are able to produce new λ -type deformations leading to topologically distinct target spaces in a robust and fundamental manner. Using the similarities between this asymmetric λ -model and its vectorial cousin we demonstrate classical integrability and show the one-loop beta functions to stay marginally relevant for compact groups and irrelevant for non-compact groups. To end our general discussion of this model, we present a simple technique to construct integrable boundary conditions in which we, moreover, exploit the residual asymmetric gauge symmetry.

As an example we consider the $\text{SL}(2, R)/\text{U}(1)$ model where unlike the compact $\text{SU}(2)$ there is such a non-trivial outer automorphism. We show that employing our procedure

²⁰After analytical continuation to Euclidean worldsheet signature one should check that $\oint_w dz \Psi_{(\pm)}^{\text{SL}}(z) V(\phi(w), \tilde{x}(w)) = \oint_{\bar{w}} d\bar{z} \bar{\Psi}_{(\pm)}^{\text{SL}}(\bar{z}) V(\phi(\bar{w}), \tilde{x}(\bar{w}))$. Note that a translation to [74] should be done in the large k limit and by the substitution $\phi \rightarrow \varphi/2$, $x \rightarrow \phi/2$, $b \rightarrow 2b$, $R \rightarrow 2a$. Doing so one indeed finds $\Psi_{(\pm)}^{\text{SL}} \propto \Psi_{(\mp)}^{\text{Fateev}}$ up to an irrelevant overall factor.

we are able to find an integrable deformation of the theory in which the gauged symmetry acts axially. Geometrically, and at large k , we have an integrable deformation of the cigar geometry corresponding to the Euclideanised Witten black hole. The cigar geometry itself receives $\frac{1}{k}$ corrections and it would be doubtless valuable to find a description of the λ -deformation that takes these corrections into account. Continuing at large k , we analyse also the boundary conditions preserving integrability in the deformed cigar. We see this can be done straightforwardly and observe the D-branes proposed at the (non-rational) CFT point to be integrable in the deformation.

As well as demonstrating the concept for this broader class of deformations we believe this example could hold some further interest in its own right. Let us entertain some speculation about how the deformation translates to both the Sine-Liouville (SL) dual and in turn to the matrix model description of this picture. An initial step is made here by identifying for small deformation parameters in the cigar a bilinear of the non-compact parafermions as the operators that drive the deformation. Demanding agreement between the SL at large values of the radial coordinate suggests strongly the same parafermionic bilinear deformation should be considered in the SL model. However the λ -model goes much further since it provides a resummation to all orders in λ of this deformation; what this looks like in the SL theory is far from clear. One possible root to shed light on this could be to combine the Sfetsos procedure with the path integral derivation of FZZ. When successful, one can continue and probe, using the deformed SL theory and integrability, the region behind the horizon.

It is also interesting to ask what the deformation does at the level of the S-matrix. For the case of similar deformations of *compact* parafermionic theories it has long been known that the S-matrix has a kink structure and in the $k \rightarrow \infty$ limit matches that of the O(3) sigma-model [71]. A similar expectation holds for general λ -deformations, the underlying S-matrix has a q root-of-unity quantum group symmetry associated to a face model [75, 76]. Here it is less clear due to the non-compactness of the theory but one might well anticipate a similar q -deformation to hold. Further one might ask what this structure might relate to in the postulated dual matrix model description of the cigar [41].

A final enticing direction is to employ similar techniques in the context of geometries relevant to black hole microstates. For instance a static configuration of NS5-branes on a circle admits a description as a gauged WZW model [77, 78], and more general solutions (supertubes and spectral flows of supertubes) can also be realised as gauged WZW models [79, 80]. It seems quite possible that the techniques developed here may be applicable to such situations. We leave that for future work.

Acknowledgments

We thank Ben Hoare, Tim Hollowood, Carlos Nunez and Kostas Sfetsos for useful discussions that aided this project and to Panagiotis Betzios, Gaston Giribet, Olga Papadoulaki and David Turton for useful communications on the manuscript. A Conventions and sigma models (WZW, PCM and SSSM)

In this appendix, we briefly introduce some basic ingredients and conventions for the gauging procedure of section 2.

For the general formulae of this paper we adopt conventions for compact and semi-simple groups G , although they should be changed conveniently when working out the non-compact $SL(2, R)/U(1)$ example in section 3. We denote the generators of the Lie algebra \mathfrak{g} of G by T_A and pick a basis in which they are Hermitean, i.e. $[T_A, T_B] = iF_{AB}^C T_C$ with real structure constants F_{AB}^C and $A = \{1, \dots, \dim G\}$. They are normalised in such a way that the ad-invariant Cartan-Killing metric $\langle \cdot, \cdot \rangle : \mathfrak{g} \times \mathfrak{g} \rightarrow \mathbb{R}$, taken to be $\langle T_A, T_B \rangle = \frac{1}{x_R} \text{Tr}(T_A T_B)$ with x_R the index of the representation R , has unit entries. The left-(right-)invariant Maurer-Cartan one-forms are expanded in the Lie algebra as $g^{-1}dg = -iL^A T_A$ ($dg g^{-1} = -iR^A T_A$) and in explicit local coordinates X^μ , $\mu \in \{1, \dots, \dim G\}$ as $g^{-1}dg = -iL^A_\mu(X) T_A dX^\mu$ ($dg g^{-1} = -iR^A_\mu(X) T_A dX^\mu$). The adjoint action is denoted by $D_g T_A = g T_A g^{-1} = (D_g)^B{}_A T_B$, hence $(D_g)_{AB} = \langle T_A, g T_B g^{-1} \rangle$ and $R^A = (D_g)^A{}_B L^B$.

Finally, considering the G/H coset, we denote the generators of the subgroup $H \subset G$ with Lie algebra \mathfrak{h} by T_a , $a = \{1, \dots, \dim H\}$ and the remaining generators by T_α , $\alpha = \{\dim H + 1, \dots, \dim G\}$. We assume the Lie algebra \mathfrak{g} to have a symmetric space decomposition $\mathfrak{g} = \mathfrak{g}^{(0)} \oplus \mathfrak{g}^{(1)}$, with $\mathfrak{g}^{(0)} \equiv \mathfrak{h}$, defined by a \mathbb{Z}_2 grading $[\mathfrak{g}^{(i)}, \mathfrak{g}^{(j)}] \subset \mathfrak{g}^{(i+j \bmod 2)}$.

We consider the WZW model on a Lie group manifold G at level k [4] with the action,

$$S_{\text{WZW},k}(g) = -\frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau \langle g^{-1} \partial_+ g, g^{-1} \partial_- g \rangle - \frac{k}{24\pi} \int_{M_3} \langle \bar{g}^{-1} d\bar{g}, [\bar{g}^{-1} d\bar{g}, \bar{g}^{-1} d\bar{g}] \rangle, \quad (\text{A.1})$$

with $g : \Sigma \rightarrow G$ a Lie group element and \bar{g} an extension of g into $M_3 \subset G$ such that $\partial M_3 = g(\Sigma)$. To cancel ambiguities from the choice of M_3 in the path integral the level k should be integer quantised for compact groups while for non-compact cases it can be free [4, 81]. The two-dimensional manifold Σ can be thought of as a worldsheet on which we have fixed the metric as $\text{diag}(+1, -1)$, the Levi-Civita as $\epsilon_{\tau\sigma} = 1$ and we have units in which $\alpha' = 1$. We analytically continue to Euclidean coordinates by taking $\sigma_+ = \tau + \sigma \rightarrow -iz$ and $\sigma_- = \tau - \sigma \rightarrow -i\bar{z}$ and will use the term *holomorphic* abusively to mean either $f(\sigma^+)$ or $f(z)$. The WZW model on group manifolds is known to have an exact CFT formulation originating from the $G_L(\sigma^+) \times G_R(\sigma^-)$ symmetry generated by the holomorphically conserved currents $J_+(\sigma^+) = -k \partial_+ g g^{-1}$ and $J_-(\sigma^-) = k g^{-1} \partial_- g$ whose components satisfy two commuting Kac-Moody algebra's.

We consider moreover the PCM model on a Lie group manifold G with a coupling constant κ^2 ,

$$S_{\text{PCM},\kappa^2}(\hat{g}) = -\frac{\kappa^2}{\pi} \int d\sigma d\tau \langle \hat{g}^{-1} \partial_+ \hat{g}, \hat{g}^{-1} \partial_- \hat{g} \rangle, \quad \hat{g} \in G, \quad (\text{A.2})$$

which has a global $G_L \times G_R$ symmetry. From the PCM model the SSSM model on the G/H coset manifold can be obtained by gauging an $H_R \subset G$ subgroup acting as,

$$\widehat{g} \rightarrow \widehat{g}h. \tag{A.3}$$

The gauge-invariant action is then,

$$S_{\text{SSSM},\kappa^2}(\widehat{g}, B_{\pm}) = -\frac{\kappa^2}{\pi} \int d\sigma d\tau \langle (\widehat{g}^{-1} \partial_+ \widehat{g} - B_+), (\widehat{g}^{-1} \partial_- \widehat{g} - B_-) \rangle, \tag{A.4}$$

with B_{\pm} the gauge fields taking values in the Lie algebra $\mathfrak{g}^{(0)} \equiv \mathfrak{h}$ of H and transforming under the gauge transformation as $B_{\pm} \rightarrow h^{-1} (B_{\pm} + \partial_{\pm}) h$. This model is easily shown to be classically integrable when $\mathfrak{g} = \mathfrak{g}^{(0)} \oplus \mathfrak{g}^{(1)}$ has a symmetric space decomposition [8, 17].

Note that when working with non-compact groups, where one usually picks a generator basis $[T_A, T_B] = F_{AB}^C T_C$ with F_{AB}^C real, one should analytically continue in the above models $k \rightarrow -k$ and $\kappa^2 \rightarrow -\kappa^2$.

ABSTRACT: We show that the geometric interpretation of D-branes in WZW models as twisted conjugacy classes persists in the λ -deformed theory. We obtain such configurations by demanding that a monodromy matrix constructed from the Lax connection of the λ -deformed theory continues to produce conserved charges in the presence of boundaries. In this way the D-brane configurations obtained correspond to “integrable” boundary configurations. We illustrate this with examples based on $SU(2)$ and $SL(2, \mathbb{R})$, and comment on the relation of these D-branes to both non-Abelian T-duality and Poisson-Lie T-duality. We show that the D2 supported by D0 charge in the λ -deformed theory map, under analytic continuation together with Poisson-Lie T-duality, to D3 branes in the η -deformation of the principal chiral model.

1 Introduction

The study of two-dimensional quantum field theories with boundaries has rich physical and mathematical significance. In the context of open string theory, the boundary conditions describe D-branes, an essential non-perturbative ingredient of string theory. More generally 2d conformal field theories with boundaries have applications in condensed matter systems including boundary critical behaviour, percolation models and quantum impurity problems (see e.g. [1–3]). When the correct CFT description is available the application of boundary conformal field theory (BCFT) can render the physics tractable [4, 5]. Another interesting class of theories comes from integrable systems;¹ here one is lead to ask (both classically and quantum mechanically) what boundary conditions can be implemented such that the integrability of the system is preserved. The present paper will in some way consider both contexts; we aim to study boundary effects in field theories that are integrable and at some point in the parameter space are connected to conformal field theories.

¹See [6] or for a recent set of useful lecture notes [7].

Our primary motivation will be that of string theory; i.e. we are interested in understanding the D-branes admitted by a given curved closed string background. In general this is a very demanding problem since one would like to have a precise CFT formulation, see e.g. [8, 9]. A simple example is provided by the Wess-Zumino-Witten (WZW) model [10] describing closed strings propagating in a group manifold supported by Neveu-Schwarz flux. Whilst BCFT can be employed here to give an algebraic description of the D-brane [11] our interest will lie in the elegant geometric picture developed through a number of works [12–15]. By identifying possible gluing conditions at the boundary it is determined that D-branes are described by (twisted) conjugacy classes. For example in the $SU(2)_k$ WZW model one finds two D0-branes and a further $k - 1$ D2-branes that are blown up to wrap the conjugacy classes described by $S^2 \subset S^3$.

When an explicit CFT description is unknown and one has just a non-linear sigma-model describing strings in a curved background, giving a precise description of D-branes is challenging. However in a special circumstance, namely when the sigma-model is integrable, progress can be made. One can seek boundary conditions that preserve integrability and hope that they are amenable to a simple interpretation as D-branes. What is meant by *preserve integrability*? At a classical level it is natural to demand that the boundary condition preserves a large number of conserved charges. There are typically two sorts of conserved charges at play, higher spin local charges and non-local charges (e.g. for the principal chiral model (PCM) see [16] for local charges and the construction of a non-local Yangian \times Yangian structure starts with [17–19]). In this work we will focus our attention on the boundary conditions that preserve some portion of the tower of non-local charges obtained from a monodromy matrix. We anticipate that the same boundary conditions will also preserve higher spin local charges. We shall see that this quite naturally generalises the gluing conditions used in the case of the WZW model. This approach has its origins in [20, 21] and has been used in a variety of contexts including the identification of integrable boundary conditions for strings in bosonic sigma models [22], in Green-Schwarz sigma models [23],² for the $O(N)$ sigma model [25, 26], the principal chiral model [27, 28], open spin chains (e.g. [29, 30] although the literature is vast) and affine Toda field theories [31]. For methods based on the conservation of local spin charges see e.g. [32–35].

The present manuscript will seek to make a bridge between the two above ways of determining boundary conditions. The λ -deformed WZW model introduced by Sfetsos in [36] provides an ideal arena to do this. At a classical level the λ -deformation is an integrable 1+1 dimensional field theory that depends on a parameter $\lambda \in [0, 1]$. At $\lambda = 0$ the WZW model is recovered while in a scaling limit as $\lambda \rightarrow 1$ one find the non-Abelian T-dual to the principal chiral model. For generic values of λ the dynamics can be encoded by means of a Lax connection and so a natural question to ask is what boundary conditions can be placed on a λ -model that preserve integrability. Should one wish, once such boundary conditions are established, the limit $\lambda \rightarrow 0$ can be taken providing an alternative route to the D-brane configurations of the WZW model. It is tricky to apply integrability techniques directly to the WZW model due to the chiral nature of the current, so one can think of λ as providing

²In the context of the AdS/CFT correspondence see also [24] and references therein.

a convenient alleviation of this. What we shall see in this paper is that, through a number of pleasing algebraic cancelations, the twisted conjugacy classes define integrable boundary conditions even in the deformed model.³ Moreover, when a quantisation condition is required on the worldvolume flux of D-branes the cancellations are such that the result is independent of the (continuous) deformation parameter λ as it must indeed be for consistency.

A further motivation for the present study comes from duality. To fully establish a duality one would like to have access to its action on both perturbative and non-perturbative degrees of freedom. Consider conventional Abelian target space duality in the absence of any NS two-form potential: here the interpretation is quite simple, a T-duality transverse to a Dp brane produces a $D(p+1)$ brane whilst when performed along a direction of the worldvolume a $D(p-1)$ is produced. This can be seen rather simply by considering the open string boundary conditions; since T-duality acts as a reflection on right-movers, Neumann N and Dirichlet D boundary conditions are interchanged. For more exotic notions of target space duality, e.g. non-Abelian [45, 46] or Poisson-Lie [47, 48], such an understanding is less refined (although see [49–55] and recent work in [56–58]) one reason being that the geometries concerned are not flat making it harder to identify the appropriate boundary conditions. Here however we will have access to an elegant description of D-brane boundary conditions in the λ -model whose interplay with duality can be readily studied. For instance by taking the $\lambda \rightarrow 1$ limit on our D-brane configurations we will gain information about the brane spectrum of the non-Abelian T-dual theory. It is also known that after appropriate analytic continuations the λ -model produces a geometry that is Poisson-Lie T-dual to the integrable η -deformed principal chiral model [59–62]. By examining this analytic continuation on our D-brane configurations we will too gain information about the brane spectrum of the Poisson-Lie T-dual theory. We study this interplay of duality with D-brane configurations in the case of the $SU(2)$ theory. Here we find that under either the “ $\lambda \rightarrow 1 +$ non-Abelian T-duality” or “analytic continuation + PL T-duality” procedures, the D2 branes discovered in the λ -model are transformed to space-filling D3 branes.

The structure of the paper is as follows. We will briefly review in section 2 the salient features of integrable λ -deformations of WZW models, in section 3 we will explain the strategy used to derive integrable boundary conditions and then apply it directly to the λ -deformed WZW. We illustrate this in section 4 in the context of examples based on both $SU(2)$ and $SL(2, \mathbb{R})$ theories, where in the latter case we see the possibility of twisting conjugacy classes by an algebra outer automorphism. In section 5 we explore the relation of these D-brane configurations to both non-Abelian and Poisson-Lie T-duality. In the appendices we establish our conventions and the necessary ingredients of the general sigma model and the WZW model.

³When taken in isolation the λ -deformation is actually a marginally relevant deformation of the WZW and is not a CFT [37]. However we continue to use the terminology of D-branes to describe boundary conditions. It is expected that when applied to super-cosets the λ -deformation becomes a true marginal integrable deformation [37–39] which hopefully makes this usage somewhat acceptable to a string theorist. Moreover, they provide genuine supergravity solutions when a suitable ansatz is made for the RR fluxes and the dilaton [40–44].

2 λ -deformations

First, we will briefly review the construction of [36] in order to set up the sigma model action from which the background fields can be read off and a Lax connection representing the equations of motion can be found. The isotropic λ deformation from group manifolds is obtained by starting with a sum of a PCM on G for a group element $\tilde{g} \in G$,⁴

$$S_{\text{PCM}}(\tilde{g}) = -\frac{\kappa^2}{\pi} \int d\sigma d\tau \langle \tilde{g}^{-1} \partial_+ \tilde{g} \tilde{g}^{-1} \partial_- \tilde{g} \rangle, \quad (2.1)$$

and a WZW model on G for a different group element $g \in G$ as in eq. (B.1). Altogether, this action has a global $G_L \times G_R$ symmetry for the PCM and a $G_L(z) \times G_R(\bar{z})$ symmetry group for the WZW. One continues by gauging simultaneously the left symmetry action of the PCM and the diagonal action of the WZW acting as,

$$G_L: \quad \tilde{g} \rightarrow h^{-1} \tilde{g}, \quad G_{\text{diag}}: g \rightarrow h^{-1} g h, \quad (2.2)$$

with $h \in G$, using a common gauge field $A = A^A T_A$ transforming as,

$$A \rightarrow h^{-1} A h - h^{-1} dh. \quad (2.3)$$

The total model is made gauge invariant by replacing the derivatives in the PCM by a covariant derivative $\tilde{D}_\pm \tilde{g} = \partial_\pm \tilde{g} - A_\pm \tilde{g}$ (i.e. by minimal substitution), and by replacing the WZW model (B.1) with the G/G gauged WZW model,

$$S_{\text{gWZW},k}(g, A) = S_{\text{WZW},k}(g) + \frac{k}{\pi} \int d\sigma d\tau \langle A_- \partial_+ g g^{-1} - A_+ g^{-1} \partial_- g + A_- g A_+ g^{-1} - A_- A_+ \rangle. \quad (2.4)$$

Finally, we can fix the gauge to $\tilde{g} = 1$ to find,

$$S_{k,\lambda}(g, A) = S_{\text{WZW},k}(g) - \frac{k}{\lambda\pi} \int d\sigma d\tau \langle A_+ O_{g^{-1}} A_- \rangle + \frac{k}{\pi} \int d\sigma d\tau \langle A_- \partial_+ g g^{-1} - A_+ g^{-1} \partial_- g \rangle, \quad (2.5)$$

where we introduced the useful operator,

$$O_g = (\mathbf{1} - \lambda D)^{-1}, \quad (2.6)$$

given in terms of the adjoint action $D(T_A) = \text{ad}_g T_A = g T_A g^{-1} = T_B D^B_A(g)$. For the isotropic λ -model, which is the model we consider throughout this paper, we have,

$$\lambda_{AB} = \lambda \langle T_A, T_B \rangle \equiv \lambda \eta_{AB}, \quad \lambda = \frac{k}{k + \kappa^2}. \quad (2.7)$$

The gauge fields are now auxiliary and can be integrated out. Varying the action $S_{k,\lambda}(g)$ with respect to A_\pm we find the constraints,

$$A_+ = \lambda O_g \partial_+ g g^{-1}, \quad A_- = -\lambda O_{g^{-1}} g^{-1} \partial_- g, \quad (2.8)$$

⁴See appendix B for conventions.

Substituting these constraints into eq. (2.5) gives,

$$\begin{aligned}
S_{k,\lambda}(g) &= S_{\text{WZW},k}(g) + \frac{k\lambda}{\pi} \int d\sigma d\tau R_+^A (O_{g^{-1}})_{AB} L_-^B \\
&= \frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau L_+^A \eta_{AB} L_-^B + \frac{k\lambda}{\pi} \int d\sigma d\tau R_+^A (O_{g^{-1}})_{AB} L_-^B \\
&\quad + \frac{k}{24\pi} \int_{M_3} F_{ABC} L^A \wedge L^B \wedge L^C,
\end{aligned} \tag{2.9}$$

in which Lie algebra indices out of position are raised and lowered with the metric $\eta = \langle \cdot, \cdot \rangle$ and we work in term of the Maurer-Cartan forms $L = g^{-1}dg = -iL^A T_A$ and $R = dgg^{-1} = -iR^A T_A$. From the above λ action it is straightforward to read off the target space data which can be expressed in terms of the left-invariant forms L^A as:

$$\begin{aligned}
ds_{\lambda}^2 &= k (O_{g^{-1}} + O_g - \eta)_{AB} L^A \otimes L^B, \\
B_{\lambda} &= B_{\text{WZW}} + \frac{k}{2} (O_{g^{-1}} - O_g)_{AB} L^A \wedge L^B,
\end{aligned} \tag{2.10}$$

where we have used that $R^A = D^A_B(g)L^B$ and in which $dB_{\text{WZW}} = \frac{k}{6} F_{ABC} L^A \wedge L^B \wedge L^C$. Equivalently we can use the identity (and this will proof useful later),

$$O_{g^{-1}} + O_g - \eta = (1 - \lambda^2) O_g \eta O_{g^{-1}} = (1 - \lambda^2) O_{g^{-1}} \eta O_g, \tag{2.11}$$

to express the target space metric as,

$$ds_{\lambda}^2 = k \eta_{AB} E^A \otimes E^B, \quad E = \sqrt{1 - \lambda^2} O_{g^{-1}} L, \tag{2.12}$$

with E the vielbein bringing us to the flat frame. In addition the Gaussian elimination of the gauge fields, when performed in a path integral, results in a non-constant dilaton profile,

$$\Phi = \Phi_0 + \frac{1}{2} \log \det O_{g^{-1}}, \tag{2.13}$$

in which constants are absorbed into Φ_0 . Finally, one can derive the classical energy momentum tensor of the λ -model to find,

$$T_{\pm\pm} = k (1 - \lambda^2) \langle A_{\pm}, A_{\pm} \rangle. \tag{2.14}$$

There are two interesting limits at play here [36]; for $\lambda \rightarrow 0$ we see from eq. (2.8) that the fields A_{\pm} will freeze out and, hence, one will reproduce the well-understood WZW model (see appendix B), allowing consistency checks of analyses of the deformation. For small λ the WZW is deformed by a current-current bilinear. In the $\lambda \rightarrow 1$ limit one reproduces the non-Abelian T-dual of the principal chiral model. This limit is more subtle and should be taken by $k \rightarrow \infty$ in eq. (2.7) and expanding group elements around the identity (but see section 5 for more details).

To establish the classical integrability of the λ model it is convenient to work with eq. (2.5) but where we take the gauge fields on-shell eq. (2.8) (although see [36] for the proof of integrability starting from eq. (2.9)). In this way any variation of the action with

respect to A_{\pm} vanishes and calculations simplify. From eq. (2.5) we then find the equation of motion for the group element g to be,

$$D_+(g^{-1}D_-g) = F_{+-}, \tag{2.15}$$

where we introduced the derivative $D_{\pm}\cdot = \partial_{\pm}\cdot - [A_{\pm}, \cdot]$ and the field strength $F_{+-} = \partial_+A_- - \partial_-A_+ - [A_+, A_-]$. Using the on-shell expression for A_{\pm} , eq. (2.8), this can be rewritten as,

$$\partial_{\pm}A_{\mp} = \pm \frac{1}{1+\lambda} [A_+, A_-]. \tag{2.16}$$

Hence, effectively we have recast one second order equation for the field g , by the constraints, as two first order equations for A_{\pm} . It is now straightforward to show that the following Lax connection,

$$\mathcal{L}_{\pm}(z) = -\frac{2}{1+\lambda} \frac{A_{\pm}}{1 \mp z}, \quad z \in \mathbb{C}, \tag{2.17}$$

satisfying the flatness condition $d\mathcal{L} + \mathcal{L} \wedge \mathcal{L} = 0$ is equivalent to the equations of motion (2.16) thereby ensuring its classical integrability [63] (see also the next section).

3 Integrable boundary conditions

3.1 General methodology

This section closely follows [22, 23] for obtaining open string boundary conditions that preserve integrability based on a method first introduced by Cherdnik and Sklyanin [20, 21] in the context of two-dimensional integrable systems. We add here a slightly more general procedure applicable to integrable sigma models which has not been clearly spelled out yet in the literature (however, see [28] for a recent usage hereof in the case of the PCM) but which can lead to distinct integrable D-brane configurations.

Consider first a general (1+1)-dimensional field theory in a spacetime (or worldsheet) Σ parametrised by (τ, σ) on a periodic or infinite line with a global symmetry group G . The model is said to be classically integrable when its equations of motion can be recast in a zero curvature condition of a $\mathfrak{g}^{\mathbb{C}}$ -valued Lax connection one-form $\mathcal{L}(z)$ depending on a spectral parameter $z \in \mathbb{C}$ [63],

$$d\mathcal{L}(z) + \mathcal{L}(z) \wedge \mathcal{L}(z) = 0. \tag{3.1}$$

The Lax $\mathcal{L}(z)$ is defined up to a local gauge transformation by a Lie group element $g(\tau, \sigma) \in G$ given by,

$$\mathcal{L}(z) \rightarrow \mathcal{L}^g(z) = g\mathcal{L}(z)g^{-1} - dg g^{-1}, \tag{3.2}$$

leaving the zero curvature condition (3.1) invariant. In this case, an infinite set of conserved charges can be obtained from the usual transport matrix $T(b, a; z)$ defined by,

$$T(b, a; z) = \overleftarrow{P} \exp \left(- \int_a^b d\sigma \mathcal{L}_{\sigma}(\tau, \sigma; z) \right), \tag{3.3}$$

where we included the explicit dependence on the (worldsheet) coordinates and the arrow specifies the ordering of the integral as per [6]. The transport matrix satisfies the following useful properties,

$$\delta T(b, a; z) = - \int_a^b d\sigma T(b, \sigma; z) \delta \mathcal{L}_\sigma(\tau, \sigma; z) T(\sigma, a; z), \quad (3.4)$$

$$\partial_\sigma T(\sigma, a; z) = - \mathcal{L}_\sigma(\tau, \sigma; z) T(\sigma, a; z), \quad (3.5)$$

$$\partial_\sigma T(b, \sigma; z) = T(b, \sigma; z) \mathcal{L}_\sigma(\tau, \sigma; z), \quad (3.6)$$

$$T(a, a; z) = 1, \quad (3.7)$$

and under the gauge transformation (3.2) it transforms as,

$$T(b, a; z) \rightarrow T^g(b, a; z) = g(\tau, b) T(b, a; z) g^{-1}(\tau, a). \quad (3.8)$$

Using the flatness of the Lax $\mathcal{L}(z)$ together with the above properties, one can now show that,

$$\partial_\tau T(b, a; z) = T(b, a; z) \mathcal{L}_\tau(\tau, a; z) - \mathcal{L}_\tau(\tau, b; z) T(b, a; z). \quad (3.9)$$

Therefore, under periodic boundary conditions $\sigma \simeq \sigma + 2\pi$ (for e.g. the closed string) we find that the trace of the *monodromy matrix* $T(2\pi, 0; z)$ is conserved,⁵

$$\partial_\tau \text{Tr} T(2\pi, 0; z)^n = 0 \quad \forall n \in \mathbb{N}. \quad (3.10)$$

Different sets of conserved charges (local or non-local) can then be obtained from expanding the monodromy matrix or its gauge transformed form around suitable values of the spectral parameter leading typically to Yangian algebra's or quantum groups for the non-local sets of charges, see e.g. [64].

For later convenience, we define here also a generalised transport matrix,

$$T^\Omega(b, a; z) = \overleftarrow{P} \exp \left(- \int_a^b d\sigma \Omega [\mathcal{L}_\sigma(\tau, \sigma; z)] \right), \quad (3.11)$$

where Ω is a constant Lie algebra automorphism. This generalised transport matrix behaves under time derivation as,

$$\partial_\tau T^\Omega(b, a; z) = T^\Omega(b, a; z) \Omega [\mathcal{L}_\tau(\tau, a; z)] - \Omega [\mathcal{L}_\tau(\tau, b; z)] T^\Omega(b, a; z), \quad (3.12)$$

such that $\partial_\tau \text{Tr} T^\Omega(2\pi, 0; z)^n = 0$ for all $n \in \mathbb{Z}$, and under gauge transformations as,

$$T^\Omega(b, a; z) \rightarrow \omega(g(b)) T^\Omega(b, a; z) \omega(g^{-1}(a)), \quad (3.13)$$

where the map $\omega : G \rightarrow G$ is defined as $\omega(e^{tX}) = e^{t\Omega[X]}$ for t small and $X \in \mathfrak{g}$. Here we assumed the corresponding Lie group G to be connected to the identity (in this case ω is a constant Lie *group* automorphism also).

⁵Alternatively, on the infinite line with suitable asymptotic fall-off conditions we find immediately that $\partial_\tau T(+\infty, -\infty; z) = 0$.

When the model is considered on a finite line, e.g. $\sigma \in [0, \pi]$ in the context of sigma models describing open strings, the charges obtained from the above procedure are generically not conserved. Similarly to the loss of conservation of momentum along the spatial direction, integrability might be spoiled. However, with the appropriate boundary conditions one can still obtain an infinite set of conserved charges from the so called *boundary monodromy* object $T_b(z)$ that involves the transport matrix T from the $\sigma = 0$ end of the open string to the $\sigma = \pi$ end *glued* to the generalised transport matrix T^Ω in the reflected region, i.e. going in the other direction. At the boundaries we include the possibility of non-trivial effects incorporated by the so-called reflection matrices U_0 and U_π that are in the Lie group G . Hence we define,⁶

$$T_b(z) = U_0 T_R^\Omega(2\pi, \pi; z) U_\pi^{-1} T(\pi, 0; z), \tag{3.14}$$

where the allowed boundary conditions are encoded in conditions on the reflection matrices and the automorphism Ω . As discussed in [22, 23] the reflection matrices are taken to be constant in time and independent of the spectral parameter.⁷ The transport matrix $T_R(2\pi, \pi; z)$ in the reflected region is constructed from the transformation $\sigma \rightarrow \sigma_R = 2\pi - \sigma$ when $\sigma \in [\pi, 2\pi]$. We will assume in the following the reflected generalised transport matrix to have the form,

$$T_R^\Omega(2\pi, \pi; z) = T^\Omega(0, \pi; -z), \tag{3.15}$$

which will indeed be the case for the λ model.

In general this strongly depends on the specific form of the Lax connection $\mathcal{L}(z)$ but the following procedure can be easily adapted to other cases. Similar to the bulk model, we impose integrability by requiring that the time derivative of the boundary monodromy matrix is given by a commutator,

$$\partial_\tau T_b(z) = [T_b(z), N(z)], \tag{3.16}$$

for some matrix $N(z)$, such that $\text{Tr} T_b(z)^n$ is conserved for any $n \in \mathbb{N}$. Explicitly we find using the formulae (3.9) and (3.12) that,

$$\begin{aligned} \partial_\tau T_b(z) = & U_0 [T^\Omega(0, \pi; -z) \mathcal{L}_\tau^\Omega(\pi; -z) - \mathcal{L}_\tau^\Omega(0; -z) T^\Omega(0, \pi; -z)] U_\pi^{-1} T(\pi, 0; z) \\ & + U_0 T^\Omega(0, \pi; -z) U_\pi^{-1} [T(\pi, 0; z) \mathcal{L}_\tau(0; z) - \mathcal{L}_\tau(\pi; z) T(\pi, 0; z)], \end{aligned} \tag{3.17}$$

discarding here the τ -dependence and using the notation $\mathcal{L}^\Omega(z) = \Omega[\mathcal{L}(z)]$. One can show that the integrability condition (3.16) sufficiently holds for $N(z) = \mathcal{L}_\tau(0; z)$ when we require the following boundary conditions on both the open string ends:

$$\mathcal{L}_\tau(\tau, 0; z) = U_0 \Omega[\mathcal{L}_\tau(\tau, 0; -z)] U_0^{-1}, \tag{3.18}$$

⁶When the Lie algebra automorphism Ω is taken to be inner we recover the discussion of [22] up to a suitable redefinition of the reflection matrices. The possibility of Ω to be outer, however, leads to interesting non-trivial boundary conditions.

⁷These conditions are preferred for the interpretation of the boundary conditions as physical D-brane configurations. However the spectral parameter independence e.g. might be relaxed as in [28] where the objective is to map the boundary conditions to known boundary scattering matrices of the quantum theory containing a free parameter.

and similarly on $\sigma = \pi$ (but where in principal the reflection matrix U_π can be different allowing the open string to connect different D-branes). Substituting the Lax connection of the considered model in eq. (3.18) imposes integrable boundary conditions on the field variables, together with consistency conditions on the automorphism Ω and the reflection matrix U as will be clear in the coming subsection.

However this is not the end of the story: the above procedure leads to sufficient conditions for integrability of the boundary model but they are not necessary. We can cook up any exotic boundary monodromy matrix $T_b(z)$; as long as it satisfies $\partial_\tau T_b(z) = [T_b(z), N(z)]$ for some $N(z)$ an infinite set of conserved charges can be constructed. It is e.g. an interesting possibility to consider also a gauge transformation in the reflected region,

$$\begin{aligned} T_b(z, \delta) &= U_0 T_R^{g\Omega} \left(2\pi, \pi; \tilde{\delta}_R; w \right) U_\pi^{-1} T(\pi, 0; \delta; z) \\ &= U_0 \omega(g(0)) T^\Omega \left(0, \pi; \tilde{\delta}; -w \right) \omega(g(\pi))^{-1} U_\pi^{-1} T(\pi, 0; \delta; z), \end{aligned} \quad (3.19)$$

where we used eq. (3.13) and eq. (3.15) and we included in the transport matrix⁸ the possible dependence on δ representing (multiple) deformation parameters. Moreover, in the reflected region there is the possibility that the spectral parameter and the deformation parameters change, meaning $w = F(z)$ and $\tilde{\delta} = G(\delta)$ for some suitable functions F and G . Although we will not consider this for the λ -deformed model, we are convinced that a detailed investigation of this possibility in other integrable models will lead to interesting results and we hope to return to this point in the future.

3.2 Applied to λ -deformations

Having the Lax connection of the isotropic λ -deformation on group manifolds at hand one can now derive the integrable boundary conditions corresponding to the boundary monodromy matrix $T_b(z)$ given in eq. (3.14). One can check that eq. (3.15) indeed holds for the Lax (2.17). Using now the constraints (2.8) we can write the Lax in a convenient form in terms of the Maurer-Cartan forms $L_- = g^{-1} \partial_- g$ and $R_+ = \partial_+ g g^{-1}$,

$$\mathcal{L}_\tau(z) = \frac{2\lambda}{1+\lambda} \frac{1}{1-z^2} \left(O_{g^{-1}}[L_-] - O_g[R_+] - z \left(O_{g^{-1}}[L_-] + O_g[R_+] \right) \right), \quad (3.20)$$

where recall $O_g = (\mathbf{1} - \lambda D)^{-1}$. Plugging the above into the result (3.18) and requiring the reflection matrices to be z -independent leads to the following boundary conditions,⁹

$$O_{g^{-1}}[L_-]|_{\partial\Sigma} = -\Omega \cdot O_g[R_+]|_{\partial\Sigma}, \quad (3.21)$$

where, for consistency, Ω should be a constant *involutive* Lie algebra automorphism. A further restriction comes from demanding the (classical) conformal boundary condition (see eq. (A.7)) which requires the energy-momentum tensor to satisfy $T_{++}| = T_{--}|$. Using the

⁸The cumbersome notation $T_R^{g\Omega}$ represents the gauge transformed transport, acted on by the automorphism Ω and reflected.

⁹Here we absorbed the reflection matrices $U_{0/\pi}$ (which are essentially an additional inner automorphism action) into the definition of the automorphism Ω and discarded the indication of the open string end. However one should keep in mind that in principle Ω can be different on each end.

form of the stress tensor of the λ model (2.14) we require that Ω preserves the inner product $\langle \cdot, \cdot \rangle$. This is important for the boundary conditions to preserve conformal invariance in the WZW limit $\lambda \rightarrow 0$ [4, 5, 11–15]. Summarising, Ω is a constant Lie algebra metric-preserving involutive automorphism:

$$\Omega \in \text{Aut}(\mathfrak{g}), \quad \Omega^2 = 1, \quad \Omega^T \eta \Omega = \eta. \tag{3.22}$$

The integrable boundary conditions thus obtained reduce in the $\lambda \rightarrow 0$ limit exactly to chiral-algebra preserving symmetric D-branes of the WZW model [4, 5, 11–14] (in the terminology of [14] the type D conditions (B.8)).

3.3 Interpretation as twisted conjugacy classes

Like in the WZW case, we desire a geometrical interpretation of the (integrable) boundary conditions (3.21) as Dirichlet and Neumann conditions on $g : \partial\Sigma \rightarrow N$ defining a D-brane N . In this regard it is important to realise that eq. (3.21) takes values in the tangent space of G at the identity $T_e G \simeq \mathfrak{g}$. To interpret the geometry of the D-brane configurations one needs local conditions on an arbitrary point $g \in G$ obtained by translating eq. (3.21) to $T_g G$ (which is non-trivial for non-Abelian group manifolds). However, as λ deformations of WZW theories deform only the target space data while the tangent space $T_g G$ is independent of the choice of metric, it is clear that only the size of the classical D-branes can change while their topology must be unaffected compared to the well-known WZW branes. We will show here that this is indeed the case leading to (integrable) boundary conditions corresponding to D-brane configurations that are (twisted) conjugacy classes [12–14].

First, we should split the tangent space $T_g G$ at $g \in G$ orthogonally to the D-brane N with respect to the λ -deformed metric (2.12) (assuming the metric restricts non-degenerately to N),

$$T_g G = T_g N \oplus T_g N^\perp. \tag{3.23}$$

Important here is that the object $\tilde{\Omega}_g \equiv O_{g^{-1}}^{-1} \cdot \Omega \cdot O_g$ gluing left to right currents in eq. (3.21) is easily shown to preserve the deformed metric (2.12) at g provided that Ω preserves the inner product $\eta = \langle \cdot, \cdot \rangle$. Indeed, writing the metric as

$$G_\lambda = k E^T \eta E = k (1 - \lambda^2) L^T O_{g^{-1}} \eta O_g L = k (1 - \lambda^2) L^T O_g \eta O_{g^{-1}} L, \tag{3.24}$$

we have $\tilde{\Omega}_g^T G_\lambda \tilde{\Omega}_g = G_\lambda$. Moreover, it is straightforward to show that the deformed metric at g is invariant under an adjoint action by g , i.e. $D^T G_\lambda D = G_\lambda$.

With these properties of the deformed metric at hand we can now exactly follow the procedure used in the WZW case of [14, 15] for finding the tangent space $T_g N$ to the D-brane when treating $\tilde{\Omega}_g$ as the gluing matrix. This leads to,

$$T_g N = \left\{ u - O_{g^{-1}}^{-1} \cdot \Omega \cdot O_g [g^{-1} u] g \mid \forall u \in T_g G \right\}. \tag{3.25}$$

Using the transitivity property of left and right translations on group manifolds, together with Ω being an automorphism (and thus bijective), there exists for every $u \in T_g G$ a Lie algebra element X such that,

$$u = -g O_{g^{-1}}^{-1} \Omega [X]. \tag{3.26}$$

Hence, $T_g N$ is equivalently given by,

$$\begin{aligned} T_g N &= \left\{ O_g^{-1} [X] g - g O_{g^{-1}}^{-1} \Omega [X] \mid \forall X \in \mathfrak{g} \right\} \\ &= \left\{ (\mathbf{1} + \lambda \Omega) [X] g - g (\lambda \mathbf{1} + \Omega) [X] \mid \forall X \in \mathfrak{g} \right\}. \end{aligned} \quad (3.27)$$

Contrary to the WZW case, we have here the extra property on the Lie algebra automorphism Ω that it is involutive, $\Omega^2 = 1$, and thus defines a symmetric space decomposition of the Lie algebra \mathfrak{g} :

$$\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{k}, \quad (3.28)$$

where $\Omega[\mathfrak{h}] = \mathfrak{h}$, $\Omega[\mathfrak{k}] = -\mathfrak{k}$ and,

$$[\mathfrak{h}, \mathfrak{h}] \subset \mathfrak{h}, \quad [\mathfrak{h}, \mathfrak{k}] \subset \mathfrak{k}, \quad [\mathfrak{k}, \mathfrak{k}] \subset \mathfrak{h}. \quad (3.29)$$

Hence, also $T_g N$ splits accordingly,

$$T_g N = \left\{ (1 + \lambda) (Hg - gH) \mid \forall H \in \mathfrak{h} \right\} \oplus \left\{ (1 - \lambda) (Kg + gK) \mid \forall K \in \mathfrak{k} \right\}, \quad (3.30)$$

It is now possible to rescale $(1 + \lambda)H \rightarrow H$ and $(1 - \lambda)K \rightarrow K$ such that,

$$\begin{aligned} T_g N &= \left\{ Hg - gH \mid \forall H \in \mathfrak{h} \right\} \oplus \left\{ Kg + gK \mid \forall K \in \mathfrak{k} \right\} \\ &= \left\{ Xg - g\Omega[X] \mid \forall X \in \mathfrak{g} \right\}. \end{aligned} \quad (3.31)$$

As expected, this is exactly the tangent space to the twisted conjugacy class $C_\omega(g)$ defined by,¹⁰

$$C_\omega(g) = \left\{ h g \omega(h^{-1}) \mid \forall h \in G \right\}, \quad (3.32)$$

shown explicitly in [14, 15]. Hence, the worldvolumes N of the integrable D-brane configurations lie on twisted conjugacy classes $C_\omega(g)$ of the group G on which the deformation is based. In the λ -deformed background only the size of the branes (determined by the induced deformed metric) change, as also illustrated in the following section. The twisted conjugacy classes are classified by the quotient $\text{Out}_0(G) = \text{Aut}_0(G)/\text{Inn}_0(G)$ of metric-preserving outer automorphisms of G since two automorphisms that are related by an inner automorphism in $\text{Inn}_0(G)$ lead to twisted conjugacy classes that differ simply by a group translation [15]. However, the involution condition $\omega^2 = 1$ from integrability does not allow these group translation to be arbitrary and in practice there will only be a small number of them, depending on the dimensionality of G . When the group automorphism ω is taken to be the identity element of $\text{Out}_0(G)$, the twisted conjugacy classes reduce to regular conjugacy classes [12].

Note finally that, using Frobenius' integrability theorem and Ω being an automorphism, the D-brane N is a submanifold of G eliminating the possibility of intersecting integrable D-brane configurations [14, 15] using the methodology outlined in section 3.1.

¹⁰Recall the definition of the map $\omega : G \rightarrow G$ under eq. eq. (3.13).

4 Examples

In this section we will apply the above observations explicitly in two simple examples: the λ deformation based on the $SU(2)$ and $SL(2, \mathbb{R})$ Lie groups. In the compact $SU(2)$ case only regular conjugacy classes exist and we will derive the boundary equations explicitly for them (necessary for section 5). Moreover we will show that the flux quantisation condition remains independent of λ . We will perform a semi-classical analysis of the spectrum of quadratic fluctuations and demonstrate that turning on λ will lift the zero modes of the WZW branes. In the non-compact $SL(2, R)$ the study of both regular and twisted conjugacy classes is possible. Here we will focus on the classical aspects showing only the twisted conjugacy classes to be (classically) physical in contrary to the regular conjugacy classes. Moreover we find again the flux quantisation to remain independent of λ .

4.1 The S^3 deformation

For $\mathfrak{su}(2)$ the metric-preserving algebra automorphisms form the group of rotations $SO(3)$ while $Out_0(SU(2))$ is known to be trivial. The D-branes in the S^3 manifold therefore lie on regular conjugacy classes. In light of this we choose the following convenient parametrisation for the $SU(2)$ group element,

$$\begin{pmatrix} \cos \alpha + i \cos \beta \sin \alpha & e^{-i\gamma} \sin \alpha \sin \beta \\ -e^{i\gamma} \sin \alpha \sin \beta & \cos \alpha - i \cos \beta \sin \alpha \end{pmatrix}, \quad (4.1)$$

such that the S^3 is given by an S^2 parametrised by $\beta \in [0, \pi]$ and $\gamma \in [0, 2\pi]$ fibred over an interval $\alpha \in [0, \pi]$. Regular conjugacy classes are distinguished by $\text{Tr}(g) = 2 \cos \alpha$ constant and so correspond to this S^2 . Note that integrability only allows group translations from involutive inner automorphisms that correspond here to rotations over an angle π . For the WZW analysis of these D2-branes see we refer to [65, 67–69].

We first recall the target space geometry of the λ -deformed theory [36],

$$\begin{aligned} ds_\lambda^2 &= 2k \left(\frac{1+\lambda}{1-\lambda} d\alpha^2 + \frac{1-\lambda^2}{\Delta} \sin^2 \alpha (d\beta^2 + \sin^2 \beta d\gamma^2) \right), \\ H_\lambda &= 4k \frac{2\lambda\Delta + (1-\lambda^2)^2}{\Delta^2} \sin^2 \alpha \sin \beta d\alpha \wedge d\beta \wedge d\gamma, \\ e^{-2\Phi} &= e^{-2\Phi_0} \Delta, \end{aligned} \quad (4.2)$$

where $\Delta = 1 + \lambda^2 - 2\lambda \cos 2\alpha$. Here we note that in performing the Gaussian integration to arrive at the λ model a dilaton (2.13) is produced. In the metric observe that, and this will be important, that the deformation leaves the S^2 intact changing only the radius of this sphere as it is fibred over α .

The integrable boundary condition obtained from (3.21) with $\Omega = 1$ reads,

$$\begin{aligned} \partial_- \alpha| &= -\partial_+ \alpha|, \\ (1 + \lambda^2 - 2\lambda \cos 2\alpha) \partial_- \beta| &= (2\lambda - (1 + \lambda^2) \cos 2\alpha) \partial_+ \beta - (1 - \lambda^2) \sin \beta \sin 2\alpha \partial_+ \gamma|, \\ (1 + \lambda^2 - 2\lambda \cos 2\alpha) \partial_- \gamma| &= (2\lambda - (1 + \lambda^2) \cos 2\alpha) \partial_+ \gamma + (1 - \lambda^2) \csc \beta \sin 2\alpha \partial_+ \beta|. \end{aligned} \quad (4.3)$$

It is immediately clear that α obeys a Dirichlet boundary condition and $X^a = \{\beta, \gamma\}$ obey (generalised) Neumann boundary conditions (A.4) which should take the standard form,

$$\widehat{G}_{ab}(X)\partial_\sigma X^b = \mathcal{F}_{ab}\partial_\tau X^b, \tag{4.4}$$

in which $\mathcal{F}_{ab} = \widehat{B}_{ab} + 4\pi F_{ab}$ ¹¹ (see also appendix A). We first re-express the Neumann boundary condition as,

$$\partial_\sigma \beta| = -\frac{\lambda-1}{\lambda+1} \cot \alpha \sin \beta \partial_\tau \gamma|, \quad \partial_\sigma \gamma| = \frac{\lambda-1}{\lambda+1} \cot \alpha \csc \beta \partial_\tau \beta|, \tag{4.5}$$

and making use of the metric restricted to $\alpha = \text{const}$ we extract the two-form,

$$\mathcal{F} = \frac{k}{2\Delta}(1-\lambda)^2 \sin 2\alpha \sin \beta d\beta \wedge d\gamma. \tag{4.6}$$

We can now evaluate the DBI action (A.10),

$$S_{\text{DBI}} = T_2 \int e^{-\Phi} \sqrt{\widehat{G} + \mathcal{F}} = 4\pi k T_2 e^{-\Phi_0} \sin \alpha. \tag{4.7}$$

where we absorbed a factor of $1-\lambda$ into the constant dilaton $e^{-\Phi_0}$. Naively this would suggest that the only stable D-branes are the ones for which this quantity is minimised i.e. the D0 branes located at $\alpha = 0$ and $\alpha = \pi$. However the flux quantisation stabilises the branes in other locations in a slightly subtle way. There are two well defined forms at play; the NS three form H and a two-form on the D-brane submanifold ω which is, by virtue of the construction, equal to the two-form \mathcal{F} locally. The quantisation is now a statement that the relative cohomology class $[(H, \omega)]/2\pi$ be integral [51, 70–72] demanded by consistency for the definition of the WZ term in the action (2.5) (see also appendix B). Put plainly, the difference in periods of ω over the D2-brane worldvolume N and H on an extension B whose boundary is the D2-brane $\partial B = N$ should be integral i.e.

$$\frac{1}{4\pi} \int_N \omega - \frac{1}{4\pi} \int_B H \in 2\pi \mathbb{Z}. \tag{4.8}$$

For the case at hand, let us locate the D2 brane at $\alpha = \alpha_*$ and integrate H over an extension $\alpha \in [0, \alpha_*]$. This yields

$$\frac{1}{4\pi} \int_B H = -2k\alpha_* + \frac{k(1-\lambda)^2 \sin 2\alpha_*}{\Delta_*}. \tag{4.9}$$

At the same time we have

$$\frac{1}{4\pi} \int_N \omega = \frac{k(1-\lambda)^2 \sin 2\alpha_*}{\Delta_*}, \tag{4.10}$$

so that in the combination entering the quantisation condition eq. (4.8) all dependence on the deformation parameter λ drops out and one recovers the conventional result for the WZW model; there are, in addition to the D0-branes, stabilised D2's located at¹²

$$\alpha_* = \frac{n\pi}{k}, \quad n = 1 \dots k-1. \tag{4.11}$$

¹¹For the level k to obey the conventional quantisation we have used units in which $\alpha' = 2$.

¹²We are assuming throughout that we are in the semi-classical regime and so ignore any consequences of the shift $k \rightarrow k+2$ [1].

Let us now evaluate the dynamics of fluctuations of this D-brane. For that we need to consider dependence on the target space time coordinate; i.e. we need to introduce an extra time-like dimension to the target space. We will choose a synchronous gauge and let the coordinates of the worldvolume of the D2 be $X^a = (t, \beta, \gamma)$. Following [65] we examine fluctuations of the transverse scalar and worldvolume gauge field in the DBI action,

$$S = T_2 \int e^{-\Phi} \sqrt{-\det(\widehat{G}_{ab} + \mathcal{F}_{ab})}, \tag{4.12}$$

where,

$$\mathcal{F}_{ab} = B_{ab} + 2\pi\alpha'(\partial_a A_b - \partial_b A_a). \tag{4.13}$$

For direct comparison to [65] we reinstate explicit factors of α' . It should be emphasised that the metric \widehat{G} needs to be pulled back to the worldvolume according to,

$$\widehat{G}_{ab} = G_{\mu\nu} \partial_a X^\mu \partial_b X^\nu, \tag{4.14}$$

which induces derivatives for fluctuations in the transverse scalar. To perform this analysis it is helpful to pick a gauge for the antisymmetric field [36],

$$B = -k\alpha' \left(\alpha - \frac{(1-\lambda)^2}{\Delta} \cos \alpha \sin \alpha \right) \sin \beta d\beta \wedge d\gamma. \tag{4.15}$$

Then we make the ansatz for fluctuations,

$$\alpha = \alpha_* + \delta(X), \quad A_t = 0, \quad A_\beta = \frac{k}{2\pi} a_\beta(X), \quad A_\gamma = \frac{k}{2\pi} \alpha_* (\cos \beta - 1) + \frac{k}{2\pi} a_\gamma(X). \tag{4.16}$$

Now the procedure is to expand the DBI action to quadratic order in the fluctuation and to extract classical equations of motion.¹³ The intermediate steps of this calculation are extremely unedifying and made algebraically complicated by the appearance of the function $\Delta(\alpha)$ in various places. However, somewhat remarkably to a large extent all of the complications cancel out to leave a very simple result. In terms of the covariant fluctuation $g(t, \beta, \gamma) = -\frac{1}{\sin \beta} (\partial_\beta \alpha_\gamma - \partial_\gamma \alpha_\beta)$ we find equations of motion,

$$\frac{d^2}{dt^2} \begin{pmatrix} \delta \\ g \end{pmatrix} = -\frac{1}{k\alpha'} \frac{1+\lambda^2}{1-\lambda^2} \begin{pmatrix} 2 + \frac{(1+\lambda)^2}{1+\lambda^2} \square & 2 \\ 2\square & \frac{(1+\lambda)^2}{1+\lambda^2} \square \end{pmatrix} \begin{pmatrix} \delta \\ g \end{pmatrix}, \tag{4.17}$$

in which \square is the Laplacian on the S^2 . This operator can be diagonalised in terms of an expansion in spherical harmonics. In the l^{th} sector (i.e. where $\square = l(l+1)$) we find that the eigenvalues are,

$$\frac{1}{k(1-\lambda^2)} (1+l) ((1+\lambda)^2 l + 2(1+\lambda^2)), \quad \frac{1}{k(1-\lambda^2)} l (l(1+\lambda)^2 - (1-\lambda)^2). \tag{4.18}$$

These are all positive, hence stable fluctuations of positive mass. Since g carries no s -wave as a consequence of flux-quantisation and that the s -wave of δ has a frequency squared of

¹³As in [65] in the expansion there is a linear term proportional to the fluctuation of the quantised D0 charge which must necessarily vanish and so we neglect it in what follows.

$\frac{2}{k\alpha} \frac{1+\lambda^2}{1-\lambda^2}$ — it is not a moduli. It is interesting to notice that the p -wave triplet (i.e. $l = 1$) acquires a positive mass for $\lambda \neq 0$; this lifting of zero modes is a reflection of the fact that one of the $SU(2)$ symmetries is broken in the target space metric and so we are not longer free to move the S^2 of the D-brane about the S^3 . Put another way, in the undeformed theory these zero modes on the worldvolume are associated Goldstone modes from breaking the $SU(2)$ global symmetry of the target space by the D-brane; in the deformed theory there is no longer such an $SU(2)$ symmetry to be broken and hence no corresponding Goldstone. A further feature of the spectrum is that it inherits a \mathbb{Z}_2 invariance $\lambda \rightarrow \lambda^{-1}$, $k \rightarrow -k$ displayed by the λ -deformed worldsheet theory [66].

4.2 The AdS_3 deformation

For the $\mathfrak{sl}(2, \mathbb{R})$ algebra it can be shown that the metric-preserving automorphisms form the group $SO(1, 2) = SO(1, 2)^+ \cup SO(1, 2)^-$ where $SO(1, 2)^+$ correspond to the usual rotations and boosts, while $SO(1, 2)^-$ transformations are obtained from an additional reflection and time-reversal. The metric-preserving outer automorphism group $Out_0(SL(2, \mathbb{R}))$ descends from the latter and can be shown to have, besides the identity, one non-trivial element given in convenient representation by the conjugation $\omega(g) = \omega_1 g \omega_1^{-1}$ with

$$\omega_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \notin SL(2, \mathbb{R}). \tag{4.19}$$

The corresponding Lie algebra automorphism Ω defined by $\Omega[T_A] = \Omega^B{}_A T_B = \omega_1 T_A \omega_1^{-1}$ is readily shown to be an involution and therefore defining with (3.21) consistent integrable boundary conditions. Note that we might as well represent the non-trivial $Out_0(SL(2, \mathbb{R}))$ element by a conjugation with,

$$\omega_2 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \notin SL(2, \mathbb{R}), \tag{4.20}$$

which is connected to ω_1 with an involutive inner automorphism that corresponds in $SO(1, 2)$ with a rotation over π . Moreover, it is important to emphasise that this inner automorphism is the only allowed group translation leading to integrable D-brane configurations in AdS_3 . We are thus allowed to make two distinguished cases in the analysis of D-branes in the λ -deformed AdS_3 corresponding to regular and twisted conjugacy classes.

First, let us parametrise the $SL(2, \mathbb{R})$ in a general way as,

$$g = \begin{pmatrix} X_0 + X_1 & X_2 + X_3 \\ X_2 - X_3 & X_0 - X_1 \end{pmatrix} \tag{4.21}$$

with X_i , $i = \{0, 1, 2, 3\}$, real and with the defining relation $-X_0^2 + X_1^2 + X_2^2 - X_3^2 = -1$, making apparent the AdS_3 embedding.

The regular conjugacy classes (obtained by taking ω the identity) are distinguished by $Tr(g) = 2X_0$ constant and substituting this into the defining relation one finds the geometry of the corresponding D-branes (see also [68, 69, 73]). The geometry will depend

on the values of X_0 ; for $X_0 > 1$ the conjugacy classes correspond to de Sitter D1-strings, for $X_0 < 1$ they correspond to H_2 instantons and for $X_0 = 1$ to the future- and past light-cone. In the next, we will consider only the former de Sitter D1-strings since the study of instantons is beyond the goal of this paper and for the latter case the metric will be degenerate. However, as shown by [73], the de Sitter WZW-branes are tachyonic and, as we will shortly touch upon, they will stay so when turning on the deformation.

The twisted conjugacy classes (3.32) are obtained by conjugation with ω_1 ,

$$C_\omega(g) = \{h g \omega_1 h^{-1} \mid \forall h \in G\} \omega_1^{-1}, \tag{4.22}$$

and are thus distinguished by $\text{Tr}(g \omega_1) = 2X_1$ constant. The corresponding D-brane configurations are, for any $X_1 \in \mathbb{R}$, two-dimensional Anti de Sitter D1-strings (see also [73]). Equivalently, when conjugating with ω_2 , twisted conjugacy classes will be distinguished by $\text{Tr}(g \omega_2) = 2X_2$ constant corresponding again to AdS D1-strings. The choice of representation depends on how one wants to analyse these D-brane configurations together with the choice of parametrisation of the $\text{SL}(2, \mathbb{R})$ group element. In both cases, however, one sees from the defining AdS₃ relation that the *integrable* AdS₂ branes are static configurations. In the WZW case, these D-branes configurations are shown to be physical in [73].

dS D1-strings. A convenient parametrisation to describe the dS D1-strings is one where we replace in (4.21) the elements by,

$$X_0 = \cosh \psi, \quad X_3 = \sinh \psi \sinh \tau, \quad X_1 + iX_2 = \sinh \psi \cosh \tau e^{i\phi} \tag{4.23}$$

with $\psi \in [0, \infty[$, $\tau \in]-\infty, \infty[$ and $\phi \in [0, 2\pi]$ (although, they are not good global coordinates). Here the AdS₃ is build up out of fixed ψ -slices of dS₂ spacetimes parametrised by τ and ϕ corresponding to the dS D1-strings. Note that in this coordinate system we describe D1-strings that are static configurations in AdS₃.

The target space geometry of the λ -deformed AdS₃ is,

$$\begin{aligned} ds_\lambda^2 &= 2k \left(\frac{1+\lambda}{1-\lambda} d\psi^2 + \frac{1-\lambda^2}{\widehat{\Delta}} \sinh^2 \psi (-dt^2 + \cosh^2 t d\phi^2) \right) \\ H_\lambda &= 4k \frac{2\lambda \widehat{\Delta} + (1-\lambda^2)^2}{\widehat{\Delta}^2} \sinh^2 \psi \cosh \tau d\psi \wedge d\tau \wedge d\phi \\ e^{-2\Phi} &= e^{-2\Phi_0} \widehat{\Delta} \end{aligned} \tag{4.24}$$

with $\widehat{\Delta} = 1 + \lambda^2 - 2\lambda \cosh 2\psi$. In these coordinates it is obvious that the deformation leaves the dS₂ D1-strings intact but changing the radius with a squashing factor $\frac{1-\lambda^2}{\widehat{\Delta}}$.

Comparing the integrable boundary conditions obtained from (3.21) with $\Omega = 1$ with the boundary conditions from the sigma model approach, i.e. Dirichlet (A.3) and (generalised) Neumann (A.4), one can extract the two-form \mathcal{F} on the dS D1-brane to find,

$$\mathcal{F} = k \frac{(1-\lambda)^2}{\widehat{\Delta}} \sinh 2\psi \cosh \tau d\tau \wedge d\phi. \tag{4.25}$$

See also [12, 70, 71] for a general formula in terms of the gluing matrix. The induced metric \widehat{G} on the D1-brane is obtained simply by enforcing $\psi = \text{constant}$ in eq. (4.24). The DBI action now evaluates to (absorbing a factor $1 - \lambda$ into the constant dilaton),

$$S_{\text{DBI}} = T_1 \int e^{-\Phi} \sqrt{-\det(\widehat{G}_{ab} + \mathcal{F}_{ab})} = 4\pi k T_1 e^{-\Phi_0} \int d\tau \sqrt{-\sinh^2 \psi \cosh^2 \tau} \quad (4.26)$$

and, hence, is supercritical.

One could equally perform this analysis in the global cylindrical coordinates along the lines of [73] to describe dynamical configurations of a circular D1-string and argue that these are unphysical trajectories. We expect however no new information to be gained.

Anti de Sitter D1-strings. At first sight a logical coordinate system to describe the AdS D1-strings seems to be the global AdS coordinates where the elements of (4.21) are replaced by,

$$X_0 + iX_3 = \cosh \psi \cosh \omega e^{i\tau}, \quad X_1 = \sinh \psi, \quad X_2 = \cosh \psi \sinh \omega \quad (4.27)$$

with $\{\psi, \tau, \omega\} \in \mathbb{R}^3$. The twisted conjugacy class (4.22) (obtained by conjugation with ω_1 of eq. (4.19)) lie along fixed ψ -slices which correspond to AdS₂ spacetimes parametrised by τ and ω .

In this coordinate system the target space geometry of the λ -deformed theory is,

$$\begin{aligned} ds_\lambda^2 = & 2k \frac{1 + \lambda}{1 - \lambda} \left(\frac{\widetilde{\Delta} + 4\lambda(\cos^2 \tau \cosh^2 \omega - 1)}{\widetilde{\Delta}} d\psi^2 + 2\lambda \frac{\sin 2\tau \cosh^2 \omega \sinh 2\psi}{\widetilde{\Delta}} d\psi d\tau \right. \\ & - 2\lambda \frac{\cos^2 \tau \sinh 2\omega \sinh 2\psi}{\widetilde{\Delta}} d\psi d\omega + \cosh^2 \psi \left(-\frac{(1 + \lambda)^2 - 4\lambda \cos^2 \tau}{\widetilde{\Delta}} \cosh^2 \omega d\tau^2 \right. \\ & \left. \left. + 2\lambda \frac{\sin 2\tau \sinh 2\omega}{\widetilde{\Delta}} d\tau d\omega + \frac{(1 - \lambda)^2 - 4\lambda \cos^2 \tau \sinh^2 \omega}{\widetilde{\Delta}} d\omega^2 \right) \right) \\ H_\lambda = & 4k \frac{2\lambda \widetilde{\Delta} + (1 - \lambda^2)^2}{\widetilde{\Delta}} \cosh^2 \psi \cosh \omega d\psi \wedge d\tau \wedge d\omega \\ e^{-2\Phi} = & e^{-2\Phi_0} \widetilde{\Delta} \end{aligned} \quad (4.28)$$

with $\widetilde{\Delta} = (1 + \lambda^2) - 4\lambda \cos^2 \tau \cosh^2 \omega \cosh^2 \psi$. One can readily verify that in the WZW $\lambda \rightarrow 0$ limit the metric reduces to the obvious slicing of AdS₃ by AdS₂ spacetimes along ψ . However, when turning on the deformation this slicing becomes obscure and one can not read of a “squashing” factor of the AdS D1-strings in contrary to the dS case of above. An explicit analysis of the integrable boundary conditions (3.21) with the conjugation by ω_1 teaches us however that it is indeed the ψ direction that is Dirichlet. The induced metric \widehat{G} on the brane is thus obtained by enforcing ψ constant in (4.28). Comparing again the integrable boundary conditions to the ones obtained from the general sigma model, we can extract the gauge invariant two-form \mathcal{F} on the AdS D1-string,

$$\mathcal{F} = k \frac{(1 + \lambda)^2}{\widetilde{\Delta}} \sinh 2\psi \cosh \omega d\tau \wedge d\omega. \quad (4.29)$$

The DBI action simply gives,

$$S_{\text{DBI}} = T_1 \int e^{-\Phi} \sqrt{-\det(\widehat{G}_{ab} + \mathcal{F}_{ab})} = 2k T_1 e^{-\Phi_0} \int d\tau d\omega \cosh \psi \cosh \omega, \quad (4.30)$$

where we absorbed a factor of $1 + \lambda$ into the constant $e^{-\Phi_0}$. The action is readily minimised when $\psi_0 = 0$ where the D1-string is still of finite size. However, when making appropriate gauge choices for the induced antisymmetric field \widehat{B} and the U(1) field strength F , in particular one where $A_\tau = 0$, one can identify the usual quantisation condition from the Gauss constraint of QED₂ (following [73]) given by,

$$4\pi T_1 e^{-\Phi_0} \frac{\widetilde{\Delta} \mathcal{F}_{\tau\omega}}{\sqrt{-\widetilde{\Delta} \det(\widehat{G}_{ab} + \mathcal{F}_{ab})}} = 4\pi T_1 e^{-\Phi_0} \sinh \psi = q \in \mathbb{Z} \quad (4.31)$$

with the integer q known to be the number of fundamental strings bound to the D1-string [74]. Similar to the SU(2) example we thus have again, due to a flux quantisation condition, additional locations where the D1-strings are stabilised, independent of the value of λ . However, contrary to the SU(2) case, this does not descend from topological conditions of the boundary WZW (see also appendix B) as AdS₃ is topologically trivial.

One could instead also consider the twisted conjugacy class obtained from conjugation by ω_2 of eq. (4.20). The corresponding worldvolume is then characterised by $X_2 = \cosh \psi \sinh \omega$ constant and is obtained from the previous fixed ψ -slices by a rotation over π in the spatial directions. The analysis of these worldvolumes are easily done in the Poincaré coordinates $(t, x, u) \in \mathbb{R}^3$ that are obtained by,

$$X_0 + X_1 = u, \quad X_0 - X_1 = \left(\frac{1}{u} + u(x+t)(x-t) \right), \quad X_2 \pm X_3 = u(x \pm t). \quad (4.32)$$

Eliminating then the coordinate u by $ux = C$ with C a constant one can identify the gauge-invariant two-form \mathcal{F} to be,

$$\mathcal{F} = 2k \frac{(1 + \lambda)^2}{\Delta_P} \frac{C^2}{x^2} dt \wedge dx, \quad (4.33)$$

with the dilaton factor Δ_P in Poincaré coordinates. The Gauss constraint similarly quantises the constant C as,

$$4\pi T_1 e^{-\Phi_0} C = q \in \mathbb{Z}, \quad (4.34)$$

where again a factor of $1 + \lambda$ was absorbed in the constant $e^{-\Phi_0}$.

We conclude that from a classical point of view the AdS D1-strings in the λ background are still physical. Moreover they are stabilised in the same manner as in the WZW case, i.e. due to flux quantisation. Semi-classically it would be interesting to perform a stability analysis of the quadratic fluctuations as was done for SU(2) in section 4.1. In the λ case we expect the same stability conclusion as the WZW case (see e.g. [75, 76]) accompanied with a lifting of zero modes. However, we will not pursue this interesting point here.

5 Relation to generalised T-dualities

5.1 The non-Abelian T-dual limit

In a scaling limit $\lambda \rightarrow 1$ the λ -deformation recovers the non-Abelian T-dual of the principal chiral model [36]. To achieve this limit one expands the group element around the identity,

$$g = \mathbf{1} + \frac{i}{k} v^A T_A + \mathcal{O}\left(\frac{1}{k^2}\right), \quad (5.1)$$

and takes $k \rightarrow \infty$ to find,

$$L_-^A = -\frac{\partial_- v^A}{k} + \mathcal{O}\left(\frac{1}{k^2}\right), \quad R_+^A = -\frac{\partial_+ v^A}{k} + \mathcal{O}\left(\frac{1}{k^2}\right), \quad D_{AB} = \eta_{AB} + \frac{F_{AB}{}^C v_C}{k}. \quad (5.2)$$

In this limit the λ -deformed action (2.9) becomes the non-Abelian T-dual with respect to the G_L action of the PCM (2.1),

$$S = \frac{1}{\pi} \int \partial_+ v_A (\mathcal{M}^{-1})^{AB} \partial_- v_B + \mathcal{O}\left(\frac{1}{k}\right), \quad \text{with } \mathcal{M} = \kappa^2 \eta_{AB} + F_{AB}{}^C v_C. \quad (5.3)$$

For the case of SU(2) in the parametrisation used in eq. (4.1) this limit is achieved by taking $\alpha = \frac{r}{2k}$ with

$$v_1 = -\frac{r}{\sqrt{2}} \sin \beta \sin \gamma, \quad v_2 = \frac{r}{\sqrt{2}} \sin \beta \cos \gamma, \quad v_3 = \frac{r}{\sqrt{2}} \cos \beta. \quad (5.4)$$

The metric becomes

$$ds_{NAIT}^2 = \frac{1}{\kappa^2} \left(dr^2 + \frac{r^2 \kappa^4}{r^2 + \kappa^4} ds^2(S^2) \right). \quad (5.5)$$

where $ds^2(S^2) = d\beta^2 + \sin^2 \beta d\gamma^2$. The first point to note is that in the limit the two-sphere remains intact so one anticipates that the D-branes described previously are preserved. Performing the $\lambda \rightarrow 1$ limit procedure on the boundary conditions of eq. (4.3) yields,

$$\begin{aligned} \partial_- r| &= -\partial_+ r|, \\ (r^2 + \kappa^4) \partial_- \beta| &= (r^2 - \kappa^4) \partial_+ \beta - 2r\kappa^2 \sin \beta \partial_+ \gamma| \\ (r^2 + \kappa^4) \partial_- \gamma| &= 2r\kappa^2 \csc \beta \partial_+ \beta + (r^2 - \kappa^4) \partial_+ \gamma|. \end{aligned} \quad (5.6)$$

To understand these conditions it is useful to work instead with the following combination of worldsheet derivatives

$$\mathring{L}_+ = -\mathcal{M}^{-T} \partial_+ v, \quad \mathring{L}_- = +\mathcal{M}^{-1} \partial_- v, \quad (5.7)$$

which can be used to construct a Lax connection for the dynamics of the non-Abelian T-dual theory eq. (5.3):

$$\mathring{L}_\pm[z] = \frac{1}{1 \mp z} \mathring{L}_\pm, \quad [\partial_+ + \mathring{L}_+, \partial_- + \mathring{L}_-] = 0. \quad (5.8)$$

In terms of these the boundary conditions of eq. (5.6) take a remarkably simple form

$$\mathring{L}_+| = \mathring{L}_-|. \quad (5.9)$$

This property of the boundary conditions holds in general, at least in the case where we set the extra automorphism $\Omega = 1$, and follows due to the limit

$$\frac{1}{k + \kappa^2} O_g \rightarrow \mathcal{M}^{-T}, \tag{5.10}$$

from eq. (3.21).

Now for the punchline. The non-Abelian T-dual theory described by eq. (5.3) is classically equivalent to the principal chiral theory

$$S_{\text{PCM}} = -\frac{\kappa^2}{\pi} \int d\sigma d\tau \langle \tilde{g}^{-1} \partial_+ \tilde{g} \tilde{g}^{-1} \partial_- \tilde{g} \rangle. \tag{5.11}$$

The T-duality transformation rules are non-local in terms of the coordinates of the sigma-models but in terms of world sheet derivatives are a canonical transformation of the form

$$\tilde{L}_\pm^a = \dot{L}_\pm, \quad \tilde{g}^{-1} \partial_\pm \tilde{g} = -i \tilde{L}_\pm^a T_a. \tag{5.12}$$

Thus we can immediately conclude that under non-Abelian T-duality the D2-brane described by the boundary condition (5.6) results in

$$\tilde{g}^{-1} \partial_\sigma \tilde{g} | = 0, \tag{5.13}$$

i.e. a space-filling D3-brane.

This analysis agrees exactly with the integrable boundary conditions that we would obtain for the principal chiral model by substituting the Lax (5.8) into the result (3.18) (note that this holds as the Lax (5.8) satisfies eq. (3.15)) which leads to the boundary conditions,

$$\dot{L}_\pm | = \Omega(\dot{L}_\mp) | = \Omega \cdot D^T(\dot{R}_\mp) |. \tag{5.14}$$

Interestingly, these have the form of type N gluing conditions. In the context of the WZW, these type N gluings eq. (B.9) preserve conformal invariance but break the chiral-algebra (and for which a good understanding is still lacking to our knowledge). It would be interesting to relate these observations to the recently appeared [56].

5.2 The pseudo-dual limit

A second interesting limit described in [77] is a scaling limit as $\lambda \rightarrow -1$ which results in the pseudo-dual [78] of the principal chiral model. The pseudo-dual theory is obtained by replacing the currents of the PCM with scalars according to

$$\tilde{g}^{-1} \partial^\mu \tilde{g} = \epsilon^{\mu\nu} \partial_\nu \phi, \tag{5.15}$$

such that the conservation of the currents becomes a trivial consequence of the commutation of partial derivatives. The Bianchi identities and equations of motion written in terms of ϕ can be obtained from a “dual” action. However this is not a true dualisation [78] — even at the classical level the two theories are not related by a canonical transformation and at the quantum level they have striking differences. The PCM is asymptotically free where as the pseudo-dual is not. The PCM is quantum integrable whereas the pseudo-dual displays

particle production. Nonetheless it is intriguing that the pseudo-dual action follows from the λ -theory upon the scaling

$$\lambda = -1 + \frac{\kappa^2}{k^{\frac{1}{3}}}, \quad g = \mathbf{1} + \frac{i}{k^{\frac{1}{3}}} \phi^A T_A + \dots, \quad k \rightarrow \infty. \quad (5.16)$$

Evidently in taking this limit one needs to relax the requirement that $\lambda \in [0, 1]$ required of the original construction of the λ -model.

Let us see the effect of this on the boundary conditions in the context of the SU(2) theory. The scaling is quite similar; we define $\alpha = \frac{r}{2k^{\frac{1}{3}}}$ and

$$\phi^1 = -\frac{r}{\sqrt{2}} \sin \beta \sin \gamma, \quad \phi^2 = \frac{r}{\sqrt{2}} \sin \beta \cos \gamma, \quad \phi^3 = \frac{r}{\sqrt{2}} \cos \beta. \quad (5.17)$$

The limit $k \rightarrow \infty$ can then be taken in the boundary conditions of eq. (4.3) resulting simply in

$$\partial_\tau \phi^i| = 0. \quad (5.18)$$

In terms of the PCM variables we recover, as with the non-Abelian T limit, a D3-brane described by

$$\tilde{g}^{-1} \partial_\sigma \tilde{g}| = 0. \quad (5.19)$$

5.3 Poisson-Lie dual interpretation

The λ -deformed theory is closely connected to a class of integrable deformations of the principal chiral model known as η -deformation (also known as Yang-Baxter deformations) [79, 80]. To establish the relation between the λ and η theories one first performs an analytic continuation of the coordinates parameterising the λ -theory and also of the deformation parameter itself. Performing this analytic continuation in the λ -deformed action of (2.9) results in a new (real) sigma-model that is the Poisson-Lie T-dual to the η -deformation [59–62]. Our goal here is to track this connection through with the boundary conditions considered here. To make this rather technical procedure accessible we first introduce the rudiments of Poisson-Lie technology.

Poisson-Lie T-duality [47, 48] is a generalised notion of T-duality between a pair of σ -models on group manifolds \widehat{G} and \check{G} (with corresponding algebras $\widehat{\mathfrak{g}}$ and $\check{\mathfrak{g}}$) that do not enjoy isometries but instead possess a set of currents that are non-commutatively conserved with respect to the dual algebra $\check{\mathfrak{g}}$ ($\widehat{\mathfrak{g}}$). For this construction to be consistent $\mathfrak{d} = \widehat{\mathfrak{g}} \oplus \check{\mathfrak{g}}$ must define a Drinfeld double [81]. The two Poisson-Lie dual sigma-models defined in this way are of the form,

$$\begin{aligned} \widehat{S}[\widehat{g}] &= \frac{1}{t\eta} \int d^2\sigma \widehat{L}_+^T (E_0^{-1} - \widehat{\Pi})^{-1} \widehat{L}_-, \\ \check{S}[\check{g}] &= \frac{1}{t\eta} \int d^2\sigma \check{L}_+^T (E_0 - \check{\Pi})^{-1} \check{L}_-, \end{aligned} \quad (5.20)$$

in which $\widehat{L}_\pm(\check{L}_\pm)$ are pullbacks of left-invariant one-forms for $\widehat{G}(\check{G})$, E_0 is a constant matrix of freely chosen moduli, and $\widehat{\Pi}(\check{\Pi})$ is a matrix formed by the combination of the adjoint action of $\widehat{G}(\check{G})$ on itself and $\check{G}(\widehat{G})$ according to,

$$\widehat{g}^{-1} \widehat{T}_a \widehat{g} = a_a{}^b \widehat{T}_b, \quad \widehat{g}^{-1} \check{T}^b \widehat{g} = b^{ab} T_b + (a^{-1})_b{}^a \check{T}^b, \quad \widehat{\Pi}^{ab} = b^{ca} a_c{}^b, \quad (5.21)$$

where \widehat{T}_a and \check{T}^a resp. are the generators of $\widehat{\mathfrak{g}}$ and $\check{\mathfrak{g}}$ resp. The overall tension of the sigma-models has been introduced for later convenience. What will be useful in our consideration is that the two PL models are canonically equivalent [82, 83] with the canonical transformation defined by,

$$\widehat{P} = -\check{\Pi}\check{P} + \frac{t\eta}{2}\check{L}_\sigma, \quad \check{P} = -\widehat{\Pi}\widehat{P} + \frac{t\eta}{2}\widehat{L}_\sigma, \quad (5.22)$$

in which, if we let X^μ be local coordinates on \widehat{G} , we define the momentum $\widehat{P}_a = \widehat{L}_a^\mu \frac{\delta S}{\delta \dot{X}^\mu}$.¹⁴

In the context of the λ - η connection the relevant Drinfeld double is $\mathfrak{d} = \mathfrak{g}^{\mathbb{C}}$ and $\check{\mathfrak{g}}$ is identified with a Borel sub-algebra coming from the Iwasawa decomposition $\mathfrak{g}^{\mathbb{C}} = \mathfrak{g} + \mathfrak{a} + \mathfrak{n}$. The action \check{S} is defined on the group manifold $\check{G} \cong AN$ and is the one obtained by analytic continuation of the λ -deformation. The dual action, i.e. the first of eq. (5.20), is defined on the group manifold \widehat{G} and can be recast as,

$$\widehat{S} = \frac{1}{t} \int d^2\sigma \widehat{R}_+^T (\mathbf{1} - \eta \mathcal{R})^{-1} \widehat{R}_-, \quad (5.23)$$

in which \widehat{R}_\pm are right-invariant one forms (pulled back) and \mathcal{R} solves the modified classical Yang-Baxter equation. For the isotropic single parameter deformations considered here $E_0^{-1} = \frac{1}{\eta} \mathbf{1} + \mathcal{R}$. This is the integrable η -deformation [79, 80].

For didactic purpose we consider the case of the $SU(2)$ λ -deformation. In the parametrisation used in eq. (4.1) this analytic continuation amounts to a mapping between coordinates $(\alpha, \beta, \gamma) \rightarrow (y_1, y_2, \chi)$ and parameters $(k, \lambda) \rightarrow (t, \eta)$ given by,

$$y_1 + iy_2 = i \sin \alpha \sin \beta e^{i\gamma}, \quad e^\chi = \cos \alpha + i \sin \alpha \cos \beta, \quad k = \frac{i}{4t\eta}, \quad \lambda = \frac{i - \eta}{i + \eta}. \quad (5.24)$$

In this case the $\widehat{\mathfrak{g}} = \mathfrak{su}(2)$ and $\check{\mathfrak{g}} = \mathfrak{e}_3$ (Bianchi II) and we will work with group elements parametrised by,

$$\check{g} = \begin{pmatrix} e^{\frac{\chi}{2}} & e^{-\frac{\chi}{2}}(y_1 - iy_2) \\ 0 & e^{-\frac{\chi}{2}} \end{pmatrix}, \quad \widehat{g} = \begin{pmatrix} e^{\frac{1}{2}i(\phi+\psi)} \cos\left(\frac{\theta}{2}\right) & e^{\frac{1}{2}i(\phi-\psi)} \sin\left(\frac{\theta}{2}\right) \\ -e^{-\frac{1}{2}i(\phi-\psi)} \sin\left(\frac{\theta}{2}\right) & e^{-\frac{1}{2}i(\phi+\psi)} \cos\left(\frac{\theta}{2}\right) \end{pmatrix}. \quad (5.25)$$

Applying the analytic continuation eq. (5.24) to the boundary conditions eq. (4.3) yields a result that is real (as required to be a consistent boundary condition) and rather elegant when written in terms of the momentum \check{P} :

$$\begin{aligned} \check{P}_1| &= \frac{4}{t\eta} \frac{e^{2\chi}}{1 + e^{2\chi} + r^2} \check{L}_{2\sigma}|, \\ \check{P}_2| &= -\frac{4}{t\eta} \frac{e^{2\chi}}{1 + e^{2\chi} + r^2} \check{L}_{1\sigma}|, \\ \check{P}_3| &= 0. \end{aligned} \quad (5.26)$$

Notice that in these conditions all the complicated dependence on the deformation parameter η (notwithstanding the factors of $t\eta$) is subsumed into the momenta \check{P} . In this form

¹⁴We adapt the results of the [36] to our conventions and restore the overall normalisation of the sigma models.

we can now immediately apply the canonical transformation of eq. (5.22) to deduce the corresponding boundary condition for the η -deformed theory. Actually something rather special happens; the canonical transformation eq. (5.22) depends explicitly not only on the momenta \check{P}, \hat{P} and the left-invariant forms $\check{L}_\sigma, \hat{L}_\sigma$ but also on all the coordinates through the matrices $\check{\Pi}$ and $\hat{\Pi}$ in a rather complicated fashion. It is then by no means guaranteed that when the canonical transformation is applied to the boundary conditions of eq. (5.26) that what results will depend only on the coordinates (θ, ϕ, ψ) that parametrise \hat{G} . Reassuringly, however, this does indeed transpire to be the case!

We are now in a position to present the boundary conditions of the η -deformed principal chiral model obtained in this fashion. In terms of the coordinates themselves the boundary condition takes a rather simple form,

$$\begin{aligned} \partial_\sigma \psi + \sec \theta \partial_\sigma \phi &= 0, \\ \eta \partial_\tau \theta + \tan \theta \partial_\sigma \phi &= 0, \\ \eta \partial_\tau \psi - \sec \theta \partial_\sigma \theta &= 0. \end{aligned} \tag{5.27}$$

For reference the geometry corresponding to the η -deformed theory reads

$$\begin{aligned} ds^2 &= \frac{1}{t} \left((d\phi + \cos \theta d\psi)^2 + \frac{1}{1 + \eta^2} (d\theta^2 + \sin^2 \theta d\psi^2) \right), \\ B &= \frac{\eta}{t(1 + \eta^2)} \sin \theta d\theta \wedge d\psi, \quad H = dB = 0. \end{aligned} \tag{5.28}$$

Since all the coordinates enjoy (generalised) Neumann boundary condition we are describing here a space-filling brane supported by a worldvolume two-form $\mathcal{F} = B + 2\pi\alpha' F$. Making use of the above metric we can readily extract this two-form,

$$\mathcal{F} = \frac{\eta}{t(1 + \eta^2)} \sin \theta d\theta \wedge d\psi, \tag{5.29}$$

showing that $F = dA = 0$.

It is also illuminating to express the results in terms of right invariant forms,

$$\hat{R}^1 = -\cos \phi \sin \theta d\psi + \sin \phi d\theta, \quad \hat{R}^2 = \sin \phi \sin \theta d\psi + \cos \phi d\theta, \quad \hat{R}^3 = d\phi + \cos \theta d\psi. \tag{5.30}$$

such that the boundary conditions take the conventional form of a gluing,

$$\hat{R}_+^i = \mathbb{R}^i_j \hat{R}_-^j, \tag{5.31}$$

with

$$\mathbb{R} = \mathbb{O}_+^{-1} \mathbb{O}_-, \quad \mathbb{O}_\pm = \frac{1}{\mathbf{1} \pm \eta \mathcal{R}}. \tag{5.32}$$

It is easily verified that \mathbb{R} so defined is an algebra automorphism. It is worth emphasising that here the gluing between currents after the generalised duality is again with an overall plus sign (it is of the form of a WZW N-type boundary condition eq. (B.9)) whereas in the original λ -deformed WZW the gluing between currents was with an overall minus sign (i.e. of WZW D-type eq. (B.8)).

To close the circle we can again relate these boundary conditions to the general integrable boundary condition construction. First we recall that the Lax for the η -deformed PCM eq. (5.23) is given by [79, 80],

$$\mathcal{L}_{\pm}(\eta, z) = \frac{1 + \eta^2}{1 \pm z} \text{ad}_{\hat{g}^{-1}} \cdot \mathbb{O}_{\pm} \cdot \hat{R}_{\pm}. \tag{5.33}$$

Using this we can readily see that boundary condition above is obtained from,

$$\mathcal{L}_{\tau}(\eta, z)| = \mathcal{L}_{\tau}(\eta, -z)|, \tag{5.34}$$

and hence is of the form of the integrable boundary condition that one would obtain from eq. (3.14) in which the extra automorphism $\Omega = 1$ and when would choose the freedom to change the deformation parameter conveniently (see also the discussion at the end of section 3.1). Actually there is a second possibility,

$$\mathcal{L}_{\tau}(\eta, z)| = \mathcal{L}_{\tau}(-\eta, -z)|, \tag{5.35}$$

which also gives an integrable condition; this is just $\hat{R}_{+}| = \hat{R}_{-}|$.¹⁵

6 Conclusions

We have seen that integrable boundary conditions of the λ -deformed theory can be obtained by demanding that the monodromy matrix of the Lax connection generates conserved charges even in the presence of a boundary. Rather elegantly these boundary conditions can be described by (twisted) conjugacy classes, independent of the deformation parameter and indeed as the deformation is turned off the known D-brane configurations in WZW models are recovered. For the $SU(2)$ theory the picture is nice; viewing S^3 as a two-sphere fibred over an interval the conjugacy classes correspond to D2-branes wrapping the two-sphere (that shrink at the end points of the interval to D0-branes), and the effect of the λ -deformation is in essence to determine the size of the two-spheres. The quantisation of the world-volume flux remains consistent in the deformed theory — all occurrences of the deformation parameter cancel — and enforce that the D-branes sit at localised positions along the interval.

Armed with the integrable D-branes of the λ -model we were then able to show their connection to D-branes in the PCM and its η -deformation. First we could track the D-brane boundary condition through to the non-Abelian T-dual point ($\lambda = 1$) and dualise them to an N-type boundary condition of the PCM, which is also integrable. Alternatively we could perform analytical continuation to ascertain boundary conditions for a Poisson-Lie sigma model on the group manifold AN appearing in the Iwasawa decomposition $G^{\mathbb{C}} = GAN$. The boundary conditions produced in this fashion were then Poisson-Lie T-dualisable and produced N-type boundary conditions of the η -deformed PCM. Again we saw explicitly

¹⁵This later choice however appears incompatible with PL T-duality, this is easily seen since the boundary condition is equivalent to $\hat{L}_{\sigma} = 0$ and making use of the canonical transformation eq. (5.22) this leads to a PL dual condition $0 = \frac{t\eta}{2}(1 - \hat{\Pi}\check{\Pi})\check{P} + \hat{\Pi}\check{L}_{\sigma}$ which still depends on the coordinates of \hat{g} and is thus non-local.

that these D-branes of the η -deformed PCM are integrable. The exchange of N -type and D -type boundary conditions in this approach is a phenomenon that seems generic in the context of non-Abelian and Poisson-Lie theories.

Let us comment on a few interesting open problems triggered by this study.

The concerns and analysis of this paper have been predominantly classical. An important next direction is to make more precise the quantum description corresponding to the boundary conditions considered here. Assuming no Goldschmidt-Witten anomaly is encountered one might anticipate that the integrability transfers to the quantum theory. Here the situation is rather intriguing. A bulk S-matrix is conjectured — and to a certain extent derived via quantum inverse scattering — for the λ -deformation and has a factorised product form $S(\theta) = X(\theta)S^{\text{SU}(2)}(\theta) \otimes S^{\text{RSOS}_k}(\theta)$ (for the SU(2) theory), in which the first factor is the SU(2) rational solution of the Yang-Baxter equation and the second is an interaction round a face type block that is thought of as describing kink degrees of freedom [84]. A quantum integrable boundary should supplement this bulk S-matrix with a boundary ‘K-matrix’ that obeys a boundary version of the Yang-Baxter equation [20, 21]. It will be interesting, and the subject of further investigation, to establish the boundary K-matrix corresponding to integrable boundary conditions found within. Developing this line further, the quantum inverse scattering construction shows how the λ -theory can be quantised on a lattice as a spin k XXX Heisenberg chain with impurities [84]. It is appealing to establish a match between integrable boundary conditions of such spin chains (studied e.g. in [30]) and the boundary conditions of the continuum theory we constructed here.

Here we have considered just bosonic λ -theory on a group manifold. These λ -deformations have an analogue in the context of symmetric spaces [38] (i.e. deformations of gauged WZW models) which will be of interest to study, with the anticipation that the geometric description of D-branes of [85–88] persists in the deformed theory. Going further one can consider λ -deformations of theories based on supercosets with applications to the $AdS_5 \times S^5$ superstring [37, 39]. Here the deformation is expected to be truly marginal and conjectured to correspond to a root-of-unity deformation of the holographic dual gauge theory. The study of the integrable D-branes in this arena also seems profitable.

One way to introduce fermionic degrees of freedom is by considering supergroups or supercosets as target manifolds as outlined in the previous paragraph. Another way is through the supersymmetrization of the deformed σ -model thereby introducing worldsheet fermions. We expect that the results obtained in this paper carry over unchanged to the $N = (1, 1)$ supersymmetric version of the isotropically λ -deformed theory. However as is well known, going to $N = (2, 1)$ or $N = (2, 2)$ supersymmetry, which is needed when one has string theoretical applications in mind, requires additional geometrical structure(s) thereby strongly restricting the allowed target manifolds and the choices of metric and torsion on it. For example, on the integrable Yang-Baxter deformation of the PCM with a Wess-Zumino term (which is a generalization of the η -deformed PCM) it is highly unlikely that one can go beyond $N = (1, 1)$ supersymmetry [89]. As far as we know, the question whether λ -deformed theories allow for extended supersymmetry, even in the absence of boundaries, has not been addressed yet and forms an interesting open question.

A General sigma models with boundaries

To establish our sigma model conventions we briefly review the necessary basics of bosonic open strings in general curved backgrounds (see for instance [8, 9]). We discard the dilaton in this brief discussion and adapt throughout this paper the open string picture.

The string sigma model is a theory of maps $X^\mu(\tau, \sigma)$ from the worldsheet Σ parametrised by (τ, σ) to a target space manifold \mathcal{M} parametrised by X^μ with $\mu \in \{0, \dots, D-1\}$. Considering open strings, the worldsheet Σ has a boundary $\partial\Sigma$ that is mapped in the target space to a $p+1$ -dimensional submanifold¹⁶ $N \subset \mathcal{M}$ known as a Dp-brane. For a target space with metric $G_{\mu\nu}(X)$ and anti-symmetric 2-form $B_{\mu\nu}(X)$ the sigma model action is

$$S_\sigma = \frac{1}{4\pi\alpha'} \int d^2\sigma \sqrt{-g} \partial_\alpha X^\mu \left(g^{\alpha\beta} G_{\mu\nu}(X) + \epsilon^{\alpha\beta} B_{\mu\nu}(X) \right) \partial_\beta X^\nu + \int_{\partial\Sigma} d\tau A_a(X) \frac{dX^a}{d\tau}, \quad (\text{A.1})$$

with $A_a(X)$ the U(1) gauge field coupling to the end-points of the open string and $a \in \{0, \dots, p\}$ denoting the tangent directions to the worldvolume of the Dp-brane. In conformal gauge, $g_{\alpha\beta} = \text{diag}(+1, -1)$, and lightcone coordinates, $\sigma^\pm = \tau \pm \sigma$, we have

$$S_\sigma = \frac{1}{\pi\alpha'} \int d\sigma d\tau \partial_+ X^\mu (G_{\mu\nu}(X) + B_{\mu\nu}(X)) \partial_- X^\nu + \int_{\partial\Sigma} d\tau A_a(X) \frac{dX^a}{d\tau}. \quad (\text{A.2})$$

Varying the action with respect to the fields X^μ (to obtain the equations of motion) one encounters a boundary term leading to Dirichlet and (generalised) Neumann directions provided the metric splits orthogonally:

$$\text{Dirichlet: } \delta X^{\hat{a}}|_{\partial\Sigma} = 0 \quad \Rightarrow \quad \partial_\tau X^{\hat{a}}|_{\partial\Sigma} = 0, \quad (\text{A.3})$$

$$\text{Neumann: } G_{ab}(X) \partial_\sigma X^b|_{\partial\Sigma} = (B_{ab}(X) + 2\pi\alpha' F_{ab}(X)) \partial_\tau X^b|_{\partial\Sigma}, \quad (\text{A.4})$$

with $\hat{a} = p+1, \dots, D-1$ the directions normal to the Dp-brane and where we introduced the Abelian field strength $F_{ab}(X) = \partial_a A_b(X) - \partial_b A_a(X)$. The classical energy momentum tensor of the sigma model is given by

$$T_{\alpha\beta} = \partial_\alpha X^\mu G_{\mu\nu}(X) \partial_\beta X^\nu - \frac{1}{2} g_{\alpha\beta} g^{\gamma\delta} \partial_\gamma X^\mu G_{\mu\nu}(X) \partial_\delta X^\nu. \quad (\text{A.5})$$

¹⁶We do not consider the possibility of intersecting D-branes nor a stack of D-branes here.

and in light cone coordinates we have,

$$T_{\pm\pm} = \partial_{\pm} X^{\mu} G_{\mu\nu}(X) \partial_{\pm} X^{\nu}, \quad T_{+-} = 0. \quad (\text{A.6})$$

It is straightforward to see that on the boundary, imposing either Dirichlet conditions (A.3) or generalised Neumann conditions (A.4), the energy-momentum tensor satisfies

$$T_{++}|_{\partial\Sigma} = T_{--}|_{\partial\Sigma} \rightarrow T_{10}|_{\partial\Sigma} = 0. \quad (\text{A.7})$$

which we will call the (classical) conformal boundary condition. Hence, there is no momentum flow through the boundary (although A and B charge can be interchanged). If we now summarise the Dirichlet and Neumann conditions (A.3), (A.4) using a map W that combines them as,

$$\partial_{+} X^{\mu}|_{\partial\sigma} = W^{\mu}_{\nu} \partial_{-} X^{\nu}|_{\partial\sigma}, \quad (\text{A.8})$$

then the Dirichlet conditions correspond to -1 eigenvalues of W while the generalised Neumann conditions are described by all other eigenvalues. The classical conformal boundary condition eq. (A.7) then requires that W preserves the target space metric G ,

$$W^T G W = G. \quad (\text{A.9})$$

The dynamics of the Dp -brane with tension T_p is governed by the DBI action (throughout this paper we ignore the scalar fields parameterizing the fluctuations transversal to the brane),

$$S_{\text{DBI}} = T_p \int e^{-\Phi} \sqrt{\det(\widehat{G}_{ab}(X) + \mathcal{F}_{ab}(X))}, \quad (\text{A.10})$$

where $\widehat{G}_{ab}(X)$ is the induced metric on the worldvolume and $\mathcal{F}_{ab}(X)$ is the gauge-invariant worldvolume flux given by

$$\mathcal{F}_{ab}(X) = \widehat{B}_{ab}(X) + 2\pi\alpha' F_{ab}(X), \quad (\text{A.11})$$

with $\widehat{B}_{ab}(X)$ the induced anti-symmetric 2-form.

B WZW models and conventions

In this appendix we collect a number of conventions together with a short review concerning (boundary) WZW models. The WZW model is a non-linear sigma model of maps $g(\tau, \sigma)$ from a 1+1 dimensional Riemann surface Σ (with or without boundary) to a Lie group G . The model is exact conformal invariant and hence simple enough to describe strings propagating in curved backgrounds.

Before writing down the action let us make our conventions clear. We pick for the Lie algebra a basis of hermitian generators $\{T_A\}$, with $A = 1, \dots, \text{Dim}(G)$, that satisfy $[T_A, T_B] = iF_{AB}^C T_C$. The ad-invariant metric on the Lie algebra is given by $\langle T_A, T_B \rangle = \frac{1}{x_r} \text{Tr}(T_A T_B) = \eta_{AB}$ with x_r the index of the representation r . The left and right-invariant Maurer-Cartan one-forms are expanded in the Lie algebra as $L = g^{-1} dg = -iL^A T_A$ and $R = dg g^{-1} = -iR^A T_A$ respectively. They are related by an adjoint action $D(g)[T_A] =$

$D^B{}_A(g)T_B = gT_Ag^{-1}$ so that $D_{AB}(g) = \text{Tr}(g^{-1}T_AgT_B)$ and $D^T_{AB}(g) = D_{AB}(g^{-1})$. Hence, $R^A = D^A{}_B(g)L^B$.

The WZW action [10] is

$$S_{\text{WZW},k}(g) = -\frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau \langle g^{-1}\partial_+g, g^{-1}\partial_-g \rangle - \frac{k}{4\pi} \int_{M_3} H, \tag{B.1}$$

where H is the closed torsion 3-form (locally satisfying $H = dB$) given by

$$H = \frac{1}{6} \langle \bar{g}^{-1}d\bar{g}, [\bar{g}^{-1}d\bar{g}, \bar{g}^{-1}d\bar{g}] \rangle, \tag{B.2}$$

with \bar{g} the extension of g into $M_3 \subset G$ such that $\partial M_3 = g(\Sigma)$. There are two topological obstructions for the consistency of the definition of the WZW action and its quantum theory.¹⁷ First, the existence of M_3 is guaranteed only when the second homology group $H_2(G)$ is empty. Second, the path integral based on this action is insensitive to the choice of extension provided that the third cohomology class $[H]/2\pi \in H^3(G)$ is integral. For $SU(2)$ we have $H^3(SU(2)) \cong \mathbb{Z}$ requiring the level k to be integer quantised while on the other hand for $SL(2, \mathbb{R})$ we have $H^3(SL(2, \mathbb{R}))$ empty which allows the level k to be free. We want to emphasise here that comparing the WZW action, which in terms of vielbeins is,

$$S_{\text{WZW},k}(g) = \frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau L^A_+ \eta_{AB} L^B_- + \frac{k}{24\pi} \int_{M_3} F_{ABC} L^A \wedge L^B \wedge L^C, \tag{B.3}$$

to a worldsheet model (A.2) we have units in which $\alpha' = 2$, crucial for $k \in \mathbb{Z}$ when $G = SU(2)$.

The WZW model is invariant under a global $G(z) \times G(\bar{z})$ action leading to an infinite-dimensional symmetry group described by the chirally conserved holomorphic Kac-Moody currents¹⁸

$$J(z) = -k \partial g g^{-1}, \quad \bar{J}(\bar{z}) = k g^{-1} \bar{\partial} g, \tag{B.4}$$

in the conventions $z = x^0 + ix^1 = i\sigma^+$ and $\bar{z} = x^0 - ix^1 = i\sigma^-$ with the Euclidean worldsheet coordinates $(x^0, x^1) = (i\tau, \sigma)$ and lightcone coordinates $\sigma^{\pm} = \tau \pm \sigma$. At the quantum level the current algebra takes the form,

$$J^A(z)J^B(w) = \frac{iF^{AB}{}_C J^C(w)}{z-w} + \frac{k\eta^{AB}}{(z-w)^2} + \text{reg.}, \tag{B.5}$$

and analogous for the $\bar{J}\bar{J}$ OPE (hence the sign difference in the definition (B.4)). The exact conformal invariance is established through the energy-momentum tensor obtained via the Sugawara construction based on the current algebra [1],

$$T(z) = T_{zz}(z) = \frac{1}{2(k + h\nu)} \eta_{AB} (J^A J^B)(z), \tag{B.6}$$

¹⁷By construction it is obvious that these obstructions still apply for the λ model (2.5).

¹⁸Note that whether the left current is holomorphic or anti-holomorphic depends on the sign of the WZ term.

where h^\vee is the dual Coxeter number of G (here we assumed for simplicity G to be semi-simple). The central charge of the theory can then be found to be,

$$c = \frac{k \dim(G)}{k + h^\vee}, \tag{B.7}$$

and all analogous for $\bar{T}(\bar{z})$.

When considering a boundary in the WZW model one will seek boundary conditions that preserve its exact conformal invariance. Since the CFT is easily described in terms of the chiral currents (B.4) it is convenient to express these boundary conditions as a class of gluing conditions¹⁹ for the currents at $z = \bar{z}$,

$$J(z)| = \Omega \bar{J}(\bar{z})|, \tag{B.8}$$

with $\Omega : \mathfrak{g} \rightarrow \mathfrak{g}$. To preserve the exact conformal invariance the gluing condition should satisfy the conformal boundary condition $T(z)| = \bar{T}(\bar{z})|$. This translates into the condition that the gluing map Ω should be an isometry of the ad-invariant Lie algebra metric. One could further require Ω to be an algebra automorphism and, hence, the gluing condition to preserve also the infinite-dimensional current algebra (B.5). The corresponding D-brane configurations are well-understood and geometrically wrap the twisted conjugacy classes of the group [12–14]. They are known as symmetric D-branes or of ‘type D’ [14], a terminology that we will adapt. Another possibility analysed in [14, 68], where it was dubbed ‘type N’, is to consider,

$$J(z)| = -\Omega \bar{J}(\bar{z})|. \tag{B.9}$$

with Ω a metric-preserving automorphism. They preserve the conformal invariance but do not preserve the current algebra which makes them somewhat more difficult to analyse. However, as suggested in section 5 they seem to be related to the type D by generalised T-dualities in the context of the λ deformation of the WZW model.

From the sigma model point of view the WZW action (B.1) is necessarily modified when the Riemann surface Σ has a boundary $\partial\Sigma$ [51, 70–72]. The image of $g(\partial\Sigma)$ is a (D-brane) submanifold N of G on which a two-form ω lives such that the restriction of H on N coincides with $d\omega$. Locally the two-form coincides with the gauge-invariant worldvolume flux \mathcal{F} , i.e. $\omega = \hat{B} + 4\pi dA$ [72]. The action of the boundary WZW model is,

$$S_{\text{WZW},k}(g) = -\frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau \langle g^{-1} \partial_+ g, g^{-1} \partial_- g \rangle - \frac{k}{4\pi} \int_{M_3} H + \frac{k}{4\pi} \int_{D_2} \omega, \tag{B.10}$$

where $M_3 \subset G$ with boundary $\partial M_3 = g(\Sigma) + D_2$ and $D_2 \subset N$. Note that only the boundary equations of motion will depend on the two-form ω . Demanding that the boundary conditions obtained from the gluing conditions that preserve conformal invariance (B.8) coincides with the boundary conditions from the sigma model approach (A.3) and (A.4) will completely determine the two-form ω on the D-brane in terms of the gluing map Ω as in [12, 70, 71].

¹⁹To compare these gluing conditions (which take value in $T_e G$) to sigma model boundary conditions of the form (A.9) one should still translate them to $T_g G$.

Again, there are two topological obstructions for the consistency of the definition of the boundary WZW action and its quantum theory (for a detailed exposition see [51, 70, 72]). The existence of M_3 and D_2 is guaranteed only when the second relative homology $H_2(G, N)$ vanishes. The path integral is insensitive to the choice of M_3 and ω provided that the third relative cohomology class $[(H, \omega)] / 2\pi \in H^3(G, N)$ is integral. As seen in section 4 this condition enforces for $G = \text{SU}(2)$ the position of D2-branes to sit on only a discrete number of values. Locally this quantisation condition coincides with the quantisation of the worldvolume flux of the U(1) gauge-field A on the brane [65, 72]. For $G = \text{SL}(2, \mathbb{R})$ the position of the D1-strings will not be constrained by this particular topological obstruction; however, the D1-strings carry a natural quantisation descending from the Gauss constraint of two-dimensional gauge theory on the brane [73, 74].

ABSTRACT: We study generalized Kähler structures on $N = (2, 2)$ supersymmetric Wess-Zumino-Witten models; we use the well known case of $SU(2) \times U(1)$ as a toy model and develop tools that allow us to construct the superspace action and uncover the highly nontrivial structure of the hitherto unexplored case of $SU(3)$; these tools should be useful for studying many other examples. We find that *different* generalized Kähler structures on $N = (2, 2)$ supersymmetric Wess-Zumino-Witten models can be found by T-duality transformations along affine isometries.

1 Introduction

Almost since its inception it was recognized that supersymmetry and geometry go hand in hand [1]. Supersymmetric non-linear σ -models in two dimensions (NLSM) are a class of field theories where the geometric aspects are under control and can be studied both at the classical and the quantum mechanical level. They are interesting in their own right, and have many applications, including as the building blocks for type II string theories, as the description of certain moduli spaces, condensed matter physics, etc.

A non-supersymmetric NLSM is fully characterized by its target manifold, which is endowed with a metric and a closed 3-form. These models can always be supersymmetrized as long as the number of supersymmetries is bounded by $(N_+, N_-) \leq (1, 1)$ where N_+ (N_-) is the number of right-handed (left-handed) supersymmetries. No further geometric structure arises at the classical level. However, any additional supersymmetry past the first introduces a covariantly constant complex structure,¹ with respect to which the metric is hermitian. In addition, if $(N_+, N_-) \geq (2, 2)$, there are complex structures of each handedness.

In the current paper we will mostly focus on the $(N_+, N_-) = (2, 2)$ case, which requires besides the metric and the closed 3-form, two covariantly constant complex structures that both preserve metric, hence the name “bihermitian geometry”. A simple dimensional argument shows that the Lagrange density in $(2, 2)$ superspace can only be a function of a number of (constrained) scalar superfields. The Lagrange density encodes the full local geometry. In the simplest case where only chiral superfields appear, the two complex structures coincide, the 3-form vanishes and the geometry is Kähler. The Lagrange density is then precisely the Kähler potential. This suggests that the generic case describes a far reaching generalization of Kähler manifolds where the Lagrange density gets the interpretation of a

¹In general, covariantly constant with respect to a connection with torsion related to the closed 3-form.

generalized Kähler potential. This was understood to be the case in the bihermitian language of [2] in a series of papers from the NLSM perspective [3–6]. This was reinterpreted by Hitchin when he introduced the concept of generalized Kähler geometry [7], a natural generalization of Kähler geometry acting non-trivially on the sum of the tangent and cotangent bundle, and which was shown by Gualtieri [8] to coincide with bihermitian geometry. A subclass of generalized Kähler manifolds, generalized Calabi-Yau manifolds, are conformally invariant at the quantum level and provide an important class of supergravity solutions [9, 10].

The off-shell completion of a $(2, 2)$ NLSM depends on the precise choice of the right and left complex structures J_+ and J_- ; when different choices are possible, they correspond to different bihermitian structures and thus to different generalized Kähler structures. This is reflected in the supersymmetry algebra: one finds it closes off-shell modulo terms proportional to the commutator of the two complex structures $[J_+, J_-]$. As a consequence one expects that $\ker[J_+, J_-] = \ker(J_+ - J_-) \oplus \ker(J_+ + J_-)$ can be described in a manifestly supersymmetric way without introducing any further off-shell degrees of freedom. This is indeed achieved by means of chiral and twisted chiral superfields [2]. To close the supersymmetry algebra off-shell when the image $[J_+, J_-]$ is nonvanishing, one must introduce additional $(1, 1)$ auxiliary fields; in $(2, 2)$, they arise from semi-chiral superfields [3]. Any $(2, 2)$ NLSM can be described in terms of these three classes of superfields: chiral, twisted chiral and semi-chiral [6]. However, as the off-shell completion of a $(2, 2)$ NLSM fully depends on the choice made for J_+ and J_- and as this choice is not always unique, one finds that a given target manifold often admits different generalized Kähler structures.

If the generalized Kähler manifold possesses an isometry, one can T-dualize the model along that isometry [11]. Generically one ends up with a different manifold. T-duality not only affects the metric and closed 3-form, but also acts non-trivially on the complex structures [12]. Hence, T-duality alters the superfield content of a $(2, 2)$ NLSM. Two cases appear: a chiral superfield can be interchanged for a twisted chiral superfield (and vice-versa) [2] or a pair of chiral and twisted chiral superfields gets exchanged for a semi-chiral multiplet (and vice-versa) [5]. A particularly interesting case arises when the isometry is actually a Kac-Moody symmetry — then the metric and closed 3-form remain unchanged, but the complex structures still transform [13]. This is precisely the case we investigate in this paper.

A simple but non-trivial class of generalized Kähler manifolds where many of the issues discussed above can be studied quite explicitly are even-dimensional reductive Lie group manifolds [14]. The resulting σ -models are $(2, 2)$ supersymmetric Wess-Zumino-Witten (WZW) models. A complex structure on a reductive group manifold is fully determined by its action on the Lie algebra where it is almost equivalent to a Cartan decomposition of the Lie algebra: it has eigenvalue $+i$ ($-i$) on positive (negative) roots. The only freedom remains in its action on the Cartan subalgebra where the only restriction is the requirement that the Cartan-Killing metric should be hermitian. Given a choice for J_+ there is still a considerable freedom in choosing J_- , giving rise to various generalized Kähler structures on reductive even-dimensional Lie groups. For groups of low rank this can be studied systematically.

In the current paper we explore and elucidate the relation between various generalized Kähler structures on the same Lie group. We start with the well-known example of $SU(2) \times U(1)$, which allows for two generalized Kähler structures: one in terms of a chiral and a twisted chiral field [15] and one in terms of semi-chiral multiplet [4]. We show that the two generalized Kähler structures are related through T-duality transformation along an affine isometry. This can be understood as follows. Only the maximal abelian subgroup of the left and right-handed affine group acts trivially on the complex structures and thus are manifest in $(2, 2)$ superspace. T-dualizing along an affine isometry does not alter the metric or the closed 3-form [13] but it does alter the complex structures, mapping one generalized Kähler structure on $SU(2) \times U(1)$ into the other one! As a far more difficult example, we study the hitherto unexplored case of $SU(3)$; this also has (at least) two inequivalent generalized Kähler structures: one in terms of two semi-chiral multiplets and one in terms of a single semi-chiral multiplet, one chiral and one twisted chiral superfield.²

The outline of the rest of the paper is as follows. Section 2 reviews supersymmetric WZW models, which form an important class of generalized Kähler manifolds. Section 3 comprises a review of the generalized Kähler structures carried by $SU(2) \times U(1)$, in particular concentrating on relating generalized Kähler structures of different types via T-duality. Section 4 studies the generalized Kähler structures on $SU(3)$. Generalized Kähler potentials for both types of generalized Kähler structures on $SU(3)$ are derived. Section 5 has a brief summary of our results and discusses possibilities for further research. Appendix A reviews sigma models and their supersymmetric extensions to $(1, 1)$ superspace. Appendix B gives details of the $(2, 2)$ superspace description of bihermitian geometry, including explicit formulae for the complex structures J_{\pm} in terms of the generalized Kähler potential K . Appendix C discusses isometries, T-duality, and generalized $(2, 2)$ supersymmetric vector multiplets. Appendix D attempts to give insight into the art of finding holomorphic coordinates on WZW-models. Appendix E presents some particular choices of holomorphic coordinates for $SU(2) \times U(1)$ that we found but are not discussed in section 3. Appendix F describes the T-duality transformation from type $(1, 1)$ to $(0, 0)$ using the Large Vector Multiplet discussed in appendix C. Appendix G discusses another rank 2 group, $SU(2) \times SU(2)$, which admits only type $(1, 0)$ and type $(0, 1)$ generalized Kähler structures.

2 Generalized Kähler geometry on group manifolds

2.1 $(2, 2)$ sigma model description of bihermitian geometry

We briefly recap the $(2, 2)$ superspace formulation of a two-dimensional sigma model with bihermitian target space and establish the notation used in the rest of this paper.³

As always, $(2, 2)$ superspace has two commuting coordinates $\sigma^{\text{++}} = \tau + \sigma$, $\sigma^{\text{--}} = \tau - \sigma$ and four anticommuting coordinates θ^+ , $\bar{\theta}^+$, θ^- , $\bar{\theta}^-$. There are two complex spinorial

²Actually, both $SU(2) \times U(1)$ and $SU(3)$ have $(4, 4)$ supersymmetry, so in principle there are $S^2 \times S^2$ generalized Kähler structures. We expect these to fall into two deformation classes, so that our examples should be generic, but further investigation might be worthwhile.

³For background and more details about sigma models in general, see appendix A.

covariant derivatives \mathbb{D}_\pm which satisfy the algebra

$$\{\mathbb{D}_\pm, \bar{\mathbb{D}}_\pm\} = 2i\partial_\pm, \quad \mathbb{D}_\pm^2 = \bar{\mathbb{D}}_\pm^2 = 0. \quad (2.1)$$

The three types of (2, 2) superfields required to describe a generic generalized Kähler manifold are the following:

- chiral superfields $\phi, \bar{\phi}$ satisfying

$$\begin{aligned} \bar{\mathbb{D}}_+\phi &= 0, & \bar{\mathbb{D}}_-\phi &= 0, \\ \mathbb{D}_+\bar{\phi} &= 0, & \mathbb{D}_-\bar{\phi} &= 0, \end{aligned} \quad (2.2)$$

- twisted chiral superfields $\chi, \bar{\chi}$ satisfying

$$\begin{aligned} \bar{\mathbb{D}}_+\chi &= 0, & \mathbb{D}_-\chi &= 0, \\ \mathbb{D}_+\bar{\chi} &= 0, & \bar{\mathbb{D}}_-\bar{\chi} &= 0, \end{aligned} \quad (2.3)$$

- left and right semi-chiral superfields $\ell, \bar{\ell}, r, \bar{r}$ satisfying

$$\begin{aligned} \bar{\mathbb{D}}_+\ell &= 0, & \bar{\mathbb{D}}_-\bar{r} &= 0, \\ \mathbb{D}_+\bar{\ell} &= 0, & \mathbb{D}_-r &= 0. \end{aligned} \quad (2.4)$$

The action in (2, 2) superspace has the form

$$I = \int d^2\sigma d^4\theta K = \int d^2x \mathbb{D}^2 \bar{\mathbb{D}}^2 K, \quad (2.5)$$

where K is a real local function, the generalized Kähler potential, of the superfields $\ell, \bar{\ell}, r, \bar{r}, \phi, \bar{\phi}, \chi, \bar{\chi}$. The potential is defined modulo generalized Kähler transformations

$$K \mapsto K + f(\ell, \phi, \chi) + \bar{f}(\bar{\ell}, \bar{\phi}, \bar{\chi}) + g(r, \phi, \bar{\chi}) + \bar{g}(\bar{r}, \bar{\phi}, \chi), \quad (2.6)$$

which give rise to total derivatives in the component sigma model Lagrangian density.

This single function K fully encodes the local geometry of the target manifold \mathcal{M} which must be even-dimensional and has geometric structures (g, H, J_+, J_-) where⁴

- J_+ and J_- are two integrable complex structures on \mathcal{M} compatible with the metric g

$$\begin{aligned} J_+^2 &= J_-^2 = -\mathbf{1}, \\ [X, Y] + J_\pm[J_\pm X, Y] + J_\pm[X, J_\pm Y] - [J_\pm X, J_\pm Y] &= 0, \\ g(J_\pm X, J_\pm Y) &= g(X, Y), \end{aligned} \quad (2.7)$$

where X, Y are arbitrary vector fields, and

- $H = d_+^c \omega_+ = -d_-^c \omega_-$ is a closed 3-form, where d_\pm^c are the d^c operators with respect to J_\pm , and $\omega_\pm = gJ_\pm$ are the hermitian forms of the respective complex structures.

⁴See appendix B for the formulas expressing these structures in terms of the generalized potential.

A manifold carrying such a structure is known as bihermitian [2], and has been shown to be equivalent to generalized Kähler geometry [8]. Note that the second condition is equivalent to the covariant constancy

$$\nabla^{(\pm)} J_{\pm} = 0 \tag{2.8}$$

of the complex structures J_{\pm} with respect to the Bismut connections $\nabla^{(\pm)}$, which are metric connections with torsions $\pm g^{-1}H$ (first introduced by Yano — see [16], pp. 150-151). Explicitly,

$$\Gamma^{(\pm)\mu}_{\nu\rho} = \Gamma^{(0)\mu}_{\nu\rho} \pm \frac{1}{2}g^{\mu\sigma}H_{\sigma\nu\rho}, \tag{2.9}$$

where $\Gamma^{(0)}$ is the Levi-Civita connection. The torsion 3-form H enters the sigma model description via a local 2-form potential b known as the Kalb-Ramond field, with $H = db$.

A bihermitian manifold is equipped with three Poisson structures

$$\pi_{\pm} = (J_{+} \pm J_{-})g^{-1}, \tag{2.10}$$

$$\sigma = [J_{+}, J_{-}]g^{-1}. \tag{2.11}$$

The superfields (2.2)–(2.4) arising from the (2, 2) superspace description may be interpreted as coordinates adapted to these Poisson structures. More specifically, near a regular point,⁵ chiral superfields are complex coordinates along $\ker \pi_{-}$, twisted chiral superfields are complex coordinates along $\ker \pi_{+}$, and semi-chiral coordinates are holomorphic Darboux coordinates along the symplectic leaves of the foliation defined by σ [6]. The type of the generalized Kähler geometry at a point is $(\dim_{\mathbb{C}} \ker \pi_{-}, \dim_{\mathbb{C}} \ker \pi_{+})$; equivalently, a geometry of type (N_c, N_t) at a point admits a (2, 2) sigma model description with N_c chiral superfields and N_t twisted chiral superfields near that point. In general, the type is not constant on the manifold: there may be subvarieties, known as type-change loci, on which the type increases; these must have strictly positive codimension.

2.2 (1, 1) WZW models

A Wess-Zumino-Witten (WZW) model is a theory of maps from a Riemann surface Σ to a Lie group G equipped with an invariant metric and a normalized torsion form. The (1, 1) WZW model is a theory of maps from a (1, 1) super-Riemann surface to G , and has action⁶

$$kI[g] = -\frac{k}{\pi} \int_{\Sigma} d^2\sigma d^2\theta \operatorname{tr}(g^{-1}\nabla_{+}g g^{-1}\nabla_{-}g) - \frac{k}{\pi} \int_B d^3\tilde{\sigma} d^2\theta \operatorname{tr}(\tilde{g}^{-1}\partial_t\tilde{g}\{\tilde{g}^{-1}\nabla_{+}\tilde{g}, \tilde{g}^{-1}\nabla_{-}\tilde{g}\}), \tag{2.12}$$

where k is an integer (the level),⁷ “tr” is a normalized invariant bilinear form on the Lie algebra $\mathfrak{g} := \operatorname{Lie}(G)$, B is a 3-dimensional manifold with boundary $\partial B = \Sigma$ with local coordinates $\tilde{\sigma} = (t, \sigma)$, and \tilde{g} is an extension of g to B . Modulo multiples of $2\pi i$, $I[g]$ is independent of the choice of B and extension \tilde{g} .

⁵At a regular point on a manifold with a Poisson structure, the rank of the structure is constant in a sufficiently small neighborhood of the point. Here we consider a point that is regular with respect to all three Poisson structures.

⁶See appendix A for a review of (1, 1) superspace.

⁷Nonconformal models with separate normalizations of the two terms can also be studied; their extensions to (2, 2) superspace are not understood.

The Maurer-Cartan forms e_L^a, e_R^a , defined by

$$g^{-1} dg = e_L^a T_a, \quad dg g^{-1} = e_R^a T_a, \quad (2.13)$$

where T_a is a basis for the Lie algebra \mathfrak{g} , allow one to push forward tensors on the Lie algebra to the group.

The (1, 1) WZW model has symmetry group $G_L \times G_R$, acting as $g \mapsto h_L g h_R^{-1}$ (only the subgroup $(G_L \times G_R)/Z(G)$ acts nontrivially, where $Z(G)$ is the center of the group). The model also has superconformal symmetry, so the parameters h_L and h_R are allowed to be semilocal, satisfying

$$\nabla_+ h_L = 0, \quad \nabla_- h_R = 0. \quad (2.14)$$

2.3 (2, 2) WZW models

All even dimensional reductive Lie groups admit (2, 2) extensions [14]. The complex structures corresponding to the extended supersymmetries (2.7) may be pulled back to the Lie algebra

$$(\mathbb{J}_+)^a_b = (e_L)^a_\mu (J_+)^{\mu\nu} (e_L^{-1})^\nu_b, \quad (\mathbb{J}_-)^a_b = (e_R)^a_\mu (J_-)^{\mu\nu} (e_R^{-1})^\nu_b, \quad (2.15)$$

and in terms of the Lie algebra complex structures \mathbb{J}_\pm , the conditions for (2, 2) supersymmetry may be reformulated as [14]

- \mathbb{J}_\pm are constant and satisfy $\mathbb{J}_\pm^2 = -\mathbb{1}$ as well as $\eta(\mathbb{J}_\pm X, \mathbb{J}_\pm Y) = \eta(X, Y)$ where η is the Killing form and X, Y are arbitrary Lie algebra elements.
- Further, they obey $f(X, \mathbb{J}_\pm Y, \mathbb{J}_\pm Z) + f(\mathbb{J}_\pm X, Y, \mathbb{J}_\pm Z) + f(\mathbb{J}_\pm X, \mathbb{J}_\pm Y, Z) = f(X, Y, Z)$, where $f(X, Y, Z) = \eta([X, Y], Z)$ is the alternating form constructed from the structure constants and η .

These conditions were solved in [14] where it was shown that \mathbb{J}_\pm may be characterized by a choice of Cartan subalgebra and positive direction. The complex structures are diagonal on the positive and negative roots with eigenvalue $+i$ and $-i$ respectively, and map the Cartan subalgebra to itself in a way that makes the Killing form hermitian. Since any two Cartan decompositions of a Lie algebra are related by group conjugation, the only freedom lies in the choice of the action on the Cartan subalgebra.

Let us now turn to the superfield content, or type, allowed for a particular WZW model. A choice of \mathbb{J}_+ and \mathbb{J}_- on the Lie algebra fixes the superfield content. The numbers of chiral (2.2) and twisted chiral superfields (2.3)

$$N_c = \dim_{\mathbb{C}} \ker(J_+ - J_-), \quad N_t = \dim_{\mathbb{C}} \ker(J_+ + J_-) \quad (2.16)$$

can be computed by noting that $\ker(J_+ \pm J_-) = \ker(\mathbb{J}_+ \pm e_L e_R^{-1} (\mathbb{J}_-) e_R e_L^{-1})$ and that $e_L e_R^{-1}$ is a transformation in the adjoint representation. The number of sets of semi-chiral superfields (2.4) is then $(N - N_c - N_t)/2$, where $2N$ is the (real) dimension of the Lie group.

This can be easily analyzed for rank two groups. Here, one has essentially two choices for the Lie algebra complex structures: either they are equal $\mathbb{J}_+ = \mathbb{J}_-$, or they are opposite on the Cartan subalgebra $\mathbb{J}_+|_{\text{CSA}} = -\mathbb{J}_-|_{\text{CSA}}$. For the former case, $N_t = \dim_{\mathbb{C}} \ker(\mathbb{J}_+ +$

Group	N	$\mathbb{J}_+ = \mathbb{J}_-$			$\mathbb{J}_+ \neq \mathbb{J}_-$		
		N_s	N_c	N_t	N_s	N_c	N_t
$SU(2) \times U(1)$	2	1	0	0	0	1	1
$SU(2) \times SU(2)$	3	1	1	0	1	0	1
$SU(3)$	4	2	0	0	1	1	1
$SO(5)$	5	2	1	0	1	2	1
G_2	7	3	1	0	2	2	1

Table 1. The coordinate content for the rank 2 non-abelian reductive Lie groups either taking the complex structures to be equal on the Lie algebra ($\mathbb{J}_+ = \mathbb{J}_-$) or having the opposite sign on the CSA ($\mathbb{J}_+ \neq \mathbb{J}_-$). The number of semi-chiral, chiral and twisted chiral coordinates are denoted N_s , N_c and N_t respectively.

$e_L e_R^{-1}(\mathbb{J}_-) e_R e_L^{-1} = 0$ always, while $N_c = \ker(\mathbb{J}_+ - e_L e_R^{-1}(\mathbb{J}_-) e_R e_L^{-1})$ can be analyzed by writing $e_L e_R^{-1} = \exp(\alpha)$ and expanding through first nontrivial order in α . A similar analysis can be done for the latter choice. The results are given in table 1. Notice that each of the rank two groups admit generalized Kähler structures of two different types.

2.4 Isometries

Of the $G_L \times G_R$ symmetry of the (2, 2) WZW model, only the subgroup $G_L \times H_R$ preserves the left complex structure J_+ , where $H_R \subset G_R$ is the maximal torus corresponding to the action of \mathbb{J}_+ on the Lie algebra as described in section 2.3. A similar statement holds for J_- , so the group of isometries preserving both complex structures of the (2, 2) extended WZW is $H_L \times H_R$.⁸ Due to the superconformal invariance of the WZW model, these are in fact Kac-Moody symmetries.

2.5 T-duality along Kac-Moody isometries

Consider the T-dual sigma model of a (2, 2) supersymmetric WZW model along some isometry $U(1) \subset H_L \times H_R$. Since the isometry preserves the bihermitian structure, the T-duality can be performed in (2, 2) superspace, and the dual model also exhibits (2, 2) supersymmetry.⁹

If, furthermore, the T-duality is along a left (right) Kac-Moody isometry $U(1) \subset H_L$, then in fact the metric, torsion and left (right) complex structure of the sigma model is unchanged [12, 13]. Indeed, for a left Kac-Moody isometry with Killing field k^μ , normalized so that it has unit norm, the chiral component of the Noether current (see (3.1) of [13])

$$J = (k^\mu (g_{\mu\nu} - b_{\mu\nu}) + \omega_\nu) \partial^\nu \Phi \tag{2.17}$$

vanishes, where ω is a one-form defined by $\mathcal{L}_k b = d\omega$. We assume that the b field is chosen to be invariant under k , so that $\omega = d\alpha$ is locally exact, so

$$k^\mu (g_{\mu\nu} - b_{\mu\nu}) + \partial_\nu \alpha = 0. \tag{2.18}$$

⁸As before, the group which acts faithfully is actually $(H_L \times H_R)/Z(G)$.

⁹See appendix C below for a review of T-duality in (2, 2) superspace.

Choose a coordinate system Φ^I such that $\Phi^0 = -\alpha$ and the other Φ^i are k -invariant. Contracting (2.18) with k^ν shows that in this coordinate system, the Killing field is $k = \partial/\partial\Phi^0$. Taking $\nu = I$ in (2.18) then shows that the metric and b field satisfy $e_{00} = g_{00} = 1$ and $e_{i0} = (g-b)_{0i} = 0$. Substituting $e_{00} = 1$ and $e_{i0} = 0$ into the formulas (12), (15), (16) of [12] then shows that the metric, torsion and left complex structure are unchanged by T-duality.

For a right Kac-Moody isometry, the antichiral component of the Noether current

$$\bar{J} = (k^\mu(g_{\mu\nu} + b_{\mu\nu}) - \omega_\nu) \bar{\partial}\Phi^\nu \tag{2.19}$$

vanishes. The discussion proceeds analogously: assuming that b is invariant, $\omega = d\alpha$ is exact, and in a coordinate system $\Phi^0 = \alpha$ and Φ^i such that $\mathcal{L}_k\Phi^i = 0$, we have $e_{00} = 1$ and $e_{0i} = 0$. The formulas (13), (15) and (16) of [12] then show that the metric, torsion and right complex structure are unchanged by T-duality (after a change of coordinates $\tilde{\Phi}^0 \mapsto -\tilde{\Phi}^0$ of the dual model).

However, T-duality along a left (right) isometry does change the right (left) complex structure. In particular, the structures $J_+ \pm J_-$ and $[J_+, J_-]$ are changed. Therefore, T-duality along a Kac-Moody isometry changes the type of the generalized geometry and relates the different generalized Kähler structures on the same Lie group.

In the following sections, we will perform these T-dualities in $(2, 2)$ superspace. Since in $(2, 2)$ superspace, gauging an isometry complexifies the gauge group (with respect to both complex structures), T-dualizing along isometries related by the complex structures gives rise to the same T-dual model in superspace. This also implies that isometries related by complex structures cannot be simultaneously gauged [17]. For the rank 2 Lie groups which we consider in this paper, this means that T-duality along *any* Kac-Moody isometry always leads to the same T-dual model.

2.6 General strategy for finding the generalized Kähler potential

Given the bihermitian data (g, H, J_+, J_-) , the generalized Kähler potential K can in principle be found by solving the equations (B.12)–(B.13), which relate nonlinearly the Hessian of K to g and H in adapted coordinates. This is a nonlinear second order differential equation — a difficult equation to solve. However, on the symplectic leaves of σ (2.11), there is a simplification. On each symplectic leaf, K generates the symplectomorphism between left holomorphic Darboux coordinates (left semi-chiral superfields) and right holomorphic coordinates (right semi-chiral superfields), which means that it satisfies the *first order linear* differential equations (B.9)–(B.11).

This simplification, coupled with the observation about T-duality noted above, allows one to find the generalized Kähler potentials for all the generalized Kähler structures supported by a Lie group admitting a type $(0, 0)$ structure. The strategy is as follows. First, we find left and right holomorphic coordinates on the Lie group. This can be done by expanding the left and right invariant frames about the origin, taking the leading term to be given by the holomorphic Lie algebra generators, and solving for the higher order terms order by order using the Maurer-Cartan equations. (See appendix D for more details.) Next, for the type $(0, 0)$ structure, identify combinations $\ell, \tilde{\ell}$ and r, \tilde{r} of left and right

holomorphic coordinates that are Darboux for σ . This yields one-form symplectic potentials $\theta_L = \tilde{\ell} d\ell + \bar{\tilde{\ell}} d\bar{\ell}$ and $\theta_R = r d\tilde{r} + \bar{r} d\bar{\tilde{r}}$ for the (local) symplectic form σ^{-1} . The difference $\theta_L - \theta_R$ is closed, and can be integrated to give the generalized Kähler potential $K = \int \theta_L - \theta_R$. Next, the potentials for the generalized geometries of other types on the Lie group can be obtained by T-duality, as discussed above.

We illustrate this strategy for $SU(2) \times U(1)$ by first computing the type (0, 0) structure, and then T-dualizing along a Kac-Moody isometry to obtain the type (1, 1) generalized Kähler potential, reproducing a previously known result. We then apply this to $SU(3)$, constructing the type (1, 1) generalized Kähler potential from the type (0, 0) potential.

3 $SU(2) \times U(1)$

The generalized Kähler geometry of $SU(2) \times U(1)$ has been studied in detail [15, 18]. In this section, we revisit these results as a warm up for the $SU(3)$ model.

The outline of the section is as follows. First, we choose complex structures J_{\pm} on the Lie group and find complex coordinates. As discussed in section 2.3, generalized Kähler structures of two types are admissible depending on the choice of complex structures. Next, we find generalized Kähler potentials for each of the two types. These potentials can be written down in various different forms, differing from one another by generalized Kähler transformations and coordinate transformations. Different choices of potentials suit different purposes and the relations between them are illuminating. Finally, we relate the generalized geometries of the two different types by T-duality.

3.1 Coordinates and generalized Kähler potential

On the Lie algebra, take the basis $\{h, \bar{h}, e, \bar{e}\}$ where

$$h = \begin{pmatrix} \zeta & 0 \\ 0 & -\bar{\zeta} \end{pmatrix}, \quad \bar{h} = \begin{pmatrix} \bar{\zeta} & 0 \\ 0 & -\zeta \end{pmatrix}, \quad e = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad \bar{e} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad (3.1)$$

$\zeta = \frac{1}{2}(1+i)$, $\bar{\zeta} = \frac{1}{2}(1-i)$. The two complex structures on the Lie algebra compatible with the choice of Cartan subalgebra h, \bar{h} are

$$\mathbb{J}_1 = \text{diag}(i, -i, i, -i), \quad \mathbb{J}_2 = \text{diag}(-i, i, i, -i). \quad (3.2)$$

Depending on whether one takes J_{\pm} induced from the same or from different Lie algebra complex structures $\mathbb{J}_1, \mathbb{J}_2$, one gets generalized Kähler structures of different types on $SU(2) \times U(1)$.

3.1.1 Type (0, 0)

If one takes J_+ and J_- both induced from the same Lie algebra complex structure, say \mathbb{J}_1 , then generically the resulting generalized Kähler structure has type (0, 0); in other words, $[J_+, J_-]$ has full rank at generic points of the group.¹⁰ In this case, J_+ and J_- induce the

¹⁰There are loci of positive codimension on which $\ker[J_+, J_-]$ is nontrivial.

same orientation on $SU(2) \times U(1)$. The sigma model description is in terms of one set of semi-chiral superfields.

In terms of the group element in the defining representation

$$g = \begin{pmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{pmatrix}, \tag{3.3}$$

the J_{\pm} holomorphic coordinates can be chosen to be¹¹

$$\begin{aligned} z_+^1 &= \log g_{12}^{\zeta} \bar{g}_{21}^{\bar{\zeta}}, \\ z_+^2 &= \log g_{22}^{\zeta} \bar{g}_{11}^{\bar{\zeta}}, \\ z_-^1 &= \log g_{12}^{\bar{\zeta}} \bar{g}_{21}^{\zeta}, \\ z_-^2 &= \log g_{11}^{\bar{\zeta}} \bar{g}_{22}^{\zeta}. \end{aligned} \tag{3.4}$$

Note that neither the set $(z_+^1, \bar{z}_+^1, z_-^1, \bar{z}_-^1)$ nor the set $(z_+^2, \bar{z}_+^2, z_-^2, \bar{z}_-^2)$ is nondegenerate (in each case, unitarity of g implies one real relation between these functions). These holomorphic coordinates are chosen to be Darboux with respect to the Poisson structure σ :

$$\sigma(dz_{\pm}^1, dz_{\pm}^2) = \pm 1, \quad \sigma(d\bar{z}_{\pm}^1, d\bar{z}_{\pm}^2) = \pm 1. \tag{3.5}$$

One choice of semi-chiral coordinates is

$$\ell = z_+^2, \quad \bar{\ell} = z_+^1, \quad r = z_-^2 - z_-^1, \quad \bar{r} = z_-^2, \tag{3.6}$$

satisfying $d(\tilde{\ell} d\ell + \bar{\tilde{\ell}} d\bar{\ell} + \tilde{r} dr + \bar{\tilde{r}} d\bar{r}) = 0$. Choosing polarizations such that the adapted coordinates are $\tilde{\ell}, \bar{\tilde{\ell}}$ and r, \bar{r} results in the parametrization [18]

$$g = e^{-\zeta\theta} \begin{pmatrix} e^{\tilde{\ell}+r} & e^{\bar{\tilde{\ell}}} \\ -e^{\tilde{\ell}} & e^{\tilde{\ell}+\bar{r}} \end{pmatrix}, \quad \theta = \tilde{\ell} + \bar{\tilde{\ell}} + \log(1 + e^{r+\bar{r}}) \tag{3.7}$$

and potential

$$\begin{aligned} K_0^{(0,0)} &= \int -\ell d\tilde{\ell} - \bar{\ell} d\bar{\tilde{\ell}} + \tilde{r} dr + \bar{\tilde{r}} d\bar{r} \\ &= -(\tilde{\ell} + r)(\bar{\tilde{\ell}} + \bar{r}) + \int^{-r-\bar{r}} \log(1 + e^q) dq \end{aligned} \tag{3.8}$$

satisfying $\frac{\partial K}{\partial \tilde{\ell}} = -\ell, \frac{\partial K}{\partial \bar{\tilde{\ell}}} = \bar{\tilde{\ell}}$. This potential is valid on the coordinate patch away from the off-diagonal matrices. On the other coordinate patch, away from the diagonal matrices, we choose the polarizations spanned by $\ell, \bar{\ell}$ and r, \bar{r} , which results in the parametrization

$$g = e^{-\zeta\theta} \begin{pmatrix} e^{\bar{\ell}} & e^{\bar{\ell}-r} \\ -e^{\ell-\bar{r}} & e^{\ell} \end{pmatrix}, \quad \theta = \ell + \bar{\ell} + \log(1 + e^{-(r+\bar{r})}) \tag{3.9}$$

¹¹See appendix D for a discussion of how to find such coordinates.

and potential

$$\begin{aligned}
 K_1^{(0,0)} &= \int \tilde{\ell} d\ell + \bar{\ell} d\bar{\ell} + \tilde{r} dr + \bar{r} d\bar{r} \\
 &= (\ell - \bar{r})(\bar{\ell} - r) - \int^{r+\bar{r}} \log(1 + e^q) dq + \frac{1}{2}(r^2 + \bar{r}^2)
 \end{aligned}
 \tag{3.10}$$

satisfying $\frac{\partial K}{\partial \ell} = \tilde{\ell}$, $\frac{\partial K}{\partial r} = \tilde{r}$. On the overlap of the two patches (comprising the group elements with nonvanishing entries), (3.8) and (3.10) differ by a Legendre transform

$$K_0^{(0,0)}(\tilde{\ell}, \bar{\ell}, r, \bar{r}) = K_1^{(0,0)}(\ell, \bar{\ell}, r, \bar{r}) - \ell\tilde{\ell} - \bar{\ell}\bar{r}.
 \tag{3.11}$$

This appears to be the choice of parametrization and polarization giving the simplest expression for the potential. Some other choices are given in appendix E.

3.1.2 Type (1, 1)

If one instead takes J_+ and J_- induced from different Lie algebra complex structures, say J_+ from \mathbb{J}_1 and J_- from \mathbb{J}_2 , one finds $[J_+, J_-] = 0$ everywhere. In other words, the resulting generalized Kähler structure has type (1, 1), and can be parametrized by a chiral coordinate ϕ and a twisted chiral coordinate χ . Furthermore, J_+ and J_- induce opposite orientations. In this case, the conditions that ϕ is holomorphic with respect to both J_{\pm} determine it uniquely up to a simple redefinition $\phi \rightarrow \phi'(\phi)$. Similarly, χ is also essentially unique.

One choice of parametrization of the group element is given by

$$g = e^{-\zeta\theta} \begin{pmatrix} e^{\bar{\chi}} & e^{\phi} \\ -e^{\bar{\phi}} & e^{\chi} \end{pmatrix}, \quad \theta = \log(e^{\phi+\bar{\phi}} + e^{\chi+\bar{\chi}}).
 \tag{3.12}$$

where we recall that $\zeta = \frac{1}{2}(1 + i)$. Equivalently, the chiral and twisted chiral coordinates are given by

$$\begin{aligned}
 \phi &= \log g_{12}^{\zeta} \bar{g}_{21}^{\bar{\zeta}}, \\
 \chi &= \log g_{22}^{\zeta} \bar{g}_{11}^{\bar{\zeta}}.
 \end{aligned}
 \tag{3.13}$$

This coordinate patch covers the region where all the entries of the group are nonzero. A redefinition $\hat{\phi} = e^{\phi}$, $\hat{\chi} = e^{\chi}$ allows one to reach the diagonal elements ($\hat{\phi} = 0$) and the off-diagonal elements ($\hat{\chi} = 0$).

The generalized potential for the type (1, 1) structure is known [15]

$$K_0^{(1,1)} = \frac{1}{2}(\chi - \bar{\chi})^2 + \int^{\phi+\bar{\phi}-\chi-\bar{\chi}} dq \log(1 + e^q).
 \tag{3.14}$$

By redefining $\hat{\phi} = e^{\phi}$ and checking that the limit $\hat{\phi} \rightarrow 0$ is well-defined, one can verify that this potential is valid on the coordinate patch away from the off-diagonal matrices.¹² The following potential

$$K_1^{(1,1)} = -\frac{1}{2}(\phi - \bar{\phi})^2 - \int^{-\phi-\bar{\phi}+\chi+\bar{\chi}} dq \log(1 + e^q).
 \tag{3.15}$$

¹²In [15], the variables used correspond to $\hat{\phi}, \hat{\chi}$.

is valid on the coordinate patch away from diagonal matrices, as can be seen by redefining $\hat{\chi} = e^\chi$ and checking that the limit $\hat{\chi} \rightarrow 0$ is well-defined. These two patches cover $SU(2) \times U(1)$. On the overlap of the two patches, comprising the group elements with nonvanishing entries, (3.14) and (3.15) differ by a generalized Kähler transformation $K_0^{(1,1)} - K_1^{(1,1)} = -(\chi + \bar{\chi})(\phi + \bar{\phi})$.

The generalized potentials (3.14), (3.15) were obtained by solving the second order differential equations (B.12)–(B.13)¹³ In the next subsection, we shall make use of the discussion in the previous section to derive the type (1, 1) potentials (3.14), (3.15) from the type (0, 0) potentials (3.8), (3.10) via T-duality.

3.2 Isometries

The $SU(2) \times U(1)$ WZW model has isometry group $SU(2)_L \times SU(2)_R \times U(1)$, and the subgroup preserving both complex structures J_\pm is $U(1)_L \times U(1)_R \times U(1)$. It acts on the group element g as

$$g \mapsto h_L g h_R^{-1}, \tag{3.16}$$

with

$$h_L = e^{-i(\epsilon h + \bar{\epsilon} \bar{h})}, \quad h_R = e^{i(\eta \bar{h} + \bar{\eta} h)}, \tag{3.17}$$

where h is defined in (3.1), and ϵ and η are complex parameters.

In the type (0, 0) parametrization (3.6), this corresponds to

$$\begin{aligned} \ell &\mapsto \ell + \bar{\epsilon} + \eta, & \tilde{\ell} &\mapsto \tilde{\ell} + \epsilon + \eta \\ r &\mapsto r - \eta + \bar{\eta}, & \tilde{r} &\mapsto \tilde{r} - \bar{\epsilon} - \eta. \end{aligned} \tag{3.18}$$

The parameters ϵ and η can be promoted to Kac-Moody parameters satisfying

$$\begin{aligned} \bar{\mathbb{D}}_+ \epsilon &= 0, & \mathbb{D}_\pm \epsilon &= 0, \\ \bar{\mathbb{D}}_\pm \eta &= 0, & \mathbb{D}_- \eta &= 0. \end{aligned} \tag{3.19}$$

In the type (1, 1) parametrization (3.12), this corresponds to

$$\phi \mapsto \phi + \epsilon + \eta, \quad \chi \mapsto \chi + \bar{\epsilon} + \eta. \tag{3.20}$$

The parameters ϵ and η can be promoted to Kac-Moody parameters satisfying (note the chirality constraints on ϵ differ from above)

$$\begin{aligned} \bar{\mathbb{D}}_\pm \epsilon &= 0, & \mathbb{D}_+ \epsilon &= 0, \\ \bar{\mathbb{D}}_\pm \eta &= 0, & \mathbb{D}_- \eta &= 0. \end{aligned} \tag{3.21}$$

3.3 T-duality: relating the two types

As discussed in section 2.5, T-duality along a Kac-Moody isometry relates the two generalized structures on $SU(2) \times U(1)$. This T-duality may be realized in (2, 2) superspace using the gauging prescription of [13].

¹³For special case of $SU(2) \times U(1)$, which has no semi-chiral coordinates, these equations turn out to be linear. For generic Lie groups, these equations are nonlinear and difficult to solve.

3.3.1 Type (0, 0) to type (1, 1)

We begin with the type (0, 0) generalized Kähler structure (3.8), and T-dualize along any factor of the $U(1)_L \times U(1)_R \times U(1)$ Kac-Moody isometry group. The complex structures J_{\pm} map these isometries into one another, so in superspace, where the gauge group is complexified, the gauging of any of these isometries is equivalent (up to reparametrizations).

Along $U(1)_R$. Consider first T-duality along $U(1)_R$, which acts on the semi-chiral coordinates as in (3.18) with $\epsilon = 0, \eta = i\lambda$, where λ is a real parameter. This isometry is gauged with an Semichiral Vector Multiplet (SVM) [23] (see appendix C). The combinations invariant under the $U(1)_R$ isometry are $\tilde{\ell} + \bar{\tilde{\ell}}, -\frac{1}{2}(r + \bar{r})$ and $i(\tilde{\ell} - \bar{\tilde{\ell}} + \frac{1}{2}(\bar{r} - r))$, and are respectively gauged with the potentials V^L, V^R and V' of the SVM. Starting from $K_0^{(0,0)}$ in (3.8), we add the generalized Kähler transformation term

$$K^{(0,0)} = K_0^{(0,0)} + \frac{1}{2}(\tilde{\ell}^2 + \bar{\tilde{\ell}}^2) - \frac{1}{4}(r^2 + \bar{r}^2) \tag{3.22}$$

to make the potential exactly invariant.¹⁴ The generalized Kähler transformation terms amount to redefining ℓ and \tilde{r} to the invariant combinations $\ell \mapsto \ell - \tilde{\ell}, \tilde{r} \mapsto \tilde{r} - r/2$. The resulting invariant potential is

$$K^{(0,0)} = \frac{1}{2} \left(\bar{\tilde{\ell}} - \tilde{\ell} + \frac{1}{2}(\bar{r} - r) \right)^2 - \frac{3}{8}(r + \bar{r})^2 - \frac{1}{2}(\tilde{\ell} + \bar{\tilde{\ell}})(r + \bar{r}) + \int^{-r-\bar{r}} dq \log(1 + e^q). \tag{3.23}$$

Gauging with an SVM, enforced to be flat by Lagrange multipliers Φ_I , and gauge fixing $\tilde{\ell} = \bar{\tilde{\ell}} = r = \bar{r} = 0$ yields

$$\tilde{K}^{(0,0)} = -\frac{1}{2}(V')^2 - \frac{3}{2}(V^R)^2 + V^L V^R + \int^{2V^R} dq \log(1 + e^q) - V^I \Phi_I, \tag{3.24}$$

where the Lagrange multipliers are

$$\begin{aligned} \Phi_L &= \frac{1}{2}(\phi + \bar{\phi} - \chi - \bar{\chi}), \\ \Phi_R &= \frac{1}{2}(-\phi - \bar{\phi} - \chi - \bar{\chi}), \\ \Phi' &= \frac{i}{2}(\phi - \bar{\phi} + \bar{\chi} - \chi). \end{aligned} \tag{3.25}$$

Eliminating the SVM gauge fields yields the T-dual potential

$$\begin{aligned} \tilde{K}^{(0,0)} &= -\frac{1}{2}(\chi + \bar{\chi})^2 + \int^{\phi + \bar{\phi} - \chi - \bar{\chi}} dq \log(1 + e^q) - \frac{1}{2}((\phi - \chi)^2 + (\bar{\phi} - \bar{\chi})^2) \\ &\quad + \frac{1}{4}((\phi + \bar{\chi})^2 + (\bar{\phi} + \chi)^2), \end{aligned} \tag{3.26}$$

which is precisely $K_0^{(1,1)}$ (3.14) up to a generalized Kähler transformation.

¹⁴This is not necessary but simplifies the discussion somewhat.

Along $U(1)_L$. Consider now T-duality along the $U(1)_L$ factor of $U(1)_L \times U(1)_R \times U(1)$, which acts on the coordinates as in (3.18) with $\epsilon = i\lambda, \eta = 0$, where λ is a real parameter. In this case, there is a complication because r, \bar{r} are invariant - how does the potential (3.8) couple to the SVM in this case? One way to do so is to perform a Legendre transform from r, \bar{r} to $\tilde{r}, \tilde{\bar{r}}$ (corresponding to a change in polarization), yielding the potential (we also add the generalized Kähler transformation $-\frac{1}{2}(\tilde{\ell}^2 + \tilde{\bar{\ell}}^2)$ to render the potential invariant - this amounts to redefining $\ell \rightarrow \ell + \tilde{\ell}$)

$$\begin{aligned} K^{(0,0)}(\tilde{\ell}, \tilde{\bar{\ell}}, \tilde{r}, \tilde{\bar{r}}) &= K_0^{(0,0)}(\tilde{\ell}, \tilde{\bar{\ell}}, r, \bar{r}) - \frac{1}{2}(\tilde{\ell}^2 + \tilde{\bar{\ell}}^2) - r\tilde{r} - \bar{r}\tilde{\bar{r}} \\ &= -\frac{1}{2}(\tilde{\ell} + \tilde{\bar{\ell}})^2 - r(\tilde{\ell} + \tilde{r}) - \bar{r}(\tilde{\bar{\ell}} + \tilde{\bar{r}}) - r\bar{r} + \int^{-r-\bar{r}} dq \log(1 + e^q). \end{aligned} \quad (3.27)$$

Note that \tilde{r} does indeed transform as $\tilde{r} \mapsto \tilde{r} + i\lambda$, so now the invariant combinations $\tilde{\ell} + \tilde{\bar{\ell}}$, $\tilde{\ell} + \tilde{\bar{r}}$ and $\tilde{\bar{\ell}} + \tilde{r}$ can be respectively gauged with the components $V^L, \tilde{\mathbb{V}}$ and $\tilde{\bar{\mathbb{V}}}$ of the SVM. The T-dual potential is

$$\tilde{K}^{(0,0)} = -\frac{1}{2}(V^L)^2 - r\bar{r} - r\tilde{\bar{\mathbb{V}}} - \bar{r}\tilde{\mathbb{V}} + \int^{-r-\bar{r}} dq \log(1 + e^q) - V^I \Phi_I, \quad (3.28)$$

where

$$V^I \Phi_I = V^L i(\bar{\phi} - \phi) + \tilde{\mathbb{V}}(\bar{\phi} - \chi) + \tilde{\bar{\mathbb{V}}}(\phi - \bar{\chi}). \quad (3.29)$$

Note that the variational equations of V^I are

$$0 = \left(\frac{\partial K_0^{(0,0)}}{\partial r} + \tilde{r} \right) \frac{\partial r}{\partial V^I} + \left(\frac{\partial K_0^{(0,0)}}{\partial \bar{r}} + \tilde{\bar{r}} \right) \frac{\partial \bar{r}}{\partial V^I} + \frac{\partial K^{(0,0)}}{\partial V^I}, \quad (3.30)$$

where the derivative in the last term is taken with r, \bar{r} held fixed. The two terms in parentheses vanish. In particular, the variational equation of $\tilde{\mathbb{V}}$ sets $\bar{r} = \chi - \bar{\phi}$. The T-dual potential then simplifies to

$$\tilde{K}^{(0,0)} = \frac{1}{2}(\chi - \bar{\chi})^2 + \int^{\phi + \bar{\phi} - \chi - \bar{\chi}} dq \log(1 + e^q) - \frac{1}{2}((\phi - \chi)^2 + (\bar{\phi} - \bar{\chi})^2), \quad (3.31)$$

which we recognize as (3.14) up to a generalized Kähler transformation. We have obtained the type (1, 1) potential without the need to solve second order differential equations.

3.3.2 Using the group coordinates to find the T-dual

We make an observation of the T-dualities which we performed, which we will apply to simplify the discussion in the $SU(3)$ case.

In the type (0, 0) structure, both complex structures J_{\pm} were induced from the Lie algebra structure \mathbb{J}_1 . As discussed in section 2.5, T-duality along the left Kac-Moody isometry $U(1)_L$ does not change the metric, torsion and left complex structure. Therefore, on the dual type (1, 1) structure, we know exactly what the complex structures are: J_+ is unchanged and is still induced from \mathbb{J}_1 , while J_- is changed and is now induced from \mathbb{J}_2 . The adapted coordinates for this particular generalized Kähler structure are already

known and given in (3.12). The solution to the SVM equations of motion must therefore be given by the original type (0, 0) coordinates (3.6),¹⁵ expressed in terms of the type (1, 1) coordinates of the dual (3.12), to wit

$$\begin{aligned} \ell &= \chi + \phi, & \tilde{\ell} &= \phi, \\ r &= \bar{\chi} - \phi, & \tilde{r} &= \phi - \theta, \end{aligned} \quad \text{where } \theta = \log(e^{\phi+\bar{\phi}} + e^{\chi+\bar{\chi}}). \quad (3.32)$$

Notice also that, when the isometries act as translations (all the examples we encounter in this paper are translational isometries), the Lagrange multiplier term may be written as

$$V^I \Phi_I = -\ell(\Phi) \tilde{\ell} - \bar{\ell}(\Phi) \tilde{\bar{\ell}} - r(\Phi) \tilde{r} - \bar{r}(\Phi) \tilde{\bar{r}}, \quad (3.33)$$

where $\ell(\Phi), \bar{\ell}(\Phi), r(\Phi), \bar{r}(\Phi)$ are functions of $\Phi = (\phi, \bar{\phi}, \chi, \bar{\chi})$ given in (3.32). This yields a simple integral expression for the type (1, 1) potential

$$\begin{aligned} K^{(1,1)}(\phi, \bar{\phi}, \chi, \bar{\chi}) &= \left(-\int \ell d\tilde{\ell} + \bar{\ell} d\tilde{\bar{\ell}} + r d\tilde{r} + \bar{r} d\tilde{\bar{r}} \right) - V^I \Phi_I \\ &= \int \tilde{\ell} d\ell + \tilde{\bar{\ell}} d\bar{\ell} + \tilde{r} dr + \tilde{\bar{r}} d\bar{r}, \end{aligned} \quad (3.34)$$

where the semi-chiral fields $\tilde{\ell}, \tilde{\bar{\ell}}, \tilde{r}, \tilde{\bar{r}}$ are to be understood as functions of ϕ, χ through (3.32). It is straightforward to verify, via direct substitution, that this exactly reproduces (3.31).

For another illustration of using the group coordinates to solve the vector multiplet moment map equations, see appendix F where the T-duality in the other direction, which is done with an Large Vector Multiplet (LVM) [23], is discussed.

4 SU(3)

4.1 Complex coordinates and generalized Kähler potential

On the Lie algebra, take the basis $\{h, \bar{h}, e_3, \bar{e}_3, e_1, \bar{e}_1, e_2, \bar{e}_2\}$, where

$$h = \begin{pmatrix} \frac{1}{2} + \frac{i}{2\sqrt{3}} & & & \\ & -\frac{i}{\sqrt{3}} & & \\ & & -\frac{1}{2} + \frac{i}{2\sqrt{3}} & \\ & & & \end{pmatrix}, \quad e_3 = \begin{pmatrix} 1 \\ & & & \\ & & & \\ & & & \end{pmatrix}, \quad e_1 = \begin{pmatrix} 1 \\ & & & \\ & & & \\ & & & \end{pmatrix}, \quad e_2 = \begin{pmatrix} & & & \\ & & & \\ & & & \\ & & & 1 \end{pmatrix}, \quad (4.1)$$

and the bar denotes hermitian conjugation. The two complex structures on the Lie algebra compatible with the choice of Cartan subalgebra h, \bar{h} are

$$\mathbb{J}_1 = \text{diag}(i, -i, i, -i, i, -i, i, -i), \quad \text{and} \quad \mathbb{J}_2 = \text{diag}(-i, i, i, -i, i, -i, i, -i). \quad (4.2)$$

As discussed in section 2.3, SU(3) admits generalized Kähler structures of two different types depending on whether one takes J_{\pm} induced from the same or from different Lie algebra complex structures $\mathbb{J}_1, \mathbb{J}_2$.

¹⁵With ℓ replaced with $\ell + \tilde{\ell}$ corresponding to the addition of the generalized Kähler transformation term $-\frac{1}{2}(\tilde{\ell}^2 + \bar{\tilde{\ell}}^2)$.

4.1.1 Type (0, 0)

If one takes J_+ and J_- both to be induced from the same Lie algebra complex structure, say \mathbb{J}_1 , then generically the resulting generalized Kähler structure has type (0, 0).¹⁶ The J_{\pm} complex coordinates take the simplest form when presented in an overcomplete basis,

$$\begin{aligned} z_+^{\phi} &= \log \bar{g}_{31}^{\omega} g_{13}^{\omega}, & z_+^{\chi} &= \log \bar{g}_{11}^{\omega} g_{33}^{\omega}, \\ z_+^1 &= \log \frac{g_{13}}{g_{23}}, & z_+^2 &= \log \frac{g_{23}}{g_{33}}, & z_+^3 &= \log \frac{\bar{g}_{11}}{\bar{g}_{21}}, & z_+^4 &= \log \frac{\bar{g}_{21}}{\bar{g}_{31}}, \end{aligned} \quad (4.3)$$

$$\begin{aligned} z_-^{\phi} &= \log \bar{g}_{31}^{\omega} g_{13}^{\omega}, & z_-^{\bar{\chi}} &= \log \bar{g}_{11}^{\omega} \bar{g}_{33}^{\omega}, \\ z_-^1 &= \log \frac{g_{11}}{g_{12}}, & z_-^2 &= \log \frac{g_{12}}{g_{13}}, & z_-^3 &= \log \frac{\bar{g}_{31}}{\bar{g}_{32}}, & z_-^4 &= \log \frac{\bar{g}_{32}}{\bar{g}_{33}}, \end{aligned} \quad (4.4)$$

where g_{ij} is the (i, j) th entry of the group element g in the defining representation of $SU(3)$, and $\omega = e^{i\pi/3} = \frac{1}{2}(1 + i\sqrt{3})$. For each of $+$ and $-$, the six complex coordinates satisfy two relations

$$\begin{aligned} e^{z_{\pm}^1 + z_{\pm}^3} + e^{-z_{\pm}^2 - z_{\pm}^4} + 1 &= 0, \\ z_+^{\phi} - z_+^{\chi} &= \omega(z_+^1 + z_+^2) - \bar{\omega}(z_+^3 + z_+^4), \\ z_-^{\phi} - z_-^{\bar{\chi}} &= -\bar{\omega}(z_-^1 + z_-^2) + \omega(z_-^3 + z_-^4). \end{aligned} \quad (4.5)$$

Semichiral coordinates are holomorphic coordinates that are Darboux with respect to the Poisson structure σ : $\sigma(d\ell^j, d\bar{\ell}^k) = \delta^{jk}$, $\sigma(d\ell^j, d\ell^k) = \sigma(d\bar{\ell}^j, d\bar{\ell}^k) = 0$, $\sigma(dr^j, d\bar{r}^k) = -\delta^{jk}$ and $\sigma(dr^j, dr^k) = \sigma(d\bar{r}^j, d\bar{r}^k) = 0$. One choice of semi-chiral coordinates is given by

$$\begin{aligned} \hat{\ell}^1 &= \frac{1}{3}(z_+^{\chi} + 2z_+^{\phi} - \omega z_+^1 + \bar{\omega} z_+^4) = \frac{1}{3} \log(\bar{g}_{11} \bar{g}_{21} \bar{g}_{31})^{\bar{\omega}} (g_{13} g_{23} g_{33})^{\omega}, \\ \hat{\bar{\ell}}^1 &= (\bar{\omega} - \omega)(z_+^1 + z_+^2 + z_+^3 + z_+^4) = (\bar{\omega} - \omega) \log \frac{\bar{g}_{11} g_{13}}{\bar{g}_{31} g_{33}}, \\ \hat{\ell}^2 &= z_+^{\chi} = \log \bar{g}_{11}^{\omega} g_{33}^{\omega}, \\ \hat{\bar{\ell}}^2 &= z_+^{\phi} = \log \bar{g}_{31}^{\omega} g_{13}^{\omega}, \\ \hat{r}^1 &= (\bar{\omega} - \omega)(z_-^1 + z_-^2 + z_-^3 + z_-^4) = (\bar{\omega} - \omega) \log \frac{g_{13} \bar{g}_{33}}{g_{11} \bar{g}_{31}}, \\ \hat{r}^1 &= \frac{1}{3}(z_-^{\bar{\chi}} + 2z_-^{\phi} + \bar{\omega} z_-^2 - \omega z_-^3) = \frac{1}{3} \log(g_{11} g_{12} g_{13})^{\bar{\omega}} (\bar{g}_{31} \bar{g}_{32} \bar{g}_{33})^{\omega}, \\ \hat{r}^2 &= z_-^{\bar{\chi}} = \log \bar{g}_{11}^{\omega} \bar{g}_{33}^{\omega}, \\ \hat{\bar{r}}^2 &= z_-^{\phi} = \log \bar{g}_{13}^{\omega} \bar{g}_{31}^{\omega}. \end{aligned} \quad (4.6)$$

(Recall $\omega = e^{i\pi/3} = \frac{1}{2}(1 + i\sqrt{3})$.) Choosing the polarizations defined by $\hat{\ell}^j, \hat{\bar{\ell}}^j$ and $\hat{r}^j, \hat{\bar{r}}^j$, the group element is parametrized as

$$g = \begin{pmatrix} \exp(\hat{\bar{\ell}}^2 + u\hat{h}_1) & \exp(3\hat{r}^1 - \hat{\bar{\ell}}^2 - \hat{r}^2 - \hat{h}_1 + \bar{u}\hat{h}_4) & \exp(\hat{r}^2 - \bar{u}\hat{h}_2) \\ -\exp(3\hat{\bar{\ell}}^1 - \hat{\bar{\ell}}^2 - \hat{r}^2 - \hat{h}_2 + u\hat{h}_3) & g_{22} & \exp(3\hat{\ell}^1 - \hat{\bar{\ell}}^2 - \hat{r}^2 - \hat{h}_2 + u\hat{h}_3) \\ \exp(\hat{r}^2 - \bar{u}\hat{h}_2) & -\exp(3\hat{\bar{r}}^1 - \hat{\bar{r}}^2 - \hat{\bar{\ell}}^2 - \hat{h}_1 + \bar{u}\hat{h}_4) & \exp(\hat{\bar{\ell}}^2 + u\hat{h}_1) \end{pmatrix} \quad (4.7)$$

¹⁶There are loci of positive codimension on which $\ker[J_+, J_-]$ is nontrivial.

where $u = \frac{1}{\sqrt{3}}e^{i\pi/6} = \frac{1}{2}(1 + \frac{i}{\sqrt{3}})$ and $\hat{h}_1, \hat{h}_2, \hat{h}_3, \hat{h}_4$ are functions of $\hat{\ell}^j, \bar{\ell}^j, \hat{r}^j, \bar{r}^j$, determined by the orthonormality of the first and third rows and columns;¹⁷ and finally g_{22} may be determined by unimodularity.

To find the potential, we need to express $\hat{\ell}^j, \hat{r}^j$ in terms of $\bar{\ell}^j, \bar{r}^j$. It is straightforward to verify that

$$\begin{aligned}\hat{\ell}^1 &= -\bar{h}_1 + \hat{h}_2, \\ \hat{\ell}^2 &= \hat{r}^2 - \hat{h}_2, \\ \hat{r}^1 &= -\hat{h}_1 + \hat{h}_2, \\ \hat{r}^2 &= \bar{\ell}^2 + \hat{h}_1.\end{aligned}\tag{4.8}$$

The difference between the one-form symplectic potentials adapted to the left and right semi-chiral coordinates is the closed one-form $\hat{\theta}_1 + \hat{\theta}_2$, where

$$\hat{\theta}_j = \hat{\ell}^j d\hat{\ell}^j + \bar{\ell}^j d\bar{\ell}^j - \hat{r}^j d\hat{r}^j - \bar{r}^j d\bar{r}^j \quad (\text{no sum over } j).\tag{4.9}$$

The potential is given by

$$K = \int_{\mathcal{O}}^{(\hat{\ell}^j, \bar{\ell}^j, \hat{r}^j, \bar{r}^j)} \hat{\theta}_1 + \hat{\theta}_2,\tag{4.10}$$

where \mathcal{O} is some base point. The closure condition $d(\hat{\theta}_1 + \hat{\theta}_2) = 0$ ensures that the integral is independent of path. K generates the symplectomorphism between left and right semi-chiral coordinates

$$\begin{aligned}\frac{\partial K}{\partial \hat{\ell}^j} &= \hat{\ell}^j, & \frac{\partial K}{\partial \bar{\ell}^j} &= \bar{\ell}^j, \\ \frac{\partial K}{\partial \hat{r}^j} &= -\hat{r}^j, & \frac{\partial K}{\partial \bar{r}^j} &= -\bar{r}^j.\end{aligned}\tag{4.11}$$

A different choice. In section 4.2, it will prove convenient to choose instead the following Darboux coordinates (these are adapted to the isometry considered later in section 4.2)

$$\begin{aligned}\ell^1 &= \frac{1}{3}(z_+^\chi + 2z_+^\phi - \omega z_+^1 + \bar{\omega} z_+^4) = \frac{1}{3} \log(\bar{g}_{11}\bar{g}_{21}\bar{g}_{31})^{\bar{\omega}}(g_{13}g_{23}g_{33})^\omega, \\ \bar{\ell}^1 &= (\bar{\omega} - \omega)(z_+^1 + z_+^2 + z_+^3 + z_+^4) = (\bar{\omega} - \omega) \log \frac{\bar{g}_{11}g_{13}}{\bar{g}_{31}g_{33}}, \\ \ell^2 &= z_+^\chi = \log \bar{g}_{11}g_{33}^\omega, \\ \bar{\ell}^2 &= z_+^\phi + z_+^\chi = \log(\bar{g}_{11}\bar{g}_{31})^{\bar{\omega}}(g_{13}g_{33})^\omega, \\ r^1 &= (\omega - 2\bar{\omega})(z_-^1 + z_-^2) + (2\omega - \bar{\omega})(z_-^3 + z_-^4) = (2\bar{\omega} - \omega) \log \frac{g_{13}}{g_{11}} + (\bar{\omega} - 2\omega) \log \frac{\bar{g}_{33}}{\bar{g}_{31}}, \\ \bar{r}^1 &= \frac{1}{6}(z_-^\chi - z_-^\phi + \bar{\omega} z_-^2 - \omega z_-^3) = \frac{1}{6} \log \left(\frac{g_{11}g_{12}}{g_{13}^2} \right)^{\bar{\omega}} \left(\frac{\bar{g}_{32}\bar{g}_{33}}{\bar{g}_{31}^2} \right)^\omega, \\ r^2 &= \omega(z_-^1 + z_-^2) - \bar{\omega}(z_-^3 + z_-^4) = \log \frac{g_{11}^\omega \bar{g}_{33}^{\bar{\omega}}}{g_{13}^\omega \bar{g}_{31}^{\bar{\omega}}}, \\ \bar{r}^2 &= \frac{1}{6}(z_-^\chi + 5z_-^\phi + \bar{\omega} z_-^2 - \omega z_-^3) = \frac{1}{6} \log(g_{11}g_{12}g_{13}^4)^{\bar{\omega}}(\bar{g}_{31}^4\bar{g}_{32}\bar{g}_{33})^\omega.\end{aligned}\tag{4.12}$$

¹⁷Unfortunately, it seems that $\hat{h}_1, \hat{h}_2, \hat{h}_3, \hat{h}_4$ cannot be written down in terms of elementary functions, so we have to work implicitly.

In the polarizations defined by $\ell^j, \bar{\ell}^j$ and $\tilde{r}^j, \bar{\tilde{r}}^j$, the group element is parametrized as

$$g = \begin{pmatrix} \exp(\bar{\ell}^2 + u h_1) & \exp(4\tilde{r}^1 - \bar{\ell}^2 + 2\tilde{r}^2 - h_1 + \bar{u} h_4) & \exp(-\tilde{r}^1 + \tilde{r}^2 - \bar{u} h_2) \\ -\exp(3\bar{\ell}^1 - \bar{\ell}^2 + \tilde{r}^1 - \tilde{r}^2 - \bar{h}_2 + u h_3) & g_{22} & \exp(3\ell^1 - \ell^2 + \tilde{r}^1 - \tilde{r}^2 - h_2 + u \bar{h}_3) \\ \exp(-\tilde{r}^1 + \tilde{r}^2 - \bar{u} \bar{h}_2) & -\exp(4\bar{\tilde{r}}^1 + 2\bar{\tilde{r}}^2 - \ell^2 - \bar{h}_1 + \bar{u} \bar{h}_4) & \exp(\ell^2 + u \bar{h}_1) \end{pmatrix}, \quad (4.13)$$

where h_1, h_2, h_3, h_4 are once again functions of $\ell^j, \bar{\ell}^j, \tilde{r}^j, \bar{\tilde{r}}^j$ determined by the orthonormality of the first and last rows and columns. The Darboux partners are expressed in this mixed coordinate system as

$$\begin{aligned} \tilde{\ell}^1 &= -\bar{h}_1 + h_2, \\ \tilde{\ell}^2 &= -\tilde{r}^1 + \tilde{r}^2 + \ell^2 - h_2, \\ r^1 &= -\bar{\ell}^2 - \tilde{r}^1 + \tilde{r}^2 - 2h_1 + h_2, \\ r^2 &= \bar{\ell}^2 + \tilde{r}^1 - \tilde{r}^2 + h_2. \end{aligned} \quad (4.14)$$

The generalized potential is given by

$$K^{(0,0)} = \int_{\mathcal{O}}^{(\ell^j, \bar{\ell}^j, \tilde{r}^j, \bar{\tilde{r}}^j)} \theta_1 + \theta_2, \quad \text{where } \theta = \theta_1 + \theta_2, \quad (4.15)$$

$$\theta_j = \tilde{\ell}^j d\ell^j + \bar{\tilde{\ell}}^j d\bar{\ell}^j - r^j d\tilde{r}^j - \bar{r}^j d\bar{\tilde{r}}^j \quad (\text{no sum over } j) \quad (4.16)$$

4.1.2 Type (1, 1)

If one instead takes J_+ and J_- induced from different Lie algebra complex structures, say J_+ from \mathbb{J}_1 and J_- from \mathbb{J}_2 , then generically the resulting generalized Kähler structure has type (1, 1). The biholomorphic coordinate is

$$\phi = \log \bar{g}_{31}^{\bar{\omega}} g_{13}^{\omega}, \quad (4.17)$$

and represents a chiral superfield in the (2, 2) sigma model, while the J_+ -holomorphic and J_- -antiholomorphic coordinate is

$$\chi = \log \bar{g}_{11}^{\bar{\omega}} g_{33}^{\omega}, \quad (4.18)$$

and represents a twisted chiral superfield. The other holomorphic coordinates once again take the simplest form in an overcomplete basis

$$w_+^1 = \log \frac{g_{13}}{g_{23}}, \quad w_+^2 = \log \frac{g_{23}}{g_{33}}, \quad w_+^3 = \log \frac{\bar{g}_{11}}{g_{21}}, \quad w_+^4 = \log \frac{\bar{g}_{21}}{\bar{g}_{31}}, \quad (4.19)$$

$$w_-^1 = \log \frac{g_{11}}{g_{12}}, \quad w_-^2 = \log \frac{g_{12}}{g_{13}}, \quad w_-^3 = \log \frac{\bar{g}_{31}}{\bar{g}_{32}}, \quad w_-^4 = \log \frac{\bar{g}_{32}}{\bar{g}_{33}}, \quad (4.20)$$

satisfying

$$e^{w_{\pm}^1 + w_{\pm}^3} + e^{-w_{\pm}^2 - w_{\pm}^4} + 1 = 0, \quad (4.21)$$

$$\phi - \chi = \omega(w_+^1 + w_+^2) - \bar{\omega}(w_+^3 + w_+^4), \quad (4.22)$$

$$\phi - \bar{\chi} = -\omega(w_-^1 + w_-^2) + \bar{\omega}(w_-^3 + w_-^4). \quad (4.23)$$

One choice of semi-chiral coordinates is

$$\begin{aligned}
 \hat{\ell} &= \phi - \omega w_+^1 + \bar{\omega} w_+^4 = \log g_{23}^\omega \bar{g}_{21}^{\bar{\omega}}, \\
 \hat{\bar{\ell}} &= -w_+^1 - w_+^2 + w_+^3 + w_+^4 = \log \frac{\bar{g}_{11} g_{33}}{\bar{g}_{31} g_{13}}, \\
 \hat{r} &= -w_-^1 - w_-^2 + w_-^3 + w_-^4 = \log \frac{\bar{g}_{31} g_{13}}{g_{11} \bar{g}_{33}}, \\
 \hat{\bar{r}} &= \phi + \omega w_-^2 - \bar{\omega} w_-^3 = \log g_{12}^\omega \bar{g}_{32}^{\bar{\omega}}.
 \end{aligned}
 \tag{4.24}$$

In the polarizations defined by $\hat{\ell}, \hat{\bar{\ell}}$ and $\hat{r}, \hat{\bar{r}}$, the parametrization looks relatively uncluttered

$$g = \begin{pmatrix} e^{\bar{\chi}+u\hat{f}_1} & e^{\hat{r}+u\hat{f}_4} & e^{\phi+u\hat{f}_2} \\ -e^{\bar{\ell}+u\hat{f}_3} & g_{22} & e^{\hat{\ell}+u\hat{f}_3} \\ e^{\bar{\phi}+u\hat{f}_2} & -e^{\hat{\bar{r}}+u\hat{f}_4} & e^{\chi+u\hat{f}_1} \end{pmatrix}.
 \tag{4.25}$$

(Recall $u = \frac{1}{\sqrt{3}}e^{i\pi/6} = \frac{1}{2}(1 + \frac{i}{\sqrt{3}})$.) The conditions of orthonormality on the first and third rows and columns are

$$\begin{aligned}
 e^{\phi+\chi}(e^{\bar{u}\hat{f}_1+u\hat{f}_2} + e^{u\hat{f}_1+\bar{u}\hat{f}_2}) - e^{2\hat{\ell}+\sqrt{3}\hat{f}_3} &= 0, \\
 e^{\phi+\bar{\chi}}(e^{\bar{u}\hat{\bar{f}}_1+u\hat{f}_2} + e^{u\hat{\bar{f}}_1+\bar{u}\hat{f}_2}) - e^{2\hat{\bar{r}}+\sqrt{3}\hat{f}_4} &= 0, \\
 e^{2\text{Re}(\chi+u\hat{f}_1)} + e^{2\text{Re}(\phi+u\hat{f}_2)} + e^{2\text{Re}(\hat{\ell}+u\hat{f}_3)} &= 1, \\
 e^{2\text{Re}(\chi+\bar{u}\hat{f}_1)} + e^{2\text{Re}(\phi+\bar{u}\hat{f}_2)} + e^{2\text{Re}(\hat{\bar{\ell}}+\bar{u}\hat{f}_3)} &= 1, \\
 e^{2\text{Re}(\chi+\bar{u}\hat{f}_1)} + e^{2\text{Re}(\phi+u\hat{f}_2)} + e^{2\text{Re}(\hat{r}+u\hat{f}_4)} &= 1, \\
 e^{2\text{Re}(\chi+u\hat{f}_1)} + e^{2\text{Re}(\phi+\bar{u}\hat{f}_2)} + e^{2\text{Re}(\hat{\bar{r}}+\bar{u}\hat{f}_4)} &= 1.
 \end{aligned}
 \tag{4.26}$$

The first equation of (4.26) is complex, and may be solved for \hat{f}_3 in terms of $\phi, \chi, \hat{\ell}, \hat{f}_1, \hat{f}_2$. This may then be substituted into the third and fourth equations, which are real. Similarly, the second complex equation may be solved for \hat{f}_4 in terms of $\phi, \bar{\chi}, \hat{\bar{r}}, \hat{\bar{f}}_1, \hat{f}_2$, and substituted into the fifth and sixth equations. This yields four real equations, from which we may solve for $\hat{f}_1, \hat{f}_2, \hat{\bar{f}}_1$ and $\hat{\bar{f}}_2$.¹⁸ It is not obvious, at first glance, that these 8 real equations (4.26) are independent — for instance, the equations $gg^\dagger = \mathbb{1}$ and $g^\dagger g = \mathbb{1}$ are equivalent — but we have checked that they indeed are, and hence uniquely determine the $\hat{f}_i, \hat{\bar{f}}_i$ s.

Note that these equations (4.26) exhibit two involutive symmetries. There is first a left-right symmetry given by exchanging $\chi \leftrightarrow \bar{\chi}, \hat{\ell} \leftrightarrow \hat{\bar{r}}, \hat{f}_1 \leftrightarrow \hat{\bar{f}}_1, \hat{f}_3 \leftrightarrow \hat{f}_4$, which exchanges the first, third, fourth equations with the second, fifth and sixth equations. Under this symmetry, the Darboux partners

$$\hat{\bar{\ell}} = \log \frac{\bar{g}_{11} g_{33}}{\bar{g}_{31} g_{13}} = 2\chi - 2\phi + \hat{f}_1 - \hat{f}_2,
 \tag{4.27}$$

$$\hat{r} = \log \frac{\bar{g}_{31} g_{13}}{g_{11} \bar{g}_{33}} = 2\phi - 2\bar{\chi} - \hat{\bar{f}}_1 + \hat{f}_2
 \tag{4.28}$$

¹⁸As before, it is not possible to write down $\hat{f}_1, \hat{f}_2, \hat{\bar{f}}_1, \hat{\bar{f}}_2$ using elementary functions, so we work implicitly.

are interchanged with a twist, $\hat{\ell} \leftrightarrow -\hat{r}$. Second, there is a local mirror symmetry which exchanges $\phi \leftrightarrow \chi, \hat{r} \leftrightarrow \bar{\hat{r}}, \hat{f}_1 \leftrightarrow \hat{f}_2, \hat{f}_4 \leftrightarrow \bar{\hat{f}}_4, \hat{\ell} \leftrightarrow -\hat{\ell}, \hat{r} \leftrightarrow -\bar{\hat{r}}$. This exchanges the second equation with its conjugate, and the fifth with the sixth equation, and preserves the other equations.

On top of symplectomorphisms on each symplectic leaf, the semi-chiral coordinates may also be redefined by arbitrary functions of chiral and twisted chiral coordinates (with the appropriate holomorphy)

$$\begin{aligned}\hat{\ell} &\mapsto \hat{\ell}'(\hat{\ell}, \bar{\hat{\ell}}, \phi, \chi), \\ \hat{r} &\mapsto \hat{r}'(\hat{r}, \bar{\hat{r}}, \phi, \bar{\chi}).\end{aligned}\tag{4.29}$$

There is therefore a large amount of freedom in the choice of holomorphic Darboux coordinates $\hat{\ell}, \bar{\hat{\ell}}, \hat{r}, \bar{\hat{r}}$.

A different choice. In section 4.2 we will find it convenient to use a different choice of semi-chiral coordinates (adapted to an isometry introduced later in section 4.2), given by

$$\begin{aligned}\ell &= \frac{1}{3}(w_+^\chi + 2w_+^\phi - \omega w_+^1 + \bar{\omega} w_+^4) = \frac{1}{3} \log(\bar{g}_{11} \bar{g}_{21} \bar{g}_{31})^{\bar{\omega}} (g_{13} g_{23} g_{33})^\omega, \\ \tilde{\ell} &= (\bar{\omega} - \omega)(w_+^1 + w_+^2 + w_+^3 + w_+^4) = (\bar{\omega} - \omega) \log \frac{\bar{g}_{11} g_{13}}{\bar{g}_{31} g_{33}}, \\ r &= (\omega - 2\bar{\omega})(w_-^1 + w_-^2) + (2\omega - \bar{\omega})(w_-^3 + w_-^4) = (\omega - 2\bar{\omega}) \log \frac{g_{11}}{g_{13}} + (\bar{\omega} - 2\omega) \log \frac{\bar{g}_{33}}{\bar{g}_{31}}, \\ \tilde{r} &= \frac{1}{6}(\bar{\omega} w_-^1 + 2\bar{\omega} w_-^2 - 2\omega w_-^3 - \omega w_-^4) = \frac{1}{6} \log \left(\frac{g_{11} g_{12}}{g_{13}^2} \right)^{\bar{\omega}} \left(\frac{\bar{g}_{32} \bar{g}_{33}}{\bar{g}_{31}^2} \right)^\omega.\end{aligned}\tag{4.30}$$

Note that they coincide with $\ell^1, \bar{\ell}^1, r^1, \bar{r}^1$ in (4.12). The parametrization of the group element is

$$g = \begin{pmatrix} \exp(\bar{\chi} + u f_1) & \exp(6\tilde{r} + 2\phi - \bar{\chi} - f_1 + 2f_2 + \bar{u} f_4) & \exp(\phi + u f_2) \\ -\exp(3\ell - \bar{\phi} - \bar{\chi} + u f_3) & g_{22} & \exp(3\ell - \phi - \chi + u \bar{f}_3) \\ \exp(\bar{\phi} + u \bar{f}_2) & -\exp(6\bar{\tilde{r}} + 2\bar{\phi} - \chi - \bar{f}_1 + 2\bar{f}_2 + \bar{u} \bar{f}_4) & \exp(\chi + u \bar{f}_1) \end{pmatrix},\tag{4.31}$$

with the Darboux partners given by

$$\begin{aligned}\tilde{\ell} &= -\bar{f}_1 + f_2, \\ r &= \phi - \bar{\chi} - 2f_1 + 2f_2.\end{aligned}\tag{4.32}$$

On each symplectic leaf, the generating function of the symplectomorphism (4.11) $(\ell, \bar{\ell}, \tilde{\ell}, \bar{\tilde{\ell}}) \rightarrow (r, \bar{r}, \tilde{r}, \bar{\tilde{r}})$ is formally

$$K^{(1,1)} = \int_{\mathcal{O}}^{(\ell, \bar{\ell}, \tilde{\ell}, \bar{\tilde{\ell}})} \theta_1, \quad \text{where } \theta_1 = \tilde{\ell} d\ell + \bar{\tilde{\ell}} d\bar{\ell} - r d\tilde{r} - \bar{r} d\bar{\tilde{r}},\tag{4.33}$$

where $\mathcal{O} = \mathcal{O}(\phi, \bar{\phi}, \chi, \bar{\chi})$ is collection of base points, one on each symplectic leaf. To find the explicit dependence of K on $\phi, \bar{\phi}, \chi, \bar{\chi}$, one has to, as discussed above, solve the second order nonlinear differential equations (B.12)–(B.13). However, this can be circumvented, as discussed in section 2.6, by relating the type (1, 1) generalized Kähler structure to the type (0, 0) structure (4.15).

4.2 T-duality: relating the two generalized Kähler structures

4.2.1 Isometries

The group of isometries preserving both complex structures of $SU(3)$ is $U(1)_L^2 \times U(1)_R^2$, acting on the group element as

$$g \mapsto h_L g h_R^{-1} \equiv e^{\epsilon \bar{h} - \bar{\epsilon} h} g e^{\bar{\eta} \bar{h} - \eta h}, \quad (4.34)$$

where h and \bar{h} are defined in (4.1), and ϵ and η are complex Kac-Moody parameters. In the type (0,0) structure, they obey the constraints

$$\bar{\mathbb{D}}_+ \epsilon = 0, \quad \mathbb{D}_\pm \epsilon = 0, \quad \bar{\mathbb{D}}_\pm \eta = 0, \quad \mathbb{D}_- \eta = 0, \quad (4.35)$$

and the coordinates (4.12) transform as

$$\begin{aligned} \ell^1 &\mapsto \ell^1 + \eta, & \tilde{\ell}^1 &\mapsto \tilde{\ell}^1, \\ \ell^2 &\mapsto \ell^2 + \bar{\epsilon} + \eta, & \tilde{\ell}^2 &\mapsto \tilde{\ell}^2 + \epsilon + \bar{\epsilon} + 2\eta, \\ r^1 &\mapsto r^1 + \eta - \bar{\eta}, & \tilde{r}^1 &\mapsto \tilde{r}^1 + \frac{1}{2}\bar{\eta}, \\ r^2 &\mapsto r^2 - \eta + \bar{\eta}, & \tilde{r}^2 &\mapsto \tilde{r}^2 - \bar{\epsilon} - \frac{1}{2}\bar{\eta}. \end{aligned} \quad (4.36)$$

Meanwhile, in the type (1,1) structure, ϵ and η obey (note that, as in the $SU(2) \times U(1)$ case, the chirality constraint on ϵ differs from that in the type (0,0) structure)

$$\bar{\mathbb{D}}_\pm \epsilon = 0, \quad \mathbb{D}_+ \epsilon = 0, \quad \bar{\mathbb{D}}_\pm \eta = 0, \quad \mathbb{D}_- \eta = 0, \quad (4.37)$$

and the coordinates (4.30) transform as

$$\begin{aligned} \phi &\mapsto \phi + \epsilon + \eta, & \chi &\mapsto \chi + \bar{\epsilon} + \eta, \\ \ell &\mapsto \ell + \eta, & \tilde{\ell} &\mapsto \tilde{\ell}, \\ r &\mapsto r + \eta - \bar{\eta}, & \tilde{r} &\mapsto \tilde{r} + \frac{1}{2}\bar{\eta}. \end{aligned} \quad (4.38)$$

4.2.2 T-duality from type (0,0) to type (1,1)

In this subsection, we T-dualize from the type (0,0) structure (4.15) to the type (1,1) structure along the left Kac-Moody $U(1)_L$ isometry defined by setting $\epsilon = i\lambda$ and $\eta = 0$ in (4.34), where λ is a real parameter. Under this isometry, $\ell^1, \bar{\ell}^1, \tilde{r}^1, \bar{\tilde{r}}^1$ are invariant spectator fields, while $\ell^2 \mapsto \ell^2 - i\lambda$, $\tilde{r}^2 \mapsto \tilde{r}^2 + i\lambda$. The invariance of the Darboux partners $\tilde{\ell}^j, \bar{\tilde{\ell}}^j, r^j, \tilde{r}^j$ guarantees that the potential (4.15) is invariant this isometry.

The Killing field of the isometry is

$$k = i(-\partial_{\ell^2} + \partial_{\bar{\ell}^2} + \partial_{\tilde{r}^2} - \partial_{\bar{\tilde{r}}^2}); \quad (4.39)$$

and the invariant combinations $-\ell^2 - \bar{\ell}^2$, $\tilde{r}^2 + \bar{\tilde{r}}^2$ and $i(\ell^2 - \bar{\ell}^2 + \tilde{r}^2 - \bar{\tilde{r}}^2)$ can be gauged respectively by the components V^L, V^R and V^I of the SVM. The T-dual potential is obtained by constraining the SVM to be flat using Lagrange multipliers Φ_I

$$\tilde{K}(\ell^1, \bar{\ell}^1, \tilde{r}^1, \bar{\tilde{r}}^1, \Phi_I) = K^g(\ell^1, \bar{\ell}^1, \tilde{r}^1, \bar{\tilde{r}}^1, V^I) - V^I \Phi_I, \quad (4.40)$$

where V^I are to be eliminated using their equations of motion. We make use of the observation in section 3.3.2: since the T-duality is along a left Kac-Moody isometry, the left complex structure is preserved and continues to be induced by \mathbb{J}_1 , and therefore the relation between the type (0,0) coordinates (4.12) and type (1,1) coordinates (4.17), (4.18), (4.30) is a solution to the SVM equations of motion. This relation is

$$\begin{aligned}\ell^2 &= \chi, \\ \tilde{\ell}^2 &= \phi + \chi, \\ r^2 &= \bar{\chi} - \phi, \\ \tilde{r}^2 &= \tilde{r}^1 + \phi + f_2.\end{aligned}\tag{4.41}$$

It is easily verified that this relation is consistent with (4.14). The moment maps are linear combinations of the Darboux partners since the isometry acts translationally, so the SVM equations of motion are

$$\begin{aligned}\Phi_L &= -\frac{1}{2}(\tilde{\ell}^2 + \bar{\tilde{\ell}}^2), \\ \Phi_R &= -\frac{1}{2}(r^2 + \bar{r}^2), \\ \Phi' &= \frac{i}{4}(-\tilde{\ell}^2 + \bar{\tilde{\ell}}^2 + r^2 - \bar{r}^2),\end{aligned}\tag{4.42}$$

which is once again consistent with (4.41).

As in the $SU(2) \times U(1)$ case, we can write the dual potential as an integral. Note that the invariance of the type (0,0) potential implies

$$\mathcal{L}_k K = i(-\tilde{\ell}^2 + \bar{\tilde{\ell}}^2 - r^2 + \bar{r}^2) = 0,\tag{4.43}$$

which means that the Lagrange multiplier term is

$$V^I \Phi_I = \tilde{\ell}^2(\Phi)\ell^2 + \bar{\tilde{\ell}}^2(\Phi)\bar{\ell}^2 - r^2(\Phi)\tilde{r}^2 - \bar{r}^2(\Phi)\bar{\tilde{r}}^2,\tag{4.44}$$

where $\tilde{\ell}^2, \bar{\tilde{\ell}}^2, r^2, \bar{r}^2$ are understood as functions of $\Phi = (\phi, \bar{\phi}, \chi, \bar{\chi})$ given by (4.41). Therefore, the dual potential can be written as

$$\tilde{K} = \int \theta_1 - \ell^2 d\tilde{\ell}^2 - \bar{\ell}^2 d\bar{\tilde{\ell}}^2 + \tilde{r}^2 dr^2 + \bar{\tilde{r}}^2 d\bar{r}^2.\tag{4.45}$$

In terms of the functions f_1, f_2 defined in (4.13),

$$\begin{aligned}\tilde{K} &= \left(\int (-\bar{f}_1 + f_2) d\ell + 2(f_1 - f_2) d\tilde{r} - (\chi + f_2) d\phi + (\bar{\phi} + \bar{f}_2) d\chi \right) \\ &\quad - \frac{1}{2}(\phi^2 + \chi^2) + \tilde{r}(\bar{\chi} - \phi) + \text{cc}.\end{aligned}\tag{4.46}$$

Note that the two terms on the last line are generalized Kähler transformations. In contrast to (4.33), this is an unambiguous potential for the type (1,1) structure, obtained without having to solve the nonlinear differential equations (B.12)–(B.13).

4.2.3 Type (1, 1) to type (0, 0)

One can also perform the T-duality in the other direction, gauging the same left Kac-Moody isometry of the type (1, 1) geometry with an LVM and enforcing it to be flat with semi-chiral Lagrange multipliers, and then integrating out the LVM. This would return (4.46) to the type (0, 0) potential (4.15).

5 Discussion and conclusion

5.1 Results

In this paper, we studied the generalized Kähler structures of two rank 2 groups, $SU(2) \times U(1)$ and $SU(3)$, in detail. We found coordinates that were holomorphic with respect to left-invariant and right-invariant complex structures, and formulae (in one case explicit, in the other implicit) for their generalized Kähler potentials (which have an interpretation as the Lagrange density of the sigma model in (2, 2) superspace).

We explained how rank two groups carry generalized Kähler structures of two different types, related to one another by T-duality along a Kac-Moody isometry, and how a clever trick trivializes the Legendre transform that is usually needed to relate their generalized Kähler potentials. We also gave a wealth of computational details that may be useful for future investigations.

5.2 Possible future developments

5.2.1 Type change

Apart from $SU(2) \times U(1)$, $U(1)^2$ and their products, left and right complex structures on Lie groups do not commute, and therefore semi-chiral superfields are generically present. Semichiral coordinates are accompanied by type change loci, which are loci of positive codimension on which the type of the generalized geometry changes. For $SU(2) \times U(1)$, an analysis of the type change locus for the type (0, 0) generalized geometry was performed in [18]. For $SU(3)$, this has not yet been done and is a direction for future work.

5.2.2 (4, 4) supersymmetry

The WZW models on both $SU(2) \times U(1)$ and $SU(3)$ admit a further enhancement of supersymmetry to (4, 4). Such bi-hypercomplex Lie groups were classified [14], and the whole list of them are $SU(n+1)$, $SU(2n) \times U(1)$, $SO(4n) \times U(1)^{2n}$, $SO(4n+2) \times U(1)^{2n-1}$, $SO(2n+1) \times U(1)^n$, $Sp(2n) \times U(1)^n$, $E_6 \times U(1)^2$, $E_7 \times U(1)^7$, $E_8 \times U(1)^8$, $F_4 \times U(1)^4$, $G_2 \times U(1)^2$ (and products). There always exists a choice of left and right complex structures that gives rise to a type (0, 0) generalized geometry - fully parametrized by semi-chiral coordinates. For such generalized Kähler structures, the potential is an integral of a tautological one-form and can be easily computed without having to solve nonlinear second order PDEs. Generalized geometries of other types on these Lie groups can be obtained from the type (0, 0) geometry via T-duality and (possibly repeated) applications of the technique detailed above.

Another direction for the study of (4, 4) supersymmetric models is the problem of manifestly realizing all the supersymmetries. For $SU(2) \times U(1)$, a (4, 4) formulation of

the type (1, 1) generalized geometry in biprojective superspace is known [15] (although it is not known how to define the contour for the generalized potential), while for the type (0, 0) geometry, the extra supersymmetries are not compatible with (2, 2) superspace [19]. Preliminary investigations of the SU(3) model seem to indicate that it is not compatible with the multiplet structure of biprojective superspace. It is worthwhile to conduct a more thorough investigation of off-shell (4, 4) supersymmetry for WZW models.

5.2.3 Other groups

Another obvious direction is to investigate other groups. The holomorphic structures on SU(3) are surprisingly subtle and we can expect more surprises as we investigate higher rank groups.

A Sigma models and supersymmetry

The $d = 2$ non-linear sigma model is a Lagrangian field theory of maps φ from a two-dimensional worldsheet (Σ, h) to a target Riemannian manifold (M, g) , equipped with a closed 3-form H , known as the torsion. Let b be a local 2-form potential (the Kalb-Ramond 2-form) for H , $db = H$. The action is the sum of the integrals of the pullback (via φ) of g , with respect to the volume form of h , and the pullback (via φ) of b

$$I[\varphi] = \int_{\Sigma} \sqrt{h} d^2\sigma h^{\alpha\beta} \partial_{\alpha}\varphi^{\mu} g_{\mu\nu} \partial_{\beta}\varphi^{\nu} + \int_{\Sigma} d^2\sigma \epsilon^{\alpha\beta} \partial_{\alpha}\varphi^{\mu} b_{\mu\nu} \partial_{\beta}\varphi^{\nu}. \tag{A.1}$$

The action depends only on the conformal class of h .

Any sigma model admits an (1, 1) supersymmetric extension, which moreover can be written in (1, 1) superspace as

$$I[\Phi] = \int_{\Sigma} d^2\sigma d^2\theta \nabla_{+}\Phi^{\mu} (g_{\mu\nu} + b_{\mu\nu}) \nabla_{-}\Phi^{\nu} \tag{A.2}$$

where ∇_{\pm} are the (1, 1) supercovariant derivatives satisfying the algebra

$$\{\nabla_{\pm}, \nabla_{\pm}\} = 2i\partial_{\pm}, \quad \{\nabla_{\pm}, \nabla_{\mp}\} = 0, \tag{A.3}$$

and $\Phi^{\mu}(\sigma, \theta)$ is the (1, 1) superfield which has φ^{μ} as its bottom component.

To look for extended supersymmetries, one considers the most general transformations

$$\delta\Phi^{\mu} = \epsilon_{(A)}^{+} (J_{+}^{(A)})^{\mu}_{\nu} \nabla_{+}\Phi^{\nu} + \epsilon_{(\tilde{A})}^{-} (J_{-}^{(\tilde{A})})^{\mu}_{\nu} \nabla_{-}\Phi^{\nu}, \tag{A.4}$$

where $A = 2, \dots, \mathcal{N}_+$ and $\tilde{A} = 2, \dots, \mathcal{N}_-$ indexes the extended supersymmetries. Demanding that these transformations satisfy the supersymmetry algebra implies that the $J_+^{(A)}$ and $J_-^{(\tilde{A})}$ are integrable complex structures on M , and moreover satisfy the Clifford-like relations

$$\{J_+^{(A)}, J_+^{(B)}\} = -2\delta^{AB}\mathbb{1}, \quad \{J_-^{(\tilde{A})}, J_-^{(\tilde{B})}\} = -2\delta^{\tilde{A}\tilde{B}}\mathbb{1}. \quad (\text{A.5})$$

Demanded that the action (A.2) is invariant under these transformations further implies that the metric g is hermitian with respect to all the complex structures $J_\pm^{(A)}$, and that the complex structures are covariantly constant

$$\nabla^{(+)}J_+^{(A)} = 0, \quad \nabla^{(-)}J_-^{(\tilde{A})} = 0 \quad (\text{A.6})$$

with respect to the Bismut connections $\nabla^{(\pm)}$, which are metric connections with torsions $\pm g^{-1}H$. Explicitly, the connection coefficients of the Bismut connections are

$$\Gamma^{(\pm)\mu}_{\nu\rho} = \Gamma^{(0)\mu}_{\nu\rho} \pm \frac{1}{2}g^{\mu\sigma}H_{\sigma\nu\rho}, \quad (\text{A.7})$$

where $\Gamma^{(0)}$ is the Levi-Civita connection.

For (2, 2) supersymmetry, which is the subject of discussion in this paper, this implies that the target geometry is bihermitian [2], which is equivalent to generalized Kähler geometry [8]. In the more specific case $J_+ = \pm J_-$, the manifold is Kähler [1].

For (4, 4) supersymmetry, the target geometry is bi-hypercomplex (or bi-hyperKähler with torsion). The $SU(2) \times U(1)$ and $SU(3)$ WZW models are in fact bi-hypercomplex [14], and therefore has (4, 4) supersymmetry, but the off-shell formulation of the supersymmetry is more challenging and will not be addressed in this paper.

B Local description of bihermitian geometry

The bihermitian data (g, H, J_+, J_-) of the generalized Kähler manifold may be expressed in terms of generalized Kähler potential K . Consider a (2, 2) sigma model with N_c chiral, N_t twisted chiral and N_s sets of semi-chiral superfields, which locally describes a type (N_c, N_t) generalized Kähler manifold of real dimension $2N_c + 2N_t + 4N_s$. The generalized Kähler potential, which also serves as the (2, 2) superspace Lagrange density, is a real function of the superfields

$$K = K(\ell, \bar{\ell}, \tilde{r}, \bar{\tilde{r}}, \phi, \bar{\phi}, \chi, \bar{\chi}). \quad (\text{B.1})$$

We use a convention where $c, \bar{c} = 1, \dots, N_c$ label the chiral and antichiral superfields, $t, \bar{t} = 1, \dots, N_t$ label the twisted chiral and twisted antichiral superfields, and $l, \bar{l}, r, \bar{r} = 1, \dots, N_s$ label the left, anti-left, right and anti-right semi-chiral superfields respectively. Furthermore, capital indices label the collective set of chiral, twisted chiral and semi-chiral superfields

$$L = (l, \bar{l}), \quad R = (r, \bar{r}), \quad C = (c, \bar{c}), \quad T = (t, \bar{t}). \quad (\text{B.2})$$

To express the bihermitian data in terms of the potential, we introduce the notation

$$K_{AB} = \begin{pmatrix} K_{ab} & K_{a\bar{b}} \\ K_{\bar{a}b} & K_{\bar{a}\bar{b}} \end{pmatrix}, \quad (\text{B.3})$$

where $A, B = L, R, C, T$, and K_{ab} is shorthand for the second derivative $\partial_a \partial_b K$. For example, K_{CL} is the $2N_c \times 2N_s$ matrix of second derivatives

$$K_{CL} = \begin{pmatrix} \partial_c \partial_l K & \partial_c \partial_{\bar{l}} K \\ \partial_{\bar{c}} \partial_l K & \partial_{\bar{c}} \partial_{\bar{l}} K \end{pmatrix}. \quad (\text{B.4})$$

We write $K_{AB}^{-1} = (K_{BA})^{-1}$. We also define

$$C_{AB} = JK_{AB} - K_{AB}J, \quad A_{AB} = JK_{AB} + K_{AB}J, \quad (\text{B.5})$$

where J is the square matrix

$$J = \begin{pmatrix} i\mathbf{1} & 0 \\ 0 & -i\mathbf{1} \end{pmatrix}, \quad (\text{B.6})$$

whose size varies depending on the context.

By reducing the $(2, 2)$ superspace formulation of the sigma model to $(1, 1)$ superspace and eliminating auxiliary fields arising from the semi-chiral sector, one can obtain explicit expressions for the bihermitian data in terms of the potential K (for more details, see [6]). The complex structures are (in the order L, R, C, T)

$$J_+ = \begin{pmatrix} J & & & \\ K_{RL}^{-1} C_{LL} & K_{RL}^{-1} J K_{LR} & K_{RL}^{-1} C_{LC} & K_{RL}^{-1} C_{LT} \\ & J & & \\ & & J & \end{pmatrix},$$

$$J_- = \begin{pmatrix} K_{LR}^{-1} J K_{RL} & K_{LR}^{-1} C_{RR} & K_{LR}^{-1} C_{RC} & K_{LR}^{-1} A_{RT} \\ & J & & \\ & & J & \\ & & & -J \end{pmatrix}, \quad (\text{B.7})$$

and the Poisson structure σ is

$$\sigma = \begin{pmatrix} 0 & K_{LR}^{-1} & 0 & 0 \\ -K_{RL}^{-1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}. \quad (\text{B.8})$$

Note that a change of coordinates from $(\ell, \bar{\ell}, \tilde{r}, \bar{\tilde{r}}, \phi, \bar{\phi}, \chi, \bar{\chi})$ to $(\ell, \bar{\ell}, \tilde{\ell}, \bar{\tilde{\ell}}, \phi, \bar{\phi}, \chi, \bar{\chi})$, where

$$\tilde{\ell} := \frac{\partial K}{\partial \ell}, \quad \bar{\tilde{\ell}} := \frac{\partial K}{\partial \bar{\ell}} \quad (\text{B.9})$$

diagonalizes J_+ and puts the Poisson structure in the canonical form

$$\sigma = \begin{pmatrix} 0 & \mathbf{1} & 0 & 0 \\ -\mathbf{1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}; \quad (\text{B.10})$$

while a coordinate change to $(r, \bar{r}, \tilde{r}, \bar{\tilde{r}}, \phi, \bar{\phi}, \chi, \bar{\chi})$, where

$$r := -\frac{\partial K}{\partial \tilde{r}}, \quad \bar{r} := -\frac{\partial K}{\partial \bar{\tilde{r}}} \tag{B.11}$$

diagonalizes J_- and again puts σ in the canonical form. In other words, the generalized potential K serves as the generating function of the symplectomorphism between the J_+ -holomorphic Darboux coordinates $(\ell, \bar{\ell}, \tilde{\ell}, \bar{\tilde{\ell}})$ and J_- -holomorphic Darboux coordinates $(r, \bar{r}, \tilde{r}, \bar{\tilde{r}})$ on the symplectic leaves of σ . This is an important characterization of the generalized Kähler potential which will be repeatedly used in this paper.

The metric g and 2-form potential b can be obtained from the local symplectic forms

$$\mathcal{F}_+ = \frac{1}{2}(b_+ - g)J_+ = \frac{1}{2} \begin{pmatrix} d\ell^L \\ dr^R \\ d\phi^C \\ d\chi^T \end{pmatrix}^T \begin{pmatrix} -C_{LL} & -A_{LR} & -A_{LC} & -C_{LT} \\ A_{RL} & C_{RR} & C_{RC} & A_{RT} \\ A_{CL} & C_{CR} & C_{CC} & A_{CT} \\ -C_{TL} & -A_{TR} & -A_{TC} & -C_{TT} \end{pmatrix} \begin{pmatrix} d\ell^L \\ dr^R \\ d\phi^C \\ d\chi^T \end{pmatrix} \tag{B.12}$$

$$\mathcal{F}_- = \frac{1}{2}(b_- + g)J_- = -\frac{1}{2} \begin{pmatrix} d\ell^L \\ dr^R \\ d\phi^C \\ d\chi^T \end{pmatrix}^T \begin{pmatrix} C_{LL} & C_{LR} & C_{LC} & C_{LT} \\ C_{RL} & C_{RR} & C_{RC} & C_{RT} \\ C_{CL} & C_{CR} & C_{CC} & C_{CT} \\ C_{TL} & C_{TR} & C_{TC} & C_{TT} \end{pmatrix} \begin{pmatrix} d\ell^L \\ dr^R \\ d\phi^C \\ d\chi^T \end{pmatrix}. \tag{B.13}$$

Here, b_+ and b_- are different two-form potentials for H , $db_{\pm} = H$, chosen such that b_{\pm} are $(2, 0) + (0, 2)$ forms with respect to J_{\pm} . b_+ and b_- differ by an exact form

$$\mathcal{G} = \frac{1}{2}(b_+ - b_-) = d\lambda. \tag{B.14}$$

The local symplectic two-forms \mathcal{F}_{\pm} may be interpreted as connections for flat gerbes [20].

Finally, we turn to the quantum properties of the underlying $(2, 2)$ sigma model. Denoting

$$N_+ = \begin{pmatrix} K_{\ell\bar{\ell}} & K_{l\bar{r}} & K_{l\bar{\ell}} \\ K_{\bar{r}\bar{\ell}} & K_{\bar{r}\bar{r}} & K_{\bar{r}\bar{\ell}} \\ K_{t\bar{\ell}} & K_{t\bar{r}} & K_{t\bar{\ell}} \end{pmatrix}, \quad N_- = \begin{pmatrix} K_{\ell\bar{\ell}} & K_{l\bar{r}} & K_{l\bar{c}} \\ K_{\bar{r}\bar{\ell}} & K_{\bar{r}\bar{r}} & K_{\bar{r}\bar{c}} \\ K_{c\bar{\ell}} & K_{c\bar{r}} & K_{c\bar{c}} \end{pmatrix}, \tag{B.15}$$

the one loop beta function vanishes if [21]

$$\log \frac{\det N_+}{\det N_-} = f(\ell, \phi, \chi) + \bar{f}(\bar{\ell}, \bar{\phi}, \bar{\chi}) + g(r, \phi, \bar{\chi}) + \bar{g}(\bar{r}, \bar{\phi}, \chi), \tag{B.16}$$

while the target manifold is generalized Calabi-Yau if it satisfies the stronger condition [22]

$$\log \frac{\det N_+}{\det N_-} = \text{const.} \tag{B.17}$$

We end this section with a final remark. Mapping the bihermitian data,

$$(g, H, J_+, J_-) \rightarrow (g, H, J_+, -J_-), \tag{B.18}$$

merely amounts to mapping the corresponding generalized Kähler potential

$$K(\ell, \bar{\ell}, \tilde{r}, \bar{\tilde{r}}, \phi, \bar{\phi}, \chi, \bar{\chi}) \rightarrow -K(\ell, \bar{\ell}, \bar{\tilde{r}}, \tilde{r}, \chi, \bar{\chi}, \bar{\phi}, \phi), \tag{B.19}$$

leaving any of the expressions above unchanged. This is a general symmetry of (2,2) supersymmetric sigma models.

C Isometries and T-duality

T-duality is an equivalence of the underlying physics of sigma models describing different geometries. The duality can be realized by gauging an isometry of the sigma model, and then adding a Lagrange multiplier enforcing flatness of the gauge connection, so that it is equivalent to the original model. Integrating out instead the non-dynamical gauge connection yields the T-dual model, which in general describes a different geometry [13].

In (2, 2) superspace, T-duality also changes the complex structures [12], and therefore also the type of the generalized Kähler geometry. Isometries of (2, 2) supersymmetric sigma models fall into three categories: in appropriate local coordinates, they act either on (i) a chiral or a twisted chiral coordinate, (ii) a pair of chiral and twisted chiral coordinates, or (iii) a set of semi-chiral coordinates.¹⁹ The isometries can then be gauged using an appropriate gauge connection: for (i), a usual vector multiplet; for (ii), a large vector multiplet (LVM); and for (iii) a semi-chiral vector multiplet (SVM) [23–25].

T-duality along isometries of type (i) exchanges a chiral superfield for a twisted chiral (or vice versa), so if the original generalized geometry is of type (p, q) , then the dual geometry has type $(p - 1, q + 1)$ (or $(p + 1, q - 1)$). T-dualizing along a type (ii) isometry exchanges a pair of chiral and twisted chiral coordinates for a set of semi-chirals, so the dual model has type $(p - 1, q - 1)$. Finally, for type (iii), a set of semi-chirals is exchanged for a chiral and twisted chiral, so the dual model has type $(p + 1, q + 1)$.

The LVM and SVM are novel vector multiplets which do not arise in the Kähler (torsionless) case. We briefly review these vector multiplets.

C.1 Large vector multiplet (LVM)

A type (i) isometry $k = k^\phi \partial_\phi + k^{\bar{\phi}} \partial_{\bar{\phi}} + k^\chi \partial_\chi + k^{\bar{\chi}} \partial_{\bar{\chi}}$ acts on both chiral ϕ and twisted chiral χ coordinates and is gauged with a large vector multiplet (LVM), consisting of three real vector multiplets $V^I = (V^\phi, V^\chi, V')$. Since the isometry preserves the generalized Kähler structure $\mathcal{L}_k g = \mathcal{L}_k H = \mathcal{L}_k J_\pm = 0$, the potential transforms into a generalized Kähler transformation

$$\mathcal{L}_k K = f(\phi, \chi) + \bar{f}(\bar{\phi}, \bar{\chi}) + g(\phi, \bar{\chi}) + \bar{g}(\bar{\phi}, \chi). \tag{C.1}$$

The preservation of both complex structures J_\pm implies that the components of k depend only on coordinates of the appropriate chirality

$$k^\phi = k^\phi(\phi), \quad k^{\bar{\phi}} = k^{\bar{\phi}}(\bar{\phi}), \quad k^\chi = k^\chi(\chi), \quad k^{\bar{\chi}} = k^{\bar{\chi}}(\bar{\chi}). \tag{C.2}$$

¹⁹More generally, isometries of type (i) and (ii) can also act on semi-chiral coordinates.

In this paper we deal only with invariant potentials, so we shall assume $f = \bar{f} = g = \bar{g} = 0$. Therefore,

$$\begin{aligned}
 k^\phi \partial_\phi K &= i\mu_\phi + \mu', \\
 k^{\bar{\phi}} \partial_{\bar{\phi}} K &= -i\mu_\phi + \mu', \\
 k^\chi \partial_\chi K &= i\mu_\chi - \mu', \\
 k^{\bar{\chi}} \partial_{\bar{\chi}} K &= -i\mu_\chi - \mu',
 \end{aligned} \tag{C.3}$$

for some real functions $\mu_I = (\mu_\phi, \mu_\chi, \mu')$. These functions have the interpretation as (local) moment maps with respect to the 2-form gerbe potentials \mathcal{F}_\pm of the generalized geometry, and another symplectic form \mathcal{G} we define below. Recall that generalized Kähler geometry may be reformulated as a flat biholomorphic gerbe [20] with local two-form potentials

$$\mathcal{F}_\pm = \frac{1}{2}(b_\pm J_\pm \mp \omega_\pm) = \frac{i}{2}d(\mp K_\phi d\phi \pm K_{\bar{\phi}} d\bar{\phi} + K_\chi d\chi - K_{\bar{\chi}} d\bar{\chi}) = \mp \frac{1}{2}dd_\mp^c K, \tag{C.4}$$

where subscripts of K denote derivatives, and b_\pm are local torsion potentials $db_\pm = H$ which are chosen to be $(2, 0) + (0, 2)$ with respect to the complex structures J_\pm . We also introduce the local symplectic form

$$\mathcal{G} = \frac{1}{2}(b_+ - b_-) = \frac{1}{2}d(-K_\phi d\phi - K_{\bar{\phi}} d\bar{\phi} + K_\chi d\chi + K_{\bar{\chi}} d\bar{\chi}) = \frac{1}{2}d(K_\mu J_+ J_- dX^\mu). \tag{C.5}$$

For an invariant potential K ,

$$\begin{aligned}
 \iota_k \mathcal{F}_\pm &= \mp \frac{1}{2} \mathcal{L}_k(K_\mu J_\mp dX^\mu) \pm \frac{1}{2} d\iota_k(K_\mu J_\mp dX^\mu) \\
 &= -\frac{1}{2}d(\pm\mu_\phi - \mu_\chi),
 \end{aligned} \tag{C.6}$$

$$\iota_k \mathcal{G} = \frac{1}{2} \mathcal{L}_k(K_\mu J_+ J_- dX^\mu) - \frac{1}{2} d\iota_k(K_\mu J_+ J_- dX^\mu) = d\mu', \tag{C.7}$$

which shows that the μ_I are indeed moment maps with respect to \mathcal{F}_\pm and \mathcal{G} .

Gauging the isometry in $(2, 2)$ superspace promotes the parameter to chiral and twisted chiral parameters

$$\begin{aligned}
 \delta_\Lambda &= \Lambda^\phi k^\phi \partial_\phi + \Lambda^{\bar{\phi}} k^{\bar{\phi}} \partial_{\bar{\phi}} + \Lambda^\chi k^\chi \partial_\chi + \Lambda^{\bar{\chi}} k^{\bar{\chi}} \partial_{\bar{\chi}} \\
 &= \frac{1}{4}(\Lambda^\phi + \Lambda^{\bar{\phi}} + \Lambda^\chi + \Lambda^{\bar{\chi}}) \mathcal{L}_k + i(\Lambda^\phi - \Lambda^{\bar{\phi}}) \mathcal{L}_{k_{(\phi)}} \\
 &\quad + i(\Lambda^\chi - \Lambda^{\bar{\chi}}) \mathcal{L}_{k_{(\chi)}} + (\Lambda^\phi + \Lambda^{\bar{\phi}} - \Lambda^\chi - \Lambda^{\bar{\chi}}) \mathcal{L}_{k_{(\prime)}}.
 \end{aligned} \tag{C.8}$$

where the complex conjugate vector fields k_I are defined by

$$\begin{aligned}
 k_{(\phi)} &= -\frac{1}{4}(J_+ + J_-)k = \frac{i}{2}(k^{\bar{\phi}} \partial_{\bar{\phi}} - k^\phi \partial_\phi), \\
 k_{(\chi)} &= -\frac{1}{4}(J_+ - J_-)k = \frac{i}{2}(k^{\bar{\chi}} \partial_{\bar{\chi}} - k^\chi \partial_\chi), \\
 k_{(\prime)} &= -\frac{1}{4}J_+ J_- k = \frac{1}{4}(k^\phi \partial_\phi + k^{\bar{\phi}} \partial_{\bar{\phi}} - k^\chi \partial_\chi - k^{\bar{\chi}} \partial_{\bar{\chi}}).
 \end{aligned} \tag{C.9}$$

The gauged potential is

$$\begin{aligned}
 K^g(\phi, \bar{\phi}, \chi, \bar{\chi}, V^\phi, V^\chi, V') &= K(\phi, \bar{\phi}, \chi, \bar{\chi}) + \int_0^1 dt \exp(tV^I \mathcal{L}_{k_I}) V^K \mu_K \\
 &= \exp(V^I \mathcal{L}_{k_I}) K(\phi, \bar{\phi}, \chi, \bar{\chi}),
 \end{aligned}
 \tag{C.10}$$

with implicit sums over repeated indices I, J, K (over $\phi, \chi, \bar{\phi}, \bar{\chi}$). Note that $\mathcal{L}_{k_I} K = \mu_I$.

The equations of motion of V^I from (C.10) are

$$\frac{\partial K^g}{\partial V^I} = \exp(V^J \mathcal{L}_{k_J}) \mathcal{L}_{k_I} K = \exp(V^J \mathcal{L}_{k_J}) \mu_I.
 \tag{C.11}$$

Since

$$\delta_\Lambda K^g = \exp(V^J \mathcal{L}_{k_J}) (\delta_\Lambda K + \mathcal{L}_{k_I} K \delta_\Lambda V^I),
 \tag{C.12}$$

gauge invariance of (C.10) follows provided

$$\begin{aligned}
 \delta_\Lambda V^\phi &= i(\Lambda^{\bar{\phi}} - \Lambda^\phi), \\
 \delta_\Lambda V^\chi &= i(\Lambda^{\bar{\chi}} - \Lambda^\chi), \\
 \delta_\Lambda V' &= -\Lambda^\phi - \Lambda^{\bar{\phi}} + \Lambda^\chi + \Lambda^{\bar{\chi}}.
 \end{aligned}
 \tag{C.13}$$

It is convenient to combine the gauge fields into complex combinations

$$\mathbb{V} = \frac{1}{2}(-V' + i(V^\phi - V^\chi)), \quad \tilde{\mathbb{V}} = \frac{1}{2}(-V' + i(V^\phi + V^\chi)),
 \tag{C.14}$$

which transform with semi-chiral parameters $\delta_\Lambda \mathbb{V} = \Lambda^\phi - \Lambda^\chi, \delta_\Lambda \tilde{\mathbb{V}} = \Lambda^\phi + \Lambda^\chi$. Therefore, the following are four gauge invariant semi-chiral field strengths

$$\begin{aligned}
 \mathbb{G}_+ &= \bar{\mathbb{D}}_+ \mathbb{V}, & \bar{\mathbb{G}}_+ &= \mathbb{D}_+ \mathbb{V}, \\
 \mathbb{G}_- &= \bar{\mathbb{D}}_- \tilde{\mathbb{V}}, & \bar{\mathbb{G}}_- &= \mathbb{D}_- \tilde{\mathbb{V}}.
 \end{aligned}
 \tag{C.15}$$

To enforce the flatness of the LVM, one constrains its field strengths with Lagrange multipliers of the appropriate semi-chirality,

$$\begin{aligned}
 K_{LM} &= -\frac{1}{2} V^I X_I = -(\ell \mathbb{V} + r \tilde{\mathbb{V}} + \bar{\ell} \bar{\mathbb{V}} + \bar{r} \bar{\tilde{\mathbb{V}}}) \\
 &= -\frac{1}{2} (V' X' + V^\phi X_\phi + V^\chi X_\chi),
 \end{aligned}
 \tag{C.16}$$

where $X' = -(\ell + \bar{\ell} + r + \bar{r}), X_\phi = i(\ell - \bar{\ell} + r - \bar{r}), X_\chi = i(-\ell + \bar{\ell} + r - \bar{r})$. Here I runs over the components $\phi, \chi, \bar{\phi}, \bar{\chi}$ of the vector multiplet.

To obtain the T-dual sigma model, one eliminates the flat vector fields V^I by their equations of motion, which set the moment maps μ_I equal to the Fayet-Iliopolous terms X_I .

C.2 Semichiral vector multiplet (SVM)

A type (ii) isometry $k = k^\ell \partial_\ell + k^{\bar{\ell}} \partial_{\bar{\ell}} + k^r \partial_r + k^{\bar{r}} \partial_{\bar{r}}$ acting on semi-chiral coordinates $\ell, \bar{\ell}, r, \bar{r}$ is gauged with a semi-chiral vector multiplet (SVM) consisting of three real vector multiplets $V^I = (V^L, V^R, V')$. As discussed in section 2.1, the choice of coordinates $\ell, \bar{\ell}, r, \bar{r}$ encodes

a choice of polarization on the symplectic leaves of the generalized Kähler manifold; we demand that the isometry k preserves this polarization (on top of the usual conditions of a generalized Kähler isometry). This implies

$$\mathcal{L}_k K = f(\ell) + \bar{f}(\bar{\ell}) + g(r) + \bar{g}(\bar{r}), \tag{C.17}$$

$$k^\ell = k^\ell(\ell), \quad k^r = k^r(r), \quad k^{\bar{\ell}} = k^{\bar{\ell}}(\bar{\ell}), \quad k^{\bar{r}} = k^{\bar{r}}(\bar{r}). \tag{C.18}$$

For the cases encountered in this paper, the potential K is invariant, so we shall set $f = \bar{f} = g = \bar{g} = 0$. Note that the mixed coordinate system $(\ell, \bar{\ell}, r, \bar{r})$ is not holomorphic with respect to either complex structure, so that e.g. k^ℓ may not be J_+ holomorphic despite it depending only on ℓ .

From (C.17) it follows that

$$\begin{aligned} k^\ell \partial_\ell K &= i\mu_L + \mu', \\ k^{\bar{\ell}} \partial_{\bar{\ell}} K &= -i\mu_L + \mu', \\ k^r \partial_r K &= i\mu_R - \mu', \\ k^{\bar{r}} \partial_{\bar{r}} K &= -i\mu_R - \mu', \end{aligned} \tag{C.19}$$

where $\mu_I = (\mu_L, \mu_R, \mu')$ are three real functions. In fact, the μ_I may be interpreted as moment maps. Recall that on a symplectic leaf of a generalized Kähler manifold, the inverse of the Poisson structure π is a symplectic form $\Omega = g[J_+, J_-]^{-1}$ which may be thought of as the real part of a holomorphic symplectic form with respect to *either* complex structure, $\Omega = \Omega_L + \bar{\Omega}_L = \Omega_R + \bar{\Omega}_R$, where $\Omega_L = -d(\partial_\ell K d\ell)$, $\Omega_R = -d(\partial_r K dr)$. Then, using subscripts to denote derivatives of K , we may compute

$$\begin{aligned} \iota_k \Omega_L &= k^\ell dK_\ell - (k^{\bar{\ell}} K_{\ell\bar{\ell}} + k^r K_{\ell r} + k^{\bar{r}} K_{\ell\bar{r}}) d\ell \\ &= d(k^\ell K_\ell) - \partial_\ell(k^\ell K_\ell + k^{\bar{\ell}} K_{\bar{\ell}} + k^r K_r + k^{\bar{r}} K_{\bar{r}}) d\ell \\ &= d(k^\ell K_\ell) = d(i\mu_L + \mu'), \end{aligned} \tag{C.20}$$

and similarly for Ω_R . This shows that (μ^L, μ^R, μ') are moment maps for the symplectic forms $\text{Im}(\Omega_L), \text{Im}(\Omega_R)$ and $\text{Re}(\Omega_L) = \text{Re}(\Omega_R)$ respectively.

Upon gauging, each J_\pm -(anti)holomorphic and polarized sector acquires its own gauge parameter, $\Lambda^L, \bar{\Lambda}^L, \Lambda^R, \bar{\Lambda}^R$, so that the gauge variation is

$$\begin{aligned} \delta\Lambda &= \Lambda^L k^\ell \partial_\ell + \bar{\Lambda}^L k^{\bar{\ell}} \partial_{\bar{\ell}} + \Lambda^R k^r \partial_r + \bar{\Lambda}^R k^{\bar{r}} \partial_{\bar{r}} \\ &= \frac{1}{4}(\Lambda^L + \bar{\Lambda}^L + \Lambda^R + \bar{\Lambda}^R) \mathcal{L}_k + i(\Lambda^L - \bar{\Lambda}^L) \mathcal{L}_{k_L} \\ &\quad + i(\Lambda^R - \bar{\Lambda}^R) \mathcal{L}_{k_R} + (\Lambda^L + \bar{\Lambda}^L - \Lambda^R - \bar{\Lambda}^R) \mathcal{L}_{k'}, \end{aligned} \tag{C.21}$$

where

$$\begin{aligned} k_L &= \frac{i}{2}(k^{\bar{\ell}} \partial_{\bar{\ell}} - k^\ell \partial_\ell) \\ k_R &= \frac{i}{2}(k^{\bar{r}} \partial_{\bar{r}} - k^r \partial_r) \\ k' &= \frac{1}{4}(k^\ell \partial_\ell + k^{\bar{\ell}} \partial_{\bar{\ell}} - k^r \partial_r - k^{\bar{r}} \partial_{\bar{r}}). \end{aligned} \tag{C.22}$$

Note that $\mathcal{L}_{k_I}K = \mu_I$. The gauged action is

$$\begin{aligned} K^g(\ell, \bar{\ell}, r, \bar{r}, V^L, V^R, V') &= K(\ell, \bar{\ell}, r, \bar{r}) + \int_0^1 \exp(tV^I \mathcal{L}_{k_I})(V^K \mu_K) \\ &= \exp(V^I \mathcal{L}_{k_I})K. \end{aligned} \tag{C.23}$$

The equations of motion of V^I from (C.23) are

$$\frac{\partial K^g}{\partial V^I} = \exp(V^J \mathcal{L}_{k_J}) \mathcal{L}_{k_I} K = \exp(V^J \mathcal{L}_{k_J}) \mu_I. \tag{C.24}$$

The gauge variation of K^g is

$$\delta_\Lambda K^g = \exp(V^J \mathcal{L}_{k_J}) (\delta_\Lambda K + \mathcal{L}_{k_I} K \delta_\Lambda V^I). \tag{C.25}$$

Using (C.21) and $\mathcal{L}_k K = 0$, we see that $\delta_\Lambda K^g$ vanishes provided the SVM transforms as

$$\begin{aligned} \delta_\Lambda V^L &= i(\bar{\Lambda}^L - \Lambda^L), \\ \delta_\Lambda V^R &= i(\bar{\Lambda}^R - \Lambda^R), \\ \delta_\Lambda V' &= -\Lambda^L - \bar{\Lambda}^L + \Lambda^R + \bar{\Lambda}^R. \end{aligned} \tag{C.26}$$

The gauge invariant field strengths are built out of the complex combinations

$$\mathbb{V} = \frac{1}{2}(-V' + i(V^L - V^R)), \quad \tilde{\mathbb{V}} = \frac{1}{2}(-V' + i(V^L + V^R)) \tag{C.27}$$

which transform as $\delta_\Lambda \mathbb{V} = \Lambda^L - \Lambda^R$, $\delta_\Lambda \tilde{\mathbb{V}} = \Lambda^L - \bar{\Lambda}^R$. The complex field strengths are

$$\begin{aligned} \mathbb{F} &= \bar{\mathbb{D}}_+ \bar{\mathbb{D}}_- \mathbb{V}, & \bar{\mathbb{F}} &= \mathbb{D}_+ \mathbb{D}_- \bar{\mathbb{V}}, \\ \tilde{\mathbb{F}} &= \bar{\mathbb{D}}_+ \mathbb{D}_- \tilde{\mathbb{V}}, & \bar{\tilde{\mathbb{F}}} &= \mathbb{D}_+ \bar{\mathbb{D}}_- \bar{\tilde{\mathbb{V}}}, \end{aligned} \tag{C.28}$$

which are respectively chiral and twisted chiral.

To enforce the flatness of the SVM, one constrains its field strengths with Lagrange multipliers of the appropriate chirality,

$$\begin{aligned} K_{LM} &= -\frac{1}{2} V^I \Phi_I = -(\phi \mathbb{V} + \bar{\phi} \bar{\mathbb{V}} + \chi \tilde{\mathbb{V}} + \bar{\chi} \bar{\tilde{\mathbb{V}}}) \\ &= -\frac{1}{2} (V' \Phi' + V^L \Phi_L + V^R \Phi_R), \end{aligned} \tag{C.29}$$

where $\Phi' = -(\phi + \bar{\phi} + \chi + \bar{\chi})$, $\Phi_L = i(\phi - \bar{\phi} + \chi - \bar{\chi})$, $\Phi_R = i(-\phi + \bar{\phi} + \chi - \bar{\chi})$.

To obtain the T-dual sigma model, one eliminates the flat vector fields V^I by their equations of motion, which set the moment maps μ_I equal to the Fayet-Iliopolous terms Φ_I .

D Finding complex coordinates

Suppose we have a Lie algebra complex structure (with $T_\alpha = (T_a, T_{\bar{a}})$ denoting respectively the holomorphic and antiholomorphic generators) which induces a complex structure on the Lie group, with holomorphic coordinates $x^\mu = (z^i, \bar{z}^{\bar{i}})$. For definiteness, suppose we

are working with the left complex structure, so the complex structures on the Lie algebra and group are related by conjugation by the left Maurer-Cartan frame $g^{-1}dg = e^\alpha T_\alpha$. In this appendix, we discuss how to obtain the holomorphic coordinates $z^i, \bar{z}^{\bar{i}}$ in some neighborhood around the origin from the Lie algebra complex structure.

Compatibility of the complex structures of the group and algebra implies that the Maurer-Cartan frames corresponding to the holomorphic Lie algebra generators lie in the holomorphic cotangent bundle:

$$e_i^a d\bar{z}^{\bar{i}} = 0, \quad e_{\bar{i}}^{\bar{a}} dz^i = 0. \tag{D.1}$$

Suppose we parametrize the group element as $g = \exp(\xi^\alpha(z, \bar{z})T_\alpha - \bar{\xi}^{\bar{a}}(z, \bar{z})T_{\bar{a}})$. In the cases encountered in this paper, the group is unitary, and if T_a are chosen to be hermitian, then $\bar{\xi}^{\bar{a}} = (\xi^a)^*$. The Maurer-Cartan frames are

$$\begin{aligned} e^\alpha T_\alpha &= \exp(-\mathcal{L}_{\xi-\bar{\xi}})d = \sum_{n=0}^{\infty} \frac{1}{(n+1)!} (-\mathcal{L}_{\xi-\bar{\xi}})^n d(\xi-\bar{\xi}) \\ &= d(\xi-\bar{\xi}) + \frac{1}{2}[d(\xi-\bar{\xi}), \xi-\bar{\xi}] + \frac{1}{3!}[[d(\xi-\bar{\xi}), \xi-\bar{\xi}], \xi-\bar{\xi}] + \dots, \end{aligned} \tag{D.2}$$

where $\mathcal{L}_X(Y) = [X, Y]$. In a neighborhood around the origin, we can solve for $\xi(z, \bar{z})$ order by order, by imposing (D.1). Suppose that $z = \bar{z} = 0$ at the origin, and expand ξ around it

$$\xi^\alpha(z, \bar{z}) = A_i^\alpha z^i + A_{\bar{i}}^{\bar{\alpha}} \bar{z}^{\bar{i}} + A_{ij}^\alpha z^i z^j + A_{\bar{i}\bar{j}}^{\bar{\alpha}} \bar{z}^{\bar{i}} \bar{z}^{\bar{j}} + A_{ij}^{\bar{\alpha}} \bar{z}^{\bar{i}} z^j + A_{\bar{i}\bar{j}}^\alpha z^i \bar{z}^{\bar{j}} + \dots \tag{D.3}$$

Using a holomorphic diffeomorphism, we can set $A_i^a = \delta_i^a$ and $A_{ij\dots k}^a = 0$. This allows us to identify the holomorphic coordinates z^i with the holomorphic directions at the origin $e^a|_{g=1}$ determined by the Lie algebra complex structure. We substitute this expansion into (D.2) and apply the constraint (D.1), order by order in z and \bar{z} . At leading order, we obtain

$$A_i^a = 0, \quad A_{\bar{i}}^{\bar{a}} = 0, \tag{D.4}$$

and the next order yields

$$A_{\bar{i}j}^a = 0, \quad A_{ij}^a = \frac{1}{2}f_{ij}^a, \quad A_{\bar{i}\bar{j}}^{\bar{a}} = 0, \quad A_{\bar{i}j}^{\bar{a}} = \frac{1}{2}f_{\bar{i}j}^{\bar{a}}, \tag{D.5}$$

where the integrability condition (see section 2.3) $f_{bc}^{\bar{a}} = 0, f_{b\bar{c}}^a = 0$ has been used. This process can be iterated, and in principle yields all the coefficients $A_{ij\dots kl}^{\alpha}$ in terms of the structure constants. The integrability condition ensures that solutions for the coefficients always exists. This yields a series for $\xi(z, \bar{z})$ and therefore a complex parametrization of the group in a neighborhood of the origin within the radius of convergence.

An important check on our expressions for the holomorphic coordinates comes from the integrability condition that the form

$$\Omega = \bigwedge_a \text{tr}(T_a g^{-1} dg), \tag{D.6}$$

is proportional to the holomorphic top form, and hence annihilates all holomorphic differentials dz^a .

E Other type (0, 0) potentials for $SU(2) \times U(1)$

In section 3.1.1, we found a type (0, 0) generalized Kähler potential for $SU(2) \times U(1)$ corresponding to a particular choice of parametrization and polarization. Here we explore other choices.

One choice of parametrization is

$$\ell = z_+^2, \quad \tilde{\ell} = z_+^1, \quad r = -z_-^1, \quad \tilde{r} = z_-^2, \quad (\text{E.1})$$

satisfying $\text{Re } d(\tilde{\ell} d\ell + \tilde{r} dr) = 0$. In the polarization spanned by $\tilde{\ell}, \bar{\tilde{\ell}}$ and $\tilde{r}, \bar{\tilde{r}}$, the group element is parametrized as

$$g = \begin{pmatrix} e^{\zeta\theta + \tilde{r}} & e^{-\zeta\theta + \tilde{\ell}} \\ -e^{-\zeta\theta + \bar{\tilde{\ell}}} & e^{\zeta\theta + \bar{\tilde{r}}} \end{pmatrix}. \quad (\text{E.2})$$

Unimodularity of the $SU(2)$ factor implies that θ satisfies

$$e^{\theta + \tilde{r} + \bar{\tilde{r}}} + e^{-\theta + \bar{\tilde{\ell}} + \tilde{\ell}} = 1, \quad (\text{E.3})$$

which is solved by

$$\theta = \tilde{\ell} + \bar{\tilde{\ell}} + \log f(e^{\tilde{\ell} + \bar{\tilde{\ell}} + \tilde{r} + \bar{\tilde{r}}}), \quad (\text{E.4})$$

where $f(x)$ solves the quadratic equation

$$x f^2(x) - f(x) + 1 = 0. \quad (\text{E.5})$$

The potential, satisfying $\frac{\partial K}{\partial \tilde{\ell}} = -\ell$, $\frac{\partial K}{\partial \tilde{r}} = -r$ is

$$K_2^{(0,0)} = \tilde{\ell}\tilde{r} + \bar{\tilde{\ell}}\bar{\tilde{r}} + \frac{1}{2}(\tilde{r} + \bar{\tilde{r}})^2 + \int^{\tilde{\ell} + \bar{\tilde{\ell}} + \tilde{r} + \bar{\tilde{r}}} dx \log f(e^x). \quad (\text{E.6})$$

Note that this parametrization (E.2) is related to the parametrization (3.7) in section 3.1.1 by the symplectomorphism $(r, \tilde{r}) \mapsto (r', \tilde{r}')$ with $r' = r + \tilde{r}$, $\tilde{r}' = \tilde{r}$, so we expect the potentials (E.6) and (3.8) to be related by a generalized Kähler transformation followed by a change in polarization. Indeed, it can be checked that

$$K_0^{(0,0)}(\tilde{\ell}, \bar{\tilde{\ell}}, r, \tilde{r}) = K_2^{(0,0)}(\tilde{\ell}, \bar{\tilde{\ell}}, \tilde{r}, \bar{\tilde{r}}) - \frac{1}{2}(\tilde{r}^2 + \bar{\tilde{r}}^2) + r\tilde{r} + \bar{\tilde{r}}\bar{\tilde{r}}. \quad (\text{E.7})$$

This potential (E.6) can be obtained via T-duality along $U(1)$ from the type (1, 1) potential (3.14), provided the following generalized Kähler transformation is added

$$\begin{aligned} & K_0^{(1,1)} - \frac{1}{2}(\phi - \chi)^2 - \frac{1}{2}(\bar{\phi} - \bar{\chi})^2 \\ &= -\frac{1}{2}(\phi - \bar{\phi})^2 + \frac{1}{4}(\chi - \bar{\chi} - \phi + \bar{\phi})^2 - \frac{1}{4}(\phi + \bar{\phi} - \chi - \bar{\chi})^2 + \int^{\phi + \bar{\phi} - \chi - \bar{\chi}} dq \log(1 + e^q). \end{aligned} \quad (\text{E.8})$$

Another family of parametrizations, indexed by a nonzero real parameter γ , is given by

$$\begin{aligned} \ell &= \frac{1}{2}(\gamma z_+^1 - (\gamma + 1)z_+^2), & \tilde{\ell} &= 2(-z_+^1 + z_+^2), \\ r &= \frac{1}{2}(-\gamma z_-^1 + (\gamma - 1)z_-^2), & \tilde{r} &= 2(-z_-^1 + z_-^2). \end{aligned} \quad (\text{E.9})$$

In the polarization $\ell, \bar{\ell}$ and r, \bar{r} , the potential is

$$K_3^{(0,0)} = \frac{1}{2\gamma^2}(\ell - \bar{\ell} + r - \bar{r})^2 + \frac{1}{\gamma}((r - \bar{r})^2 - (\ell - \bar{\ell})^2) - \int^{\ell + \bar{\ell} + r + \bar{r}} dx \log(e^x - 1). \quad (\text{E.10})$$

This potential can be obtained via T-duality along U(1) from the type (1,1) potential (3.14), with the addition of the generalized Kähler transformation

$$\begin{aligned} K_0^{(1,1)} + \frac{\gamma}{2}((\phi - \chi)^2 - (\phi - \bar{\chi})^2 + (\bar{\phi} - \bar{\chi})^2 - (\bar{\phi} - \chi)^2) = \\ = \frac{1}{2}(\chi - \bar{\chi})^2 - \gamma(\chi - \bar{\chi})(\phi - \bar{\phi}) + \int^{\phi + \bar{\phi} - \chi - \bar{\chi}} dq \log(1 + e^q). \end{aligned} \quad (\text{E.11})$$

F T-duality from type (1,1) to type (0,0) on SU(2) × U(1)

We begin with the type (1,1) generalized Kähler structure, with group element parametrized as in (3.12). We may perform the T-duality along any factor of the U(1)_L × U(1)_R × U(1) Kac-Moody isometry group. The complex structures J_{\pm} map these isometries into one another, so in superspace, where the gauge group is complexified, the gauging of any the isometries is equivalent up to reparametrizations.

For definiteness, let us dualize along U(1)_R, which corresponds to $\epsilon = 0, \eta = i\lambda$ in (3.20), with λ a real parameter. This isometry can be gauged with a LVM (see appendix C). The invariant combinations of fields are $\phi + \bar{\phi}, \chi + \bar{\chi}$ and $i(\bar{\phi} - \phi + \chi - \bar{\chi})$, which are respectively gauged with the components V^{ϕ}, V^{χ} and V' of the LVM. There is a subtlety involved in dualizing from $K_0^{(1,1)}$ (3.14): performing the gauging prescription of [13] on $K_0^{(1,1)}$ (and gauge fixing $\phi \rightarrow 0, \chi \rightarrow 0$) yields

$$\tilde{K}_0^{(1,1)} = -\frac{1}{2}(V^{\chi})^2 + \int^{V^{\phi} - V^{\chi}} dq \log(1 + e^q) - V^I X_I, \quad (\text{F.1})$$

in which V' appears only linearly and hence cannot be solved for. To get around this issue, we restrict the potential to be defined only on the overlap of the two patches (where all the entries of the group element are nonzero), and add generalized Kähler transformations to the potential.²⁰ For simplicity, we shall consider only invariant potentials, and in that case, the generalized Kähler transformations which can be added must be functions of $i(\phi - \chi), i(\phi + \bar{\chi})$ (and complex conjugates),

$$K^{(1,1)} \mapsto K^{(1,1)} + f(i(\phi - \chi)) + \bar{f}(-i(\bar{\phi} - \bar{\chi})) + g(i(\phi + \bar{\chi})) + \bar{g}(-i(\bar{\phi} + \chi)). \quad (\text{F.2})$$

These combinations are gauged by the complex gauge fields \mathbb{V} and $\bar{\mathbb{V}}$ respectively, so the T-dual potential is now

$$\tilde{K}^{(1,1)} = -\frac{1}{2}(V^{\chi})^2 + f(\mathbb{V}) + \bar{f}(\bar{\mathbb{V}}) + g(\tilde{\mathbb{V}}) + \bar{g}(\bar{\tilde{\mathbb{V}}}) + \int^{V^{\phi} - V^{\chi}} dq \log(1 + e^q). \quad (\text{F.3})$$

²⁰Adding these terms, which in general shifts the b -field of the original geometry, correspond to holomorphic symplectomorphisms of the T-dual geometry.

If we restrict to the case where $f(x) = \alpha x^2$ and $g(x) = \beta x^2$ are quadratic monomials, then solutions for all the gauge fields V^ϕ, V^χ, V' exist if

$$8\beta\bar{\beta} + 2(\alpha + \bar{\alpha})(\beta + \bar{\beta}) + (\alpha + \bar{\alpha} + \beta + \bar{\beta}) \neq 0. \quad (\text{F.4})$$

In order to arrive at the type $(0,0)$ potential $K_0^{(0,0)}$ obtained in (3.8), we choose $\alpha = \frac{1}{2}$ and $\beta = -\frac{1}{4}$. The dual potential becomes

$$\tilde{K}^{(1,1)} = \frac{1}{8}(V')^2 - \frac{3}{8}(V^\phi - V^\chi)^2 + \frac{1}{4}(V^\phi - V^\chi)(V^\phi + V^\chi) + \int^{V^\phi - V^\chi} dq \log(1 + e^q) - V^I X_I. \quad (\text{F.5})$$

Defining the Lagrange multipliers by

$$\begin{aligned} \frac{1}{2}(X_\phi + X_\chi) &= -\frac{1}{4}(r + \bar{r}), \\ \frac{1}{2}(X_\phi - X_\chi) &= -\frac{1}{2}(\tilde{\ell} + \bar{\tilde{\ell}}), \\ X' &= \frac{i}{4}(-r + \bar{r} - 2\tilde{\ell} + 2\bar{\tilde{\ell}}), \end{aligned} \quad (\text{F.6})$$

after some simplification the dual potential may be written as

$$\tilde{K}^{(1,1)} = -(\tilde{\ell} + r)(\bar{\tilde{\ell}} + \bar{r}) + \int^{-r - \bar{r}} dq \log(1 + e^q) + \frac{1}{2}(\tilde{\ell}^2 + \bar{\tilde{\ell}}^2) - \frac{1}{4}(r^2 + \bar{r}^2), \quad (\text{F.7})$$

which agrees with (3.8) up to a generalized Kähler transformation.

Performing the duality along the $U(1)$ factor requires a subtle maneuver (due to the fact that r is invariant - see (3.18)) which we shall illustrate here. The $U(1)$ isometry corresponds to $\text{Im } \epsilon = 0$, $\text{Im } \eta = 0$ and $\epsilon + \eta = \lambda$ with λ a real parameter. The invariant combinations $i(\phi - \bar{\phi})$, $i(\chi - \bar{\chi})$ and $\phi + \bar{\phi} - \chi - \bar{\chi}$ are gauged with V^ϕ , V^χ and V' respectively. Starting with (3.14), we add the generalized Kähler transformation $\frac{1}{2}(\phi - \bar{\chi})^2 + \frac{1}{2}(\bar{\phi} - \chi)^2$, resulting in the T-dual potential

$$\tilde{K}^{(1,1)} = -\frac{1}{2}(V^\chi)^2 + \frac{1}{2}\tilde{\mathbb{V}}^2 + \frac{1}{2}\bar{\tilde{\mathbb{V}}}^2 + \int^{-\tilde{\mathbb{V}} - \bar{\tilde{\mathbb{V}}}} dq \log(1 + e^q) - V^I X_I \quad (\text{F.8})$$

with Lagrange multipliers defined such that

$$V^I X_I = V^\chi i(\ell - \bar{\ell}) + \tilde{\mathbb{V}}(\ell + \bar{r}) + \bar{\tilde{\mathbb{V}}}(\bar{\ell} + \bar{r}). \quad (\text{F.9})$$

At this point, we can eliminate V^χ using its variational equation $V^\chi = i(\bar{\ell} - \ell)$, while $\tilde{\mathbb{V}}$ and $\bar{\tilde{\mathbb{V}}}$ are somewhat more complicated functions of $(\tilde{r} + \ell)$ and $(\bar{\tilde{r}} + \bar{\ell})$. Rather than solve them explicitly, we instead change the polarization²¹ from $\tilde{r}, \bar{\tilde{r}}$ to r, \bar{r} :

$$\begin{aligned} \tilde{K}'(\ell, \bar{\ell}, r, \bar{r}) &= \tilde{K}^{(1,1)}(\ell, \bar{\ell}, \tilde{r}, \bar{\tilde{r}}) + \tilde{r}r + \bar{\tilde{r}}\bar{r} \\ &= -\frac{1}{2}(\ell - \bar{\ell})^2 + \frac{1}{2}\tilde{\mathbb{V}}^2 + \frac{1}{2}\bar{\tilde{\mathbb{V}}}^2 + \int^{-\tilde{\mathbb{V}} - \bar{\tilde{\mathbb{V}}}} dq \log(1 + e^q) \\ &\quad - \tilde{\mathbb{V}}(\ell + \bar{r}) - \bar{\tilde{\mathbb{V}}}(\bar{\ell} + \bar{r}) + \tilde{r}r + \bar{\tilde{r}}\bar{r} \end{aligned} \quad (\text{F.10})$$

²¹In superspace language, changing the polarization is a semi-chiral duality.

Since

$$\frac{\partial \tilde{K}^{(1,1)}}{\partial \tilde{r}} = \left(\frac{\partial K^{(1,1)}}{\partial V^I} - X_I \right) \frac{\partial V^I}{\partial \tilde{r}} - \tilde{\nabla}, \quad (\text{F.11})$$

and the expression in the parentheses vanishes, the variational equation of \tilde{r} sets $r = \tilde{\nabla}$. This yields

$$\tilde{K}' = \ell \bar{\ell} - \ell r - \bar{\ell} \bar{r} + \int^{-r-\bar{r}} dq \log(1 + e^q) + \frac{1}{2}(-\ell^2 - \bar{\ell}^2 + r^2 + \bar{r}^2). \quad (\text{F.12})$$

A generalized Kähler transformation cancelling the last term on the line above, and a further change of polarization, this time on the left semi-chiral fields, brings this to (3.8):

$$K_0^{(0,0)}(\tilde{\ell}, \bar{\tilde{\ell}}, r, \bar{r}) = \tilde{K}'(\ell, \bar{\ell}, r, \bar{r}) + \frac{1}{2}(\ell^2 + \bar{\ell}^2 - r^2 - \bar{r}^2) - \ell \tilde{\ell} - \bar{\ell} \bar{\tilde{\ell}}. \quad (\text{F.13})$$

G SU(2) × SU(2)

In this appendix, we examine the two types of generalized Kähler structures on SU(2) × SU(2) and relate them by T-duality along an affine isometry. The complex structures on SU(2) × SU(2) were first written down in [12] and the generalized geometry is discussed in great detail in [18].

As discussed in section 2.3, SU(2) × SU(2) admits generalized Kähler structures of two types: choosing the complex structures to be equal on the Lie algebra leads to a type $(N_c, N_t) = (1, 0)$ generalized Kähler structure while choosing them to be opposite on the Cartan subalgebra leads to a type $(0, 1)$ structure.

We choose the basis $\{h, \bar{h}, e_1, \bar{e}_1, e_2, \bar{e}_2\}$ for the Lie algebra of SU(2) × SU(2), where

$$h = \frac{1}{2}(\sigma_{1,3} + i\sigma_{2,3}), \quad e_1 = \frac{1}{2}(\sigma_{1,1} + i\sigma_{1,2}), \quad e_2 = \frac{1}{2}(\sigma_{2,1} + i\sigma_{2,2}) \quad (\text{G.1})$$

and $\sigma_{1,i}$ (respectively $\sigma_{2,i}$), $i = 1, 2, 3$, are the sigma matrices of the first (second) SU(2) factor, and the bar denotes hermitian conjugation. The two complex structures on the Lie algebra compatible with the choice of Cartan subalgebra h, \bar{h} are

$$\mathbb{J}_1 = \text{diag}(i, -i, i, -i, i, -i) \quad \text{and} \quad \mathbb{J}_2 = \text{diag}(-i, i, i, -i, -i, i). \quad (\text{G.2})$$

G.1 Type (1, 0)

If one takes J_+ and J_- both induced from the same Lie algebra complex structure, say \mathbb{J}_1 , then generically the resulting generalized Kähler structure has type $(1, 0)$ (there are once again positive codimension type change loci). Denoting the group element in the defining representation by (g_{ij}^1, g_{ij}^2) , $i, j = 1, 2$, the chiral coordinate is

$$\phi = -\log g_{12}^1 + i \log g_{12}^2, \quad (\text{G.3})$$

while J_{\pm} coordinates on each symplectic leaf can be chosen to be

$$\begin{aligned} z_+^1 &= \log \frac{g_{12}^1}{g_{22}^1}, & z_+^2 &= \log \frac{g_{12}^2}{g_{22}^2}, \\ z_-^1 &= \log \frac{g_{12}^1}{g_{11}^1}, & z_-^2 &= \log \frac{g_{12}^2}{g_{11}^2}. \end{aligned} \quad (\text{G.4})$$

The Poisson structure in these coordinates is

$$\sigma(dz_{\pm}^1, dz_{\pm}^2) = \pm i. \tag{G.5}$$

We choose the semi-chiral coordinates

$$\begin{aligned} \ell &= z_+^1, & \tilde{\ell} &= -iz_+^2, \\ r &= z_-^2, & \tilde{r} &= iz_-^1, \end{aligned} \tag{G.6}$$

which satisfy $d(\tilde{\ell}d\ell + \bar{\tilde{\ell}}d\bar{\ell} + \tilde{r}dr + \bar{\tilde{r}}d\bar{r}) = 0$. In the polarization determined by ℓ and r , the generalized potential is²²

$$\begin{aligned} K &= F(\phi, \bar{\phi}) + \int^{(\ell, \bar{\ell}, r, \bar{r})} \tilde{\ell} d\ell + \bar{\tilde{\ell}} d\bar{\ell} + \tilde{r} dr + \bar{\tilde{r}} d\bar{r} \\ &= \frac{1}{2}(\bar{\phi} - \phi)^2 - (r + i\ell)(\bar{r} - i\bar{\ell}) - (\phi + \bar{\phi})(\ell + \bar{\ell}) + i(\bar{\phi} - \phi)(r + \bar{r}) \\ &\quad + \int^{\ell + \bar{\ell}} dq \log(1 + e^q) + \int^{r + \bar{r}} dq \log(1 + e^q) - \frac{1}{2}(\ell^2 + \bar{\ell}^2 + r^2 + \bar{r}^2). \end{aligned} \tag{G.7}$$

Here, $F(\phi, \bar{\phi}) = \frac{1}{2}(\bar{\phi} - \phi)^2$ is determined by solving the second order differential equations (B.12)–(B.13). For our later discussion of T-duality, it is convenient to add generalized Kähler transformation terms so that

$$\begin{aligned} K^{(1,0)}(\ell, \bar{\ell}, r, \bar{r}, \phi, \bar{\phi}) &= \frac{1}{2}(\bar{\phi} - \phi)^2 - (r + i\ell)(\bar{r} - i\bar{\ell}) + i(\bar{\phi} - \phi)(r + \bar{r} + i\ell - i\bar{\ell}) \\ &\quad + \int^{\ell + \bar{\ell}} dq \log(1 + e^q) + \int^{r + \bar{r}} dq \log(1 + e^q) - \frac{1}{2}(r^2 + \bar{r}^2), \end{aligned} \tag{G.8}$$

which corresponds to shifting $\tilde{\ell} \rightarrow \tilde{\ell}' = \tilde{\ell} + 2\phi + \ell = -iz_+^2 + z_+^1 + 2\phi$.

G.2 Type (0, 1)

If one takes J_+ induced from the Lie algebra complex structure \mathbb{J}_1 and J_- induced from \mathbb{J}_2 , then generically the resulting generalized Kähler structure has type (0, 1). The twisted chiral coordinate is

$$\chi = -\log g_{22}^1 + i \log g_{22}^2 \tag{G.9}$$

while J_{\pm} coordinates on the symplectic leaves can be chosen to be the same as those for the type (1, 0) structure (G.4). The Poisson structure in these coordinates, however, is now different

$$\sigma(dz_{\pm}^1, dz_{\pm}^2) = i. \tag{G.10}$$

We choose now

$$\ell = z_+^1, \quad r = z_-^2, \quad \tilde{r} = iz_-^1, \tag{G.11}$$

as before, but now

$$\tilde{\ell} = iz_+^2 \tag{G.12}$$

²²Note that, due to the relations $z_+^j + \bar{z}_+^j = z_-^j + \bar{z}_-^j$ for each $j = 1, 2$, the combinations $(\ell, \bar{\ell}, \tilde{r}, \bar{\tilde{r}})$ and $(\tilde{\ell}, \bar{\tilde{\ell}}, r, \bar{r})$ are not functionally independent.

has an extra minus sign compared to the above. This is necessary to preserve $d(\tilde{\ell}d\ell + \bar{\tilde{\ell}}d\bar{\ell} + \tilde{r}dr + \bar{\tilde{r}}d\bar{r}) = 0$. In the polarization determined by ℓ and r , the generalized potential is

$$\begin{aligned}
 K &= G(\chi, \bar{\chi}) + \int^{(\ell, \bar{\ell}, r, \bar{r})} \tilde{\ell} d\ell + \bar{\tilde{\ell}} d\bar{\ell} + \tilde{r} dr + \bar{\tilde{r}} d\bar{r} \\
 &= -\frac{1}{2}(\bar{\chi} - \chi)^2 + i(\ell r - \bar{\ell} \bar{r}) - (\chi + \bar{\chi})(\ell + \bar{\ell}) + i(\bar{\chi} - \chi)(r + \bar{r}) \\
 &\quad + \int^{\ell + \bar{\ell}} dq \log(1 + e^q) + \int^{r + \bar{r}} dq \log(1 + e^q), \tag{G.13}
 \end{aligned}$$

where $G(\chi, \bar{\chi}) = -\frac{1}{2}(\bar{\chi} - \chi)^2$ is determined by (B.12), (B.13).

For later discussion of T-duality, it is convenient to add generalized Kähler transformation terms so that

$$\begin{aligned}
 K^{(0,1)}(\ell, \bar{\ell}, r, \bar{r}, \chi, \bar{\chi}) &= -\frac{1}{2}(\bar{\chi} - \chi)^2 + i(\bar{\chi} - \chi)(r + \bar{r} + i\ell - i\bar{\ell}) \\
 &\quad + \int^{\ell + \bar{\ell}} dq \log(1 + e^q) + \int^{r + \bar{r}} dq \log(1 + e^q) - \frac{1}{2}(\ell^2 + \bar{\ell}^2) \tag{G.14}
 \end{aligned}$$

which corresponds to shifting $\tilde{\ell} \rightarrow \tilde{\ell}' = \tilde{\ell} + 2\chi - \ell = iz_+^2 - z_+^1 + 2\chi$. This matches with $\tilde{\ell}$ in (G.8) since $iz_+^2 - z_+^1 + 2\chi = -iz_+^2 + z_+^1 + 2\phi$.

G.3 T-duality

The subgroup of the isometry group preserving both complex structures is $(U(1) \times U(1))_L \times (U(1) \times U(1))_R$, acting as $g \mapsto e^{\epsilon h - \bar{\epsilon} \bar{h}} g e^{\bar{\eta} \bar{h} - \eta h}$. Under this action, the coordinates transform as

$$\begin{aligned}
 \phi &\mapsto \phi - i\bar{\epsilon} + i\eta, & \chi &\mapsto \chi + i\bar{\epsilon} + i\eta, \\
 z_+^1 &\mapsto z_+^1 + i\epsilon + i\bar{\epsilon} & z_-^1 &\mapsto z_-^1 - i\eta - i\bar{\eta}, \\
 z_+^2 &\mapsto z_+^2 + \epsilon - \bar{\epsilon} & z_-^2 &\mapsto z_-^2 + \bar{\eta} - \eta.
 \end{aligned} \tag{G.15}$$

For the type (1, 0) structure, the parameters satisfy

$$\bar{\mathbb{D}}_+ \epsilon = 0, \quad \mathbb{D}_\pm \epsilon = 0, \quad \bar{\mathbb{D}}_\pm \eta = 0, \quad \mathbb{D}_- \eta = 0, \tag{G.16}$$

while for the type (0, 1) structure, they satisfy

$$\bar{\mathbb{D}}_\pm \epsilon = 0, \quad \mathbb{D}_+ \epsilon = 0, \quad \bar{\mathbb{D}}_\pm \eta = 0, \quad \mathbb{D}_- \eta = 0. \tag{G.17}$$

In both cases, it is clear that these isometries are affine, $\partial_+ \epsilon = 0 = \partial_- \eta$.

Let us perform T-duality along the isometry with parameter $\epsilon = -i\lambda, \eta = 0$, with λ real. This isometry transforms $\phi \mapsto \phi + \lambda$ and $\chi \mapsto \chi - \lambda$ and leaves $\ell, \bar{\ell}, r, \bar{r}$ invariant. The potential (G.8) is invariant under this isometry, and can be gauged by a standard vector multiplet. Constraining the gauge field to be flat using a twisted chiral Lagrange multiplier χ returns one to the original model

$$\begin{aligned}
 \tilde{K}^{(1,0)} &= -\frac{1}{2}V^2 - (r + i\ell)(\bar{r} - i\bar{\ell}) + V(r + \bar{r} + i\ell - i\bar{\ell}) \\
 &\quad + \int^{\ell + \bar{\ell}} dq \log(1 + e^q) + \int^{r + \bar{r}} dq \log(1 + e^q) - \frac{1}{2}(r^2 + \bar{r}^2) - i(\bar{\chi} - \chi)V, \tag{G.18}
 \end{aligned}$$

where we have gauge fixed $\phi = 0$. It is now straightforward to check that integrating out the gauge field V yields the type $(0, 1)$ potential $K^{(0,1)}$ (G.14).

ABSTRACT: We investigate the integrable Yang-Baxter deformation of the 2d Principal Chiral Model with a Wess-Zumino term. For arbitrary groups, the one-loop β -functions are calculated and display a surprising connection between classical and quantum physics: the classical integrability condition is necessary to prevent new couplings being generated by renormalisation. We show these theories admit an elegant realisation of Poisson-Lie T-duality acting as a simple inversion of coupling constants. The self-dual point corresponds to the Wess-Zumino-Witten model and is the IR fixed point under RG. We address the possibility of having supersymmetric extensions of these models showing that extended supersymmetry is not possible in general.

1 Introduction

Two-dimensional non-linear sigma models hold great interest for two key reasons. First, they can provide prototypes with which to study strong coupling dynamics in a simpler setting than four-dimensional non-abelian gauge theories. Second, they are the building blocks of the worldsheet description of string theory. Under certain circumstances these theories can have a dramatic additional simplicity — that of integrability — allowing one to transcend the usual perturbative tool kit. A rather long standing question has been to establish the complete landscape of integrable sigma models.

A substantial breakthrough was made by Klimcik with the explicit demonstration that the Yang-Baxter sigma models [1] are integrable [2]; thereby providing a one-parameter integrable deformation of the principal chiral theory associated to any semi-simple Lie algebra. These theories, now often called η -deformations, have taken great prominence since they provide a Lagrangian description of a theory whose symmetry is deformed to a quantum group [3]. When extended to theories on symmetric spaces and to super-cosets, this has yielded a remarkable quantum group deformation of the $AdS_5 \times S^5$ superstring [4] opening the door to an intriguing interpretation within holography.

A surprising feature of the η -deformed theory in the context of the $AdS_5 \times S^5$ superstring is that it appears to describe a scale invariant but not Weyl invariant theory. This is seen directly by the target spacetime's failure to satisfy the equations of Type IIB supergravity but instead to obey a set of “generalised” supergravity equations [5]. Recent work has started to place these η -theories, and the generalised supergravity that govern their target spacetimes, in the context of double/exceptional field theory [6, 7] and make explicit the link to T-folds and non-geometric configurations [8]. A link between the r-matrix, satisfying a (modified) classical Yang-Baxter equation, that defines Yang-Baxter sigma models and the spacetime non-commutativity parameter has been developed in [9, 10] using the open-closed map.

Notably, the η -theory displays a so-called Poisson-Lie (PL) symmetry. This means that it possesses a generalised T-dual in the Poisson-Lie sense proposed by Klimcik and Severa [11]. The Poisson-Lie dual model, modulo an analytic continuation, has been established to be a well-known integrable deformation called the λ -deformation. Introduced by Sfetsos [12] these theories interpolate between a Wess-Zumino-Witten (WZW) [13] or a gauged WZW model and the non-abelian T-dual of the principal chiral model on a group manifold or symmetric coset space respectively. The connection between the η - and the λ -theories was first shown for explicit $SU(2)$ based examples [14, 15] and established in generality by [16, 17].

Like the η -theories, λ -models can also be applied to cosets [18] and semi-symmetric spaces [19] and are thought to encapsulate quantum group deformations with q a root of unity. In contrast to the η -theory, the target spacetimes associated to the λ -model provide genuine solutions of supergravity (with no modification) [20–24].

Given these successes a natural recent focus has been to understand potential generalisations of these approaches to include multi-parameter families of integrable models. On the side of the η -deformation (or Yang-Baxter model) notable are the two-parameter bi-Yang-Baxter deformations [25], the inclusion of a Wess-Zumino term [26] and indeed the recent synthesis of these [27]. On the λ side, multi-parameter deformations have been constructed and studied in [15, 28–30]. There is also some evidence that a Poisson-Lie connection should be present between multi-parameter η - and λ -models; for example the bi-Yang Baxter model has been shown to be related to a generalised λ -model [31]. The Yang-Baxter theory with a WZ term (YB-WZ) appears amenable to similar treatment since it can be written as an \mathcal{E} -model [32] (though the corresponding λ theory is not clearly spelt out as yet). The construction of Lax pairs directly from the \mathcal{E} -model has recently been studied in [33].

In this work we will provide further study of the multi-parameter YB-WZ model. For the case of $SU(2)$ this system was studied in [34, 35]. Specifically we shall,

- Study the one-loop renormalisation of the general YB+WZ model extending results in the literature from $SU(2)$ [34] to arbitrary groups. We will find that the conditions placed on a sigma model by integrability have an interesting interplay with renormalisation. The condition required of classical integrability is preserved by RG flow. Second, when dealing with non-simply laced algebras one finds the classical integrability condition is necessary for the renormalisation of the model not to introduce new

couplings in addition to those of the bare theory. That a classical property seems to be so tied to a very quantum calculation is notable.

- We will clarify some details of the quantum group symmetries in these models and in particular show that the parameters defining the symmetry algebra are invariants of the RG flow.
- We comment on the role of Poisson-Lie dualisation for the YB-WZ model. Considered within the framework of the \mathcal{E} -model [32], the YB-WZ can be seen as being part of a pair of Poisson-Lie dual models. In particular, it admits a formulation as an \mathcal{E} -model associated to the Drinfeld double $\mathfrak{d} = \mathfrak{g}^{\mathbb{C}}$. When the integrability condition is satisfied, the Poisson-Lie T-duality transformation preserves the structure of the action (2.2) while the coupling parameters follow very simple “radial inversion” transformation rules.
- We will examine the possible worldsheet supersymmetrisation of the YB-WZ model associated to $SU(2) \times U(1)$ which is the simplest but non-trivial example that allows $N = (2, 2)$ in the undeformed (WZW) case. While $N = (1, 1)$ supersymmetry is always possible, going beyond that requires the introduction of additional geometric structures. We show that $N = (2, 2)$ is forbidden for generic values of the deformation parameters while $N = (2, 0)$ or $N = (2, 1)$ is possible only for specific values. This leads us to conjecture that an $N = (2, 2)$ YB-WZ model is not possible in general.

The paper is organised as follows. Section 2 introduces the Yang-Baxter Wess-Zumino model together with its integrability properties relevant to the subsequent discussions. In section 3 we give an explicit derivation of the one-loop β -functions of the YB-WZ model in the case of arbitrary groups. Given the result, we find that one needs to carefully distinguish between two cases: when the group is simply-laced or not. In the former case, a consistent renormalisation does not require the model to be integrable. For the latter case, the classical integrability condition turns out to be necessary to prevent the creation of new couplings in the theory by renormalisation. A detailed discussion of the RG behaviour is given in both cases. Section 4 formulates the YB-WZ action (2.2) within the framework of the \mathcal{E} -model and derives the Poisson-Lie T-dual model. In section 5 we study the possibility of extended supersymmetry of the YB-WZ model. We end with a summary and conclusions in section 6. The conventions used throughout this paper are given in appendix A. Appendix B reviews the construction [35] of the charges of the $SU(2)$ YB-WZ model paying particular care to the overall normalisations required to expose the correct RG properties. In appendix C and D we collate a set of useful expressions which were used in the calculations of the β -functions.

2 Yang-Baxter and Yang-Baxter Wess-Zumino models

In this first section, we present the Yang-Baxter Wess-Zumino model (YB-WZ) as constructed in [26], which will be the main topic of the remainder of this paper. Given a Lie algebra \mathfrak{g} , we introduce an endomorphism $\mathcal{R} : \mathfrak{g} \rightarrow \mathfrak{g}$ skew symmetric with respect to

the Cartan-Killing product $\langle \cdot, \cdot \rangle$ ($\langle \mathcal{R}x, y \rangle = -\langle x, \mathcal{R}y \rangle$) and obeying the modified classical Yang-Baxter (mCYBE) equation,

$$[\mathcal{R}x, \mathcal{R}y] - \mathcal{R}([x, \mathcal{R}y] + [\mathcal{R}x, y]) = [x, y] \quad \forall x, y \in \mathfrak{g}, \quad (2.1)$$

which further satisfies $\mathcal{R}^3 = -\mathcal{R}$. The canonical realization of \mathcal{R} is most easily seen in a Cartan-Weyl basis for the Lie algebra where it maps generators belonging to the CSA to zero and where it acts diagonally on generators corresponding to positive (negative) roots with eigenvalue $+i$ ($-i$). Equipped with this structure, we define the YB-WZ action in worldsheet light-cone coordinates as,

$$\begin{aligned} \mathcal{S} = & -\frac{1}{2\pi} \int d\sigma d\tau \langle g^{-1} \partial_+ g, (\alpha \mathbb{1} + \beta \mathcal{R} + \gamma \mathcal{R}^2) g^{-1} \partial_- g \rangle \\ & + \frac{k}{24\pi} \int_{M_3} \langle \bar{g}^{-1} d\bar{g}, [\bar{g}^{-1} d\bar{g}, \bar{g}^{-1} d\bar{g}] \rangle. \end{aligned} \quad (2.2)$$

Here as usual the coefficient of the Wess-Zumino term, k , is an integer, quantised such that the path integral based on this action is insensitive to the choice of the extension $\bar{g} : M_3 \rightarrow G$.

A short calculation yields, after integration by parts and discarding the total derivative, the equations of motion,

$$\delta S = \frac{\alpha - \gamma}{2\pi} \int d\sigma d\tau \langle \delta g g^{-1}, \partial_+ \mathcal{K}_- + \partial_- \mathcal{K}_+ \rangle, \quad (2.3)$$

with,

$$\mathcal{K}_\pm = \frac{1}{\alpha - \gamma} ((\alpha \mp k) \mp \beta \mathcal{R}_g + \gamma \mathcal{R}_g^2) v_\pm, \quad (2.4)$$

in which we recall $v = dg g^{-1}$ are the right invariant one-forms and,

$$\mathcal{R}_g = \text{ad}_g \circ \mathcal{R} \circ \text{ad}_{g^{-1}}, \quad (2.5)$$

which, like \mathcal{R} , obeys the mCYBE and is skew symmetric with respect to the ad-invariant Cartan-Killing form $\langle \cdot, \cdot \rangle$. Using the inverse of eq. (2.4),

$$\begin{aligned} v_\pm = & (\alpha - \gamma) \left(\frac{1}{\alpha \mp k} \pm \frac{\beta}{\beta^2 + (\alpha \mp k - \gamma)^2} \mathcal{R}_g \right. \\ & \left. + \frac{\beta^2 - \gamma(\alpha \mp k - \gamma)}{(\alpha \mp k)(\beta^2 + (\alpha \mp k - \gamma)^2)} \mathcal{R}_g^2 \right) \mathcal{K}_\pm, \end{aligned} \quad (2.6)$$

in $dv - v \wedge v = 0$, one easily gets,

$$\begin{aligned} \partial_+ \mathcal{K}_- - \partial_- \mathcal{K}_+ - [\mathcal{K}_+, \mathcal{K}_-] = & \left(\frac{k}{\alpha} + \frac{\sqrt{\gamma(\alpha^2 - \alpha\gamma - k^2)}}{\sqrt{\alpha}(\alpha - \gamma)} \mathcal{R}_g \right. \\ & \left. - \frac{k\gamma}{\alpha(\alpha - \gamma)} \mathcal{R}_g^2 \right) (\partial_+ \mathcal{K}_- + \partial_- \mathcal{K}_+), \end{aligned} \quad (2.7)$$

if and only if the coefficients are related via [26],

$$\beta^2 = \frac{\gamma}{\alpha} (\alpha^2 - \alpha\gamma - k^2). \quad (2.8)$$

So we conclude that the currents \mathcal{K}_\pm are on-shell flat provided eq. (2.8) holds. This is sufficient to guarantee classical integrability as the equations of motion follow then from the flatness of the standard $\mathfrak{g}^{\mathbb{C}}$ -valued Zakharov-Mikhailov Lax connection [42],

$$\mathcal{L}_\pm(z) = \frac{1}{1 \mp z} \mathcal{K}_\pm. \tag{2.9}$$

We call the solutions to eq. (2.8) the *integrable locus*.¹ From eqs. (2.7) and (2.4) one deduces the further conditions $\alpha \neq 0$ and $\gamma \neq \alpha$, ensuring that the kinetic term is properly defined. In addition, as all parameters α, β, γ, k are real and the kinetic term should have the right sign ($\alpha > 0$), we conclude from eq. (2.8) that the allowed values of α and γ are $\alpha \in [|k|, \infty[$ and $\gamma \in [0, \frac{\alpha^2 - k^2}{\alpha}]$ or $\alpha \in]0, |k|]$ and $\gamma \in [-\frac{k^2 - \alpha^2}{\alpha}, 0]$, where on $\alpha = |k|$ we find the WZW point [13]: $\gamma = \beta = 0$.

For the particular subset of the integrable locus given by [1],

$$k = 0, \quad \alpha = \frac{1}{\tau}, \quad \beta = \frac{\eta}{\tau(1 + \eta^2)}, \quad \gamma = \frac{\eta^2}{\tau(1 + \eta^2)}, \tag{2.11}$$

the action eq. (2.2) reduces to what has become known as the η -deformed principal chiral model which is integrable [2] with the dynamics encoded in the flatness of a $\mathfrak{g}^{\mathbb{C}}$ -valued Lax connection $\mathcal{L}(z)$ depending on a spectral parameter $z \in \mathbb{C}$. This theory displays a fascinating structure of infinite symmetries [3]. At the Lagrangian level the left acting G symmetry is preserved and is complemented, as in the undeformed principal chiral model, with non-local charges furnishing a Yangian $\mathcal{Y}(\mathfrak{g})$. The right acting G symmetry is broken to its Cartan in the action eq. (2.2), but is enhanced by non-local charges to form a classical version of a quantum group $\mathcal{U}_q(\mathfrak{g})$ [3] (actually further extended to an affine $\mathcal{U}_q(\hat{\mathfrak{g}})$ [36]). Schematically, for a given simple root there exists a local charge \mathfrak{Q}^H and non-local charges \mathfrak{Q}^\pm that obey,

$$\{\mathfrak{Q}^+, \mathfrak{Q}^-\} = i \frac{q^{\mathfrak{Q}^H} - q^{-\mathfrak{Q}^H}}{q - q^{-1}}, \quad \{\mathfrak{Q}^\pm, \mathfrak{Q}^H\} = \pm i \mathfrak{Q}^\pm. \tag{2.12}$$

The quantum group parameter is given simply by $q = \exp(8\pi\tau\eta)$ which is an invariant under the renormalisation group flow of couplings [15].

The charges that generate these symmetries can be obtained by expansions around suitable values of the spectral parameter of the monodromy matrix,

$$U(z) = P \exp \left[\int d\sigma \mathcal{L}_\sigma(z) \right], \tag{2.13}$$

which is conserved by virtue of the flatness of \mathcal{L} . The Yangian left acting symmetries are found through expansions around $z = \infty$ whereas the right acting quantum group

¹To translate to [26] we have the dictionary of parameters $(\alpha, \beta, \gamma, k) \rightarrow (\eta^2, R, k', K)$

$$A = \frac{\beta}{\alpha - \gamma}, \quad \eta^2 = \frac{\gamma}{\alpha - \gamma}, \quad k' = \frac{k}{\alpha - \gamma}, \quad K = \frac{\alpha - \gamma}{4\pi}, \tag{2.10}$$

however we shall continue with the $(\alpha, \beta, \gamma, k)$ such that k gives the level of the WZW model that will appear at IR fixed points.

symmetries are found [3] via the expansion of the gauge transformed Lax around special points corresponding to poles in the twist function of the Maillet algebra [37].

Much of the story for the general η -deformed model was first established for the case of $\mathfrak{g} = \mathfrak{su}(2)$ which corresponds to the sigma model on a squashed S^3 (the Kalb-Ramond potential encoded by eq. (2.2) is pure gauge in this case and though it doesn't effect the equation of motions it corresponds to an improvement term to ensuring flatness of currents). The integrability was established many years ago by Cherednik [38]. Somewhat later the classical Yangian symmetry was shown in [39] and the (affine) quantum group symmetry in [40, 41].²

Now we turn to the case where $k \neq 0$ which is the main focus of this paper. Again historically this was first well explored for the case of $\mathfrak{g} = \mathfrak{su}(2)$. The left acting symmetry is still a Yangian [34] but the right acting symmetry is more mysterious [35] (we review the construction of the charges generating these generalised symmetries in appendix B). One finds a structure similar to an affine quantum group $\mathcal{U}_q(\widehat{\mathfrak{su}(2)})$ with,³

$$q = \exp \left[\frac{8\pi\Theta}{\Theta^2 + k^2} \right], \tag{2.14}$$

but with a modification in how the affine tower of charges is build up. Namely, instead of taking successively the Poisson bracket to access the next charges in the tower, the Poisson bracket is multiplied at each step by an additional factor,

$$\frac{\gamma^-}{\gamma^+} = -\frac{k + i\Theta}{k - i\Theta}. \tag{2.15}$$

To move down, the Poisson bracket needs to be multiplied by its inverse (see figure 2 of [35] for further details). Here the combination,

$$\Theta^2 = \frac{\alpha(\alpha - \gamma) - k^2}{\gamma}, \tag{2.16}$$

will play a distinguished role in what follows; it will be seen to be an RG invariant.

As mentioned above, several partial results were already obtained for the YB-WZ model in the particular case where $\mathfrak{g} = \mathfrak{su}(2)$. In this paper we mostly focus on the case where \mathfrak{g} is arbitrary. As we will see the general case shows several features which are absent when $\mathfrak{g} = \mathfrak{su}(2)$.⁴

3 Renormalisation of the YB-WZ model

Our aim is to calculate the β -functions for the couplings $\{\alpha, \beta, \gamma\}$ in the theory defined by eq. (2.2) without first assuming that the couplings lie on the integrable locus eq. (2.8).

²There is a small but potentially important subtlety here. In [41] the affine charges are constructed from the expansion of a trigonometric Lax at infinity and appear in the principal gradation. When the charges are extracted from the gauge transformation of the rational Lax evaluated around the poles in the twist function as in [36] they appear in the homogeneous gradation; to go between the two gradations requires a spectral parameter dependent redefinition of generators.

³Here we restore the overall normalisations to the results in [35] and map to our conventions.

⁴Mathematically all differences between the general case and the simpler case where $\mathfrak{g} = \mathfrak{su}(2)$ arise from the fact that $\mathfrak{su}(2)$ is the only simple Lie algebra where all roots are simple roots.

The coupling k being integer quantised evidently does not run. To do so we will proceed geometrically; for a general two-dimensional non-linear sigma model the β -function for the metric $G_{\mu\nu}$ and Kalb-Ramond two-form potential $B_{\mu\nu}$ in local coordinates x^μ are given by, at one-loop,

$$\begin{aligned} \mu \frac{d}{d\mu} G_{\mu\nu} &= \hat{\beta}_{\mu\nu}^G = \alpha' \left(R_{\mu\nu} - \frac{1}{4} H_{\mu\nu}^2 \right) + O(\alpha')^2, \\ \mu \frac{d}{d\mu} B_{\mu\nu} &= \hat{\beta}_{\mu\nu}^B = \alpha' \left(-\frac{1}{2} \nabla^\lambda H_{\lambda\mu\nu} \right) + O(\alpha')^2, \end{aligned} \tag{3.1}$$

where $H = dB$ is the torsion 3-form and the connections and curvatures are to be calculated using G . However, the diffeomorphism and gauge covariance of G and B means that these β -functions are ambiguous (even at one-loop order) [43, 44] allowing us to modify them by,⁵

$$\begin{aligned} \bar{\beta}_{\mu\nu}^G &= \hat{\beta}_{\mu\nu}^G + \nabla_{(\mu} W_{\nu)}, \\ \bar{\beta}_{\mu\nu}^B &= \hat{\beta}_{\mu\nu}^B + (\iota_W H)_{\mu\nu} + (d\Lambda)_{\mu\nu}, \end{aligned} \tag{3.2}$$

with W and Λ arbitrary target space one-forms. For the sigma model defined in eq. (2.2), of which the left acting G symmetry is unaltered by the deformation, the target space data is most naturally expressed in a non-orthonormal frame formalism with frames defined by the left-invariant one-forms $u = g^{-1}dg = -iu^A T_A$ as,

$$G_{AB} = \alpha \kappa_{AB} + \gamma \mathcal{R}_{AB}^2, \tag{3.3}$$

and torsion,

$$H_{ABC} = 3\beta F_{[AB}{}^D \mathcal{R}_{C]D} - k F_{ABC}. \tag{3.4}$$

Here $\kappa_{AB} = \langle T_A, T_B \rangle$, $\mathcal{R}(T_A) = \mathcal{R}^B{}_{AT_B}$ and algebra indices out of position are lowered with κ_{AB} . To completely fix things one should set $\alpha' = 2$ so that the standard normalisation of the WZW models is recovered in the case $\alpha = |k|, \beta = \gamma = 0$.

After a long battle making use of the properties listed in appendix C and the expressions of the geometry in the non-orthonormal frame listed in appendix D one finds that the β -functions are given by,

$$\begin{aligned} \hat{\beta}_{AB}^G &= -c_G \left(\frac{k^2(\alpha - 2\gamma)}{2\alpha(\gamma - \alpha)^2} - \frac{\beta^2}{(\gamma - \alpha)^2} - \frac{\gamma^2}{2(\gamma - \alpha)^2} - \frac{1}{2} \right) \kappa_{AB} - \frac{c_G}{2} \left(1 - \frac{\alpha^2 + \beta^2}{(\gamma - \alpha)^2} \right) \mathcal{R}_{AB}^2 \\ &\quad - \left(\frac{\gamma}{\alpha} \frac{k^2}{(\gamma - \alpha)^2} + \frac{\beta^2}{(\gamma - \alpha)^2} + \frac{\gamma}{(\gamma - \alpha)} \right) F_{AD}{}^C F_{BC}{}^E (\mathcal{R}^2)^D{}_E, \end{aligned} \tag{3.5}$$

$$\hat{\beta}_{AB}^B = \frac{2\beta}{\alpha - \gamma} F_{AD}{}^C F_{BC}{}^E \mathcal{R}^D{}_E + c_G \frac{\beta}{\alpha - \gamma} \mathcal{R}_{AB}. \tag{3.6}$$

The terms in blue involve tensor structures that are not present in the metric ansatz. If these terms are not removed it would mean that under the RG flow the metric would flow out of the ansatz specified by eq. (3.3). Let us exploit the diffeomorphism symmetry to

⁵Note that the Lie derivative acts on $L_W B = \iota_W H + d\iota_W B$ and the latter term being a total derivative can be discarded within the action.

try and ameliorate the situation. With this in mind, note that for a one-form W whose components W_A are constant in frame indices we have:

$$\begin{aligned} \nabla_{(A} W_{B)} &= \frac{1}{2} \frac{\gamma}{\alpha - \gamma} (F_{AD}{}^C (\mathcal{R}^2)^D{}_B + F_{BD}{}^C (\mathcal{R}^2)^D{}_A) W_C, \\ (i_W H)_{AB} &= 3\beta F_{[AB}{}^D \mathcal{R}_{C]D} G^{CE} W_E - k F_{ABC} G^{CD} W_D. \end{aligned} \tag{3.7}$$

First, we try to use an appropriate choice of W to remove the offending blue term in $\hat{\beta}^G$. However, using the properties listed in appendix C, one can show that the only sensible choice of $G^{-1}W$ involving the structure constants and the \mathcal{R} -matrix will always be Killing. Nevertheless, by taking the components W_A proportional to $F_{AB}{}^C \mathcal{R}^B{}_C$, one can show that it is again Killing but can now in fact absorb the offending first term in $\hat{\beta}^B$. Finally, we remark that for the case of $\mathfrak{g} = \mathfrak{su}(2)$ ($c_G = 4$ in our conventions) the contribution of the parameter β cancels exactly in $\hat{\beta}^G$ and can be gauged away by an appropriate gauge choice Λ in $\bar{\beta}^B$ eq. (3.2) since $\mathcal{R}_{AB} u^A \wedge u^B$ is a pure gauge improvement term for $\mathfrak{su}(2)$.

We now consider the remaining offending term in $\hat{\beta}^G$ eq. (3.5). Using a Cartan-Weyl basis for the Lie algebra and calling Lie algebra indices corresponding to positive (negative) roots as $a, b, \dots (\bar{a}, \bar{b}, \dots)$ and those corresponding to directions in the CSA by m, n, \dots one gets,

$$F_{AD}{}^C F_{BC}{}^E (\mathcal{R}^2)^D{}_E = c_G \kappa_{AB} + F_{Am}{}^C F_{BC}{}^m. \tag{3.8}$$

The second term is non-vanishing only if the index A corresponds to a positive root and the index B to the corresponding negative root (or vice-versa) so one would expect it to be proportional to \mathcal{R}_{AB}^2 . Explicit computation gives,

$$F_{am}{}^C F_{\bar{a}C}{}^m = -\kappa_{a\bar{a}} \vec{a} \cdot \vec{a} = \vec{a} \cdot \vec{a} \mathcal{R}_{a\bar{a}}^2, \tag{3.9}$$

where $\vec{a} \cdot \vec{a}$ is the length squared of the root a . In our normalization it is always equal to 2 for simply laced groups ($\mathfrak{g} = A_n, D_n, E_6, E_7$ and E_8). For the non-simply laced groups its either 2 or 1 (for $\mathfrak{g} = B_n, C_n$ and F_4) or 2 or 1/3 (for $\mathfrak{g} = G_2$). So the term in blue in eq. (3.5) can be rewritten as,

$$F_{AD}{}^C F_{BC}{}^E (\mathcal{R}^2)^D{}_E = c_G \kappa_{AB} + 2x(A, B) \mathcal{R}_{AB}^2, \tag{3.10}$$

where for simply laced groups $x(A, B) = 1$ holds. For non-simply laced groups $x(A, B)$ assumes two different values pending the values of the indices A and B . This implies that only for simply laced groups the RG stays within the ansatz specified by eq. (3.3).

However, there is a second way to remain within the ansatz eq. (3.3). Till now we did not impose any restriction on the parameters α, β, γ and k . Looking at the bothersome term in the last line of eq. (3.5) we see that it precisely vanishes at the integrable locus eq. (2.8) and we remain within the ansatz eq. (3.3) for any group (simply laced and non-simply laced)! So we should distinguish two cases: case I, a restriction to the integrable locus for general groups, and case II, a restriction to simply laced groups where we can keep the parameters general.

Before analysing both cases, we will consider a useful quantity to understand the RG flow: the Weyl anomaly coefficient $\tilde{\beta}^\Phi$. It is defined through the expectation value of the trace of the stress tensor,

$$\langle T \rangle = \frac{1}{4\pi} \tilde{\beta}^\Phi R^{(2)} + \dots, \quad \tilde{\beta}^\Phi = \frac{D}{6} - \alpha' \frac{1}{4} \left(R + 4\nabla^2 \Phi - 4(\partial\Phi)^2 - \frac{1}{12} H^2 \right) + O(\alpha')^2. \quad (3.11)$$

with D the dimension of \mathfrak{g} . The quantity $\tilde{\beta}^\Phi$, which one recognises in the spacetime effective Lagrangian for bosonic strings, can serve as a c-function for the models we are considering [45].⁶ Here we find for arbitrary groups in general,

$$\tilde{\beta}^\Phi = \frac{D}{6} + \frac{c_G D}{8} \left(\frac{1}{(\gamma - \alpha)} - \frac{k^2 + \beta^2}{3(\gamma - \alpha)^3} \right) + \frac{c_G l}{8} \left(\frac{\gamma}{(\gamma - \alpha)^2} + \frac{k^2 \gamma + \alpha \beta^2}{\alpha(\gamma - \alpha)^3} \right) \quad (3.12)$$

where l is the rank of \mathfrak{g} . Focusing on the particular case of the integrable locus (i.e. case I) this equation reduces to,

$$\tilde{\beta}^\Phi = \frac{D}{6} + \frac{c_G D}{24} \left(\frac{(\Theta^2 + \alpha^2)(\alpha^4 + k^2(\Theta^2 - 3\alpha^2) - 3\Theta^2\alpha^2)}{\alpha^3(\Theta^2 + k^2)^2} \right). \quad (3.13)$$

Whilst perhaps not so elegant, after applying the RG equations for this case we have,

$$\frac{d}{dt} \tilde{\beta}^\Phi = \frac{c_G^2 D (k^2 - \alpha^2)^2 (\alpha^2 + \Theta^2)^2 (3\alpha^4 - 2\alpha^2\Theta^2 + 3\Theta^4)}{48\alpha^6 (\Theta^2 + k^2)^4}. \quad (3.14)$$

Notice that because $(3\alpha^4 + 3\Theta^4 - 2\alpha^2\Theta^2)$ has no real roots for $\alpha^2 \in \mathbb{R}$ and $\Theta^2 \in \mathbb{R}$ we explicitly see the monotonicity of the flow $d_t \tilde{\beta}^\Phi > 0$ with $t \rightarrow \infty$ in the UV giving as required $\tilde{\beta}^\Phi|_{UV} > \tilde{\beta}^\Phi|_{IR}$. The IR is no more than the WZW CFT at $\alpha = |k|, \gamma = \beta = 0$ (for which of course $\tilde{\beta}^\Phi = \frac{D}{6} - \frac{Dh^v}{6k} + O(\frac{1}{k})^2$ in accordance with the large level expansion of $\frac{1}{6}$ times the central charge $c = \frac{k \dim G}{k+h^v}$).

3.1 Case I: general group G and restriction to the integrable locus

We will now restrict ourselves to the integrable locus, i.e. the coupling constant β satisfies eq. (2.8),

$$\beta = \pm \sqrt{\frac{\gamma}{\alpha}} \sqrt{\alpha^2 - \alpha\gamma - k^2}, \quad (3.15)$$

whilst keeping the group G arbitrary. Eqs. (3.5) and (3.6) now become,

$$\begin{aligned} \hat{\beta}_{AB}^G &= -c_G \left(\frac{k^2(\alpha - 2\gamma)}{2\alpha(\gamma - \alpha)^2} - \frac{\beta^2}{(\gamma - \alpha)^2} - \frac{\gamma^2}{2(\gamma - \alpha)^2} - \frac{1}{2} \right) \kappa_{AB} - \frac{c_G}{2} \left(1 - \frac{\alpha^2 + \beta^2}{(\gamma - \alpha)^2} \right) \mathcal{R}_{AB}^2 \\ &= -\frac{c_G}{2} \frac{k^2 - \alpha^2}{(\alpha - \gamma)^2} \kappa_{AB} - \frac{c_G}{2} \frac{\gamma}{\alpha(\alpha - \gamma)^2} (2\alpha\gamma - 3\alpha^2 + k^2) \mathcal{R}_{AB}^2, \end{aligned} \quad (3.16)$$

$$\begin{aligned} \hat{\beta}_{AB}^B &= c_G \frac{\beta}{\alpha - \gamma} \mathcal{R}_{AB} \\ &= \pm c_G \frac{1}{\alpha - \gamma} \sqrt{\frac{\gamma}{\alpha}} \sqrt{\alpha^2 - \alpha\gamma - k^2} \mathcal{R}_{AB}. \end{aligned} \quad (3.17)$$

⁶In general one would need to average, i.e. integrate this over spacetime coordinates but the special form of the metric on a group manifold means that is not needed here.

Eq. (3.16) yields the RG equations for the independent coupling constants α and γ ,

$$\begin{aligned}\frac{d\alpha}{dt} &= -\frac{c_G}{2} \frac{k^2 - \alpha^2}{(\alpha - \gamma)^2}, \\ \frac{d\gamma}{dt} &= -\frac{c_G}{2} \frac{\gamma}{\alpha(\alpha - \gamma)^2} (2\alpha\gamma - 3\alpha^2 + k^2).\end{aligned}\tag{3.18}$$

Note that eq. (3.18) is simply a rescaling of that obtained for $\mathfrak{su}(2)$ in [34]. Therefore, the group dependence in the flow equations is limited to the rate of the flow. Indeed, absorbing the factor c_G in the RG time, $t \rightarrow c_G t$, the flow can be made independent of the Lie group G . Eq. (3.17) also consistently yields the flow of the dependent parameter β ,

$$\frac{d\beta}{dt} = c_G \frac{\beta}{\alpha - \gamma}.\tag{3.19}$$

Using these equations one immediately gets,

$$\frac{d}{dt} \left(\beta^2 - \frac{\gamma}{\alpha} (\alpha^2 - \alpha\gamma - k^2) \right) = \frac{2c_G}{\alpha - \gamma} \left(\beta^2 - \frac{\gamma}{\alpha} (\alpha^2 - \alpha\gamma - k^2) \right),\tag{3.20}$$

showing that the integrable locus is preserved by the RG!

Moreover, this system has an RG invariant aside from the coefficient of the WZ term,

$$\Theta^2 = \frac{\alpha (\alpha^2 - \alpha\gamma - k^2)}{\gamma},\tag{3.21}$$

in terms of which we have a single independent RG equation,

$$\frac{d}{dt} \alpha = \frac{c_G}{2} \frac{(\alpha^2 - k^2) (\alpha^2 + \Theta^2)^2}{\alpha^2 (k^2 + \Theta^2)^2}.\tag{3.22}$$

Returning to the discussion in section 2 we see that the parameters entering the charge algebra are RG invariants since they are functions of Θ and k alone.

Discussion of the RG behaviour at the integrable locus. The case of $SU(2)$ was already considered in [34], where at first sight it appears to be different because the β coupling is a total derivative in the Lagrangian and serves merely as an improvement term in the currents. The renormalisation of this coupling in the case of $SU(2)$ can be absorbed by a gauge transformation generated by Λ of eq. (3.2). So in fact the analysis of the RG phase portraits performed in [34] is equally valid here, corroborating the group dependence of the flow. However, for completeness and later discussion we present in figure 1 the RG behaviour of the $G = SU(3)$ YB-WZ model at level $k = 4$ restricted to the integrable locus.

In this case, we have an RG invariant Θ given by eq. (3.21) which labels the RG trajectories. The only fixed point is now the WZW at $\alpha = |k| = 4$, $\beta = \gamma = 0$ in the IR. Again, on the $\alpha = \gamma$ line the one-loop result blows up and the metric is degenerate. Since we are restricted to the integrable locus, where β satisfies eq. (2.8), the physically allowed theories are located in the regions where β , or equivalently the RG invariant Θ , is real. There are two such regions indicated in green.

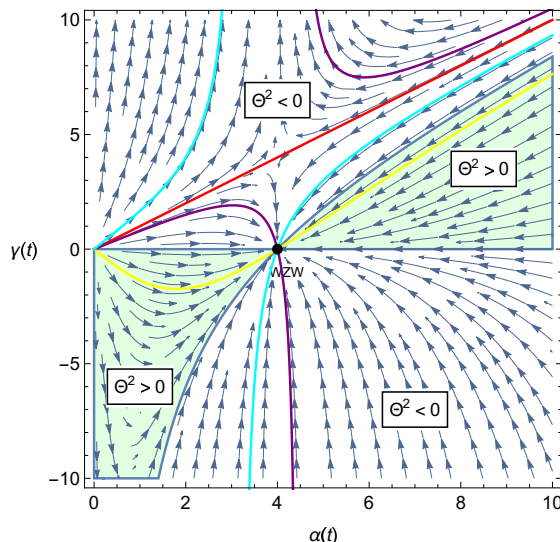

Figure 1. The RG evolution for the $G = \text{SU}(3)$ and $k = 4$ YB-WZ model restricted on the integrable locus of the couplings α vs. γ . The arrows point towards the IR. The red line $\alpha = \gamma$ depicts the points where the one-loop result blows up and it is labeled by $\Theta^2 = -k^2 = -16$. The black dot represents the WZW point ($\alpha = 4, \beta = \gamma = 0$) which is an IR fixed point with only irrelevant directions. The green regions are those where the coupling $\beta(\alpha, \gamma)$ and the RG invariant Θ are real. The yellow line portrays $\Theta^2 = 10$, the cyan line $\Theta^2 = -10$ and the purple line $\Theta^2 = -20$.

A physically allowed trajectory is portrayed by the yellow line in figure 1, along which the RG invariant has the constant real value. By varying the value of the RG invariant $\Theta \in \mathbb{R}$, we can cover the full region of physically allowed trajectories. In the green region where $\gamma < 0$, we start from the trivial fixed point at $\alpha = \gamma = 0$ in the UV and end up at the WZW in the IR in a finite RG time. In the green region where $\gamma > 0$, the WZW is again an IR fixed point but the asymptotic behaviour is not yet apparent. However, as we will see in the coming section, these two green regions are to be physically identified by a duality.

In the other regions, we have either $0 > \Theta^2 > -k^2$, represented by the cyan line, or $\Theta^2 < -k^2$, represented by the purple line. The crossover is given by $\Theta^2 = -k^2$ which corresponds to the red $\alpha = \gamma$ line. In any case, we flow either to the WZW or to a strongly γ -coupled theory in the IR. Conversely, flowing towards the UV leads either to the trivial fixed point or to an unsafe theory.

Let us analyse the behaviour around the IR WZW fixed point. If we linearise the flow around the fixed point, i.e. let $\alpha = k + \bar{\alpha}$ and $\beta = 0 + \bar{\beta}$, $\gamma = 0 + \bar{\gamma}$, we see from eqs. (3.18),

$$\frac{d\bar{\alpha}}{dt} = \frac{c_G}{k} \bar{\alpha}, \quad \frac{d\bar{\beta}}{dt} = \frac{c_G}{k} \bar{\beta}, \quad \frac{d\bar{\gamma}}{dt} = \frac{c_G}{k} \bar{\gamma}. \quad (3.23)$$

Since they all have positive sign's on the right-hand side we conclude that these are indeed irrelevant. Making use of the RG invariant eq. (3.21) and the integrable locus eq. (2.8) we can express the action as,

$$\mathcal{S} = -\frac{1}{2\pi} \int d\sigma d\tau \text{Tr} \left(g^{-1} \partial_+ g, \left(\alpha \mathbb{1} + \frac{\Theta(\alpha^2 - k^2)}{\alpha^2 + \Theta^2} \mathcal{R} + \frac{\alpha(\alpha^2 - k^2)}{\alpha^2 + \Theta^2} \mathcal{R}^2 \right) g^{-1} \partial_- g \right) + I_{WZ}, \quad (3.24)$$

where we choose the positive sign for the β -coupling. Now expanding around the IR fixed point to leading order in $\bar{\alpha}$ we have,

$$\mathcal{S} = S_{WZW_k}[g] - \frac{\bar{\alpha}}{2\pi} \int d\sigma d\tau \text{Tr} \left(g^{-1} \partial_+ g, \left(\mathbb{1} + \frac{2k\Theta}{k^2 + \Theta^2} \mathcal{R} + \frac{2k^2}{k^2 + \Theta^2} \mathcal{R}^2 \right) g^{-1} \partial_- g \right). \quad (3.25)$$

To interpret this let us now go to the Euclidean setting and define the usual WZW CFT currents,

$$J(z) = J^a(z)t^a = -\frac{k}{2} \partial g g^{-1}, \quad \bar{J}(\bar{z}) = \frac{k}{2} g^{-1} \bar{\partial} g, \quad (3.26)$$

which obey a current algebra, and are Virasoro primary with weights $(1, 0)$ and $(0, 1)$ with respect to the Sugawara stress tensor. Consider a composite field $\phi_{\ell\bar{\ell}}(z, \bar{z})$ transforming in representations labelled by ℓ and $\bar{\ell}$ under the affine $G_L \times G_R$ symmetry. This field will also be Virasoro primary and will have an anomalous dimensions $(\Delta_\ell, \bar{\Delta}_{\bar{\ell}})$. As explained in [46] the associated representation of the full Virasoro \times KM algebra is degenerate with a null vector. Because of this the anomalous dimension can be extracted as,

$$\Delta_\ell = \frac{c_\ell}{c_G + k}, \quad (3.27)$$

where $c_\ell \mathbb{I} = t_\ell^a t_\ell^a$. Examples of such primaries are $g(z, \bar{z})$, the group element itself, but also composites including the adjoint action,

$$\mathcal{D}^{ab}(z, \bar{z}) = \text{tr}(g^{-1} t^a g t^b), \quad (3.28)$$

that transforms in the adjoint of G_L on the first index and the adjoint of G_R on the second. This operator has anomalous dimension $\Delta_{\mathcal{D}} = \bar{\Delta}_{\mathcal{D}} = \frac{c_G}{c_G + k}$ and can be used to define the “wrong” currents i.e.,

$$K = K^a t^a = -\frac{k}{2} g^{-1} \partial g = g^{-1} J g \Rightarrow K^a = J^b \mathcal{D}^{ba}, \quad (3.29)$$

with dimensions $(1 + \Delta_\ell, \bar{\Delta}_{\bar{\ell}})$.

Now we can see that the deforming operator is of the form,

$$\mathcal{O}(z, \bar{z}) \sim K^a(z, \bar{z}) \mathcal{M}_{ab} \bar{J}^b(\bar{z}), \quad \mathcal{M} = \left(\mathbb{1} + \frac{2k\Theta}{k^2 + \Theta^2} \mathcal{R} + \frac{2k^2}{k^2 + \Theta^2} \mathcal{R}^2 \right), \quad (3.30)$$

and has total dimension $2 + 2\Delta_{\mathcal{D}} > 2$ and is irrelevant even without any further corrections. Suppose that we send $\Theta \rightarrow \infty$ then we are in exactly the situation considered in [13, 46] of the flow of the PCM plus a Wess-Zumino term with the WZW as the IR fixed point.

Now recall that the Callan-Symanzik equation can be used to relate the beta function to the anomalous dimension and indeed we see that in the large k limit (in which loop corrections are suppressed) the anomalous dimension of \mathcal{O} , $\gamma_{\mathcal{O}} \rightarrow \frac{c_G}{k}$ precisely in agreement with the leading order of the beta functions eq. (3.23).

It would be interesting to develop this line further and to try and ascertain all loop summation of the anomalous dimension following similar techniques to those adopted in the context of λ -models in [47]. There is however an added complexity that the deforming operator is not diagonal in the algebra indices but mixed with the inclusion of the \mathcal{M} matrix.

3.2 Case II: simply laced groups and general parameters

Although it is outside the primary purpose of this paper — which is to study integrable deformations — it is intriguing to look at the case of simply laced groups for which a consistent renormalisation did not require the model to lie on the integrable locus. It is then possible to rewrite eqs. (3.5) and (3.6) as,

$$\begin{aligned}\hat{\beta}_{AB}^G &= -\frac{c_G}{2} \frac{k^2 - \alpha^2}{(\alpha - \gamma)^2} \kappa_{AB} - \left[\frac{c_G}{2} \left(1 - \frac{\alpha^2 + \beta^2}{(\gamma - \alpha)^2} \right) + 2 \left(\frac{\gamma k^2 + \alpha \beta^2}{\alpha(\gamma - \alpha)^2} + \frac{\gamma}{(\gamma - \alpha)} \right) \right] \mathcal{R}_{AB}^2, \\ \hat{\beta}_{AB}^B &= c_G \frac{\beta}{\alpha - \gamma} \mathcal{R}_{AB}.\end{aligned}\tag{3.31}$$

This gives the following RG equations for the coupling constants α , β and γ (with RG time $t = \log \mu$):

$$\begin{aligned}\frac{d\alpha}{dt} &= -\frac{c_G}{2} \frac{k^2 - \alpha^2}{(\alpha - \gamma)^2}, \\ \frac{d\beta}{dt} &= c_G \frac{\beta}{\alpha - \gamma}, \\ \frac{d\gamma}{dt} &= -\frac{c_G}{2} \left(1 - \frac{\alpha^2 + \beta^2}{(\gamma - \alpha)^2} \right) - 2 \left(\frac{\gamma k^2 + \alpha \beta^2}{\alpha(\gamma - \alpha)^2} + \frac{\gamma}{(\gamma - \alpha)} \right).\end{aligned}\tag{3.32}$$

We will analyse the RG behaviour in some detail below. However one already notices a remarkable fact. Besides the standard WZW fixed point ($\alpha = |k|$, $\beta = \gamma = 0$), a second fixed point seems to emerge at $\alpha = |k|$, $\beta = 0$ and $\gamma = 2c_G|k|/(c_G + 4)$ iff. $c_G \neq 4$ or thus $G \neq \text{SU}(2)$. We call this point FP2. When $G = \text{SU}(2)$ the RG equations blow up on the FP2 values (since then $\alpha = \gamma$) and the second fixed point is removed. Furthermore, for $\text{SU}(2)$ one sees that the terms involving β cancel in the flow equation for $\dot{\gamma}$ and the general RG equations of the remaining α and γ will coincide with the corresponding RG equations when restricted to the integrable locus (see above).

The RG behaviour when not restricted to the integrable locus. To illustrate the existence of the second fixed point FP2, we consider the RG flow for the case of the group $G = \text{SU}(3)$, setting $k = 4$. We plot the flow in two slices of the three-dimensional coupling space (α, β, γ) in order to visualise various directions around the fixed points. Figure 2a shows the flow of α vs. γ in the $\beta = 0$ slice and figure 2b the flow of γ vs. β in the $\alpha = 4$ slice.

From the above figures 2a and 2b, we see qualitatively that the WZW fixed point exhibits three independent irrelevant directions and the FP2 fixed point one irrelevant and two relevant independent directions. This can be made precise by again analysing the linearised flows in the neighbourhood of the fixed points. In a more compact notation, denoting $\xi_i = \{\alpha, \beta, \gamma\}$ with $i \in \{1, 2, 3\}$, the linearised flow can be written as,

$$\frac{\partial \xi_i}{\partial \log \mu} = A_{ij} \delta \xi_j + \mathcal{O}(\delta \xi_i^2).\tag{3.33}$$

In the neighbourhood of the WZW point we find,

$$A_{ij}^{\text{WZW}} = \frac{c_G}{|k|} \delta_{ij},\tag{3.34}$$

Figure 2. The RG evolution of (α, β, γ) for $G = \text{SU}(3)$ and $k = 4$. The arrows point towards the IR. The red line $\alpha = \gamma$ depicts the points where the one-loop result blows up. The black dots represent the RG fixed points WZW and FP2. We see that FP2 exhibits two relevant (orange lines) and one irrelevant (black line) direction. The WZW is a true IR fixed point with only irrelevant directions.

which gives indeed three independent irrelevant directions (they have positive eigenvalues). On the other hand, in the neighbourhood of the second fixed point we find,

$$A_{ij}^{FP2} = \frac{c_G(c_G + 4)}{|k|(c_G - 4)} \begin{pmatrix} \frac{c_G+4}{c_G-4} & 0 & 0 \\ 0 & -1 & 0 \\ \frac{2(c_G+4)}{c_G-4} & 0 & -\frac{c_G+4}{c_G-4} \end{pmatrix}, \quad (3.35)$$

for which the eigenvalues read:

$$\left\{ \frac{c_G(c_G + 4)^2}{|k|(c_G - 4)^2}, -\frac{c_G(c_G + 4)}{|k|(c_G - 4)}, -\frac{c_G(c_G + 4)^2}{|k|(c_G - 4)^2} \right\}. \quad (3.36)$$

Thus, from the second fixed point indeed two relevant and one irrelevant independent directions emerge.

At the two fixed points the Ricci curvature R (D.12) evaluates to,

$$R_{\text{WZW}} = \frac{c_G D}{4|k|},$$

$$R_{\text{FP2}} = -\frac{c_G}{4(c_G - 4)^2} \left((c_G^2 - 16) D + 2c_G(c_G + 4) l \right) \frac{1}{|k|},$$

with D the dimension and l the rank of G such that the target spaces are weakly curved for large enough k and for which the one-loop result is trustworthy. Whilst there is no reason to believe that the location of FP2 (i.e. the value of γ at the fixed point) is one-loop exact, it seems likely that its existence is robust to loop corrections. It is then conceivable that

FP2 may define a CFT. This being the case, from the general dilaton β -function eq. (3.12) we can read off the effective central charge c_{eff} of FP2 at one-loop to find,

$$c_{\text{eff}} = D + \frac{c_G(c_G + 4) \left((16 + (c_G - 16)c_G)D + 6c_G^2 l \right)}{2|k|(c_G - 4)^3}. \quad (3.37)$$

Before further discussing this possibility let us explore other aspects of the RG flow.

At first sight, and consistent with $c_{UV} > c_{IR}$, is that FP2 defines a UV fixed point from which in the deep IR one arrives at the WZW theory. However, care has to be taken when traveling over the line $\alpha = \gamma$, displayed in red in the figures. In the vicinity of this line the one-loop approximation is evidently not trustworthy; the target space curvatures blow up for small values of $|\gamma - \alpha|$ as is clear from the curvature R eq. (D.12) and indeed the metric G_{AB} (3.3) becomes degenerate. In light of the apparent singularity of the one-loop flow equations where $\gamma - \alpha$ appears in denominators, it is then quite surprising that numerically a global picture emerges with flows that transgress the red line. We are then led to ask if such an RG trajectory can cross the $\alpha = \gamma$ line in a finite RG time. To show that this is possible we concentrate on the slice of $\alpha = |k|$ illustrated in figure 2b and for further simplicity consider going backwards along the orange direction $\beta = 0$ starting near to the WZW point. Along this trajectory we can calculate the RG time Δt , with $t = \log \mu$, by evaluating,

$$\Delta t = \int_{\gamma=\gamma_i}^{\gamma=\gamma_f} \frac{dt}{d\gamma} d\gamma. \quad (3.38)$$

One can show that there is no pathology associated with $\gamma = \alpha = |k|$ in this quantity. Given this, one is encouraged to take seriously the quantity $\tilde{\beta}^\Phi$ defined in eq. (3.12) as a would-be c-function for the flow connecting FP2 and WZW. For simplicity we again consider this quantity along the orange direction $\beta = 0, \alpha = |k|$ in figure 2b and plot the result in figure 3. What we see is that $\tilde{\beta}^\Phi$ is sensitive, unsurprisingly, to the singularity at $\gamma = k$. Whilst $\tilde{\beta}^\Phi|_{UV} > \tilde{\beta}^\Phi|_{IR}$ and its derivative is strictly positive, it is not a positive definite quantity and diverges at $\gamma = k$. Of course one should not read too much into this; the singularity is just symptomatic of the breakdown of the perturbative approximation. One could still expect that a correct strictly positive monotonic function exists and it agrees with this one-loop approximate result where the one-loop result is valid.

Combining the observation that the one-loop approximation is robust around the fixed points (for large k) and the unexpected global continuity of the numerical solutions in figures 2a and 2b leads us to tentatively suggest that there is indeed an RG flow between a new fixed point FP2 and an IR WZW model but that the sigma model description may not be the correct variables to reveal this.

There are several points that merit investigation:

- At FP2, $\det(G_{AB}) < 0$. This means that some currents occur in the action with a negative coefficient of their kinetic term. A conservative viewpoint would be to regard this as non-physical but this then begs the question what is the UV completion of the model? Let us instead take FP2 seriously. Should FP2 define a CFT, it is presumably non-unitary. In this case we would have an RG flow between a non-unitary UV theory and an unitary IR theory. Perhaps this suggestion is not

Figure 3. The Weyl anomaly coefficient $\tilde{\beta}^\Phi$ evaluated for $G = \text{SU}(3)$ and $k = 4$ along the orange RG trajectory $\beta = 0, \alpha = |k|$ shown in figures 2a and 2b that connects the UV FP2 to the WZW in the IR.

as outlandish as might first seem. By way of example we could consider RG flows in minimal models. It is well known [48, 49] that the $\phi_{(1,3)}$ deformation of the p^{th} minimal model $\mathcal{M}_{(p,p+1)}$ triggers an RG flow resulting in the $(p-1)^{\text{th}}$ minimal model IR.⁷ Less familiar perhaps are the RG flows involving non-unitary minimal models, i.e. $\mathcal{M}_{(p,q)}$ with p, q co-prime and $q \neq p+1$, whose study was initiated in [50–52]. More generally [53], chains of non-unitary minimal models can be connected by RG flows triggered by alternating deformations of $\phi_{(1,5)}$ and $\phi_{(2,1)}$ which then terminate in an unitary minimal model. One example from [53] is,⁸

$$\dots \mathcal{M}_{(5,12)} \xrightarrow{\phi_{(1,5)}} \mathcal{M}_{(5,8)} \xrightarrow{\phi_{(2,1)}} \mathcal{M}_{(3,8)} \xrightarrow{\phi_{(1,5)}} \mathcal{M}_{(3,4)}. \quad (3.39)$$

An other example in [53] terminates in a flow from the Yang-Lee edge singularity to the trivial $c = 0$ theory. Recently in [54] it was shown that it is possible to relax the requirement of unitary and still show the existence of a monotonic decreasing c -function along such flows. So the learning here is that it is not a manifest impossibility to conceive an RG flow between a non-unitary UV CFT and a unitary IR CFT.

- The fate of FP2 with regard to higher loop corrections needs to be established; does it persist?
- Is the postulated FP2 both scale *and* Weyl invariant?⁹
- What are the corresponding affine symmetries and the exact value of the central charge at FP2?
- What is the spectrum of primaries for this postulated CFT at FP2?

⁷More precisely this occurs when the deformation parameter is negative, when the deformation parameter is positive the flow results in a massive theory.

⁸Notice that this terminates in the unitary critical Ising model with $c = \frac{1}{2}$ and, just as with the flow between tri-critical Ising and critical Ising, the single massless Majorana fermion of the final IR theory can be interpreted as the goldstino for the spontaneous breaking of the supersymmetry present in $\mathcal{M}_{(3,8)}$.

⁹For instance in η -deformed $\text{PSU}(2, 2|4)$ current understanding is that only scale invariance holds [5].

These are evidently interesting challenges that we hope to return to in a future paper. For the present we continue with our principle concern; the YB-WZ model on the integrable locus.

4 Poisson-Lie T-duality of the YB-WZ model

Motivated by the Poisson-Lie symmetric structure of the η -deformation, one could wonder how the YB-WZ action (2.2) behaves under Poisson-Lie symmetry. Remarkably the YB-WZ model at the integrable locus features an example of the most simple realisation of PL. The Poisson-Lie duality transformation preserves the structure of the action, reshuffling the coupling constant in a surprisingly Buser-rule like manner. At the RG fixed point (the WZW) the action is self-dual. This section, being somewhat technical, can safely be omitted at a first reading and the reader can jump directly to the resulting “effective” transformation rules of the Poisson-Lie transformation of the YB-WZ model in equations (4.10).

When restricted to the integrable locus, the YB-WZ model admits a 1st order formulation as an \mathcal{E} -model [32]. We refer the reader to the original paper for full details of this construction but note here the essential ingredients of an \mathcal{E} -model, and its connection to sigma models, are:

- (i) An even dimensional real Lie-algebra \mathfrak{d}
- (ii) An ad-invariant inner product $(\cdot, \cdot)_{\mathfrak{d}} : \mathfrak{d} \otimes \mathfrak{d} \rightarrow \mathbb{R}$
- (iii) An idempotent involution \mathcal{E} that is self-adjoint with respect to the inner product
- (iv) A maximally isotropic subalgebra \mathfrak{h} (i.e. $(z_1, z_2)_{\mathfrak{d}} = 0 \forall z_{1,2} \in \mathfrak{h}$ and $\dim \mathfrak{h} = \frac{1}{2} \dim \mathfrak{d}$).

Given the data of (i)-(iii) one can construct a 1st order action known as the \mathcal{E} -model. Given further (iv) one can integrate out auxiliary fields from the \mathcal{E} -model to arrive at a non-linear sigma model. The field variables of this sigma model are sections (defined patchwise if needed) of the coset D/H (with D, H the groups corresponding to \mathfrak{d} and \mathfrak{h}). If a second maximally isotropic subalgebra $\tilde{\mathfrak{h}}$ can be found then the procedure can be repeated to yield a second non-linear sigma model on D/\tilde{H} — this is the Poisson-Lie dual.

For both the YB (η -theory) and the present case of interest, the YB-WZ theory, the relevant algebra is $\mathfrak{d} = \mathfrak{g}^{\mathbb{C}}$, viewed as a real Lie algebra with elements $z = x + iy$ with $x, y \in \mathfrak{g}$. The addition of the WZ term requires that the inner product be modified to [32],

$$(z_1, z_2)_{\mathfrak{d}} = C \text{Im} \langle e^{i\rho} z_1, z_2 \rangle, \tag{4.1}$$

where the parameters used in [32] translate to,

$$C = \frac{k^2 + \Theta^2}{8\pi\Theta}, \quad e^{i\rho} = -\frac{k + i\Theta}{k - i\Theta} = \frac{\gamma^-}{\gamma^+}, \tag{4.2}$$

which are both RG invariant and match the parameters determining the (affine tower) charge algebra in the case of $SU(2)$ established in [35], see also appendix B. The involution \mathcal{E} , whose precise definition will not be illuminating for us and can be found in eq. (3.8)

of [32], dresses up the swapping of real and imaginary parts of $z \in \mathfrak{g}^{\mathbb{C}}$ with parametric dependence on ρ and also on $e^p = -\frac{\alpha}{\mathfrak{O}}$. So unlike the innerproduct, \mathcal{E} is RG variant.

We have two maximal isotropics given by the embeddings of \mathfrak{g} :

$$\begin{aligned} \tilde{\mathfrak{h}}_{\rho} &= \left(\mathcal{R} - \tan \frac{\rho}{2} (\mathcal{R}^2 + 1) - i \right) \mathfrak{g}, \\ \tilde{\tilde{\mathfrak{h}}}_{\rho} &= \left(\mathcal{R} - \cot \frac{\rho}{2} (\mathcal{R}^2 + 1) + i \right) \mathfrak{g}. \end{aligned} \tag{4.3}$$

That these are subalgebras follows immediately since \mathcal{R} satisfies the mCYBE and $\mathcal{R}^2 + 1$ projects into the Cartan. That they are isotropic with respect to (4.1) fixes the trigonometric functions. Since $\mathfrak{h}_{\rho} = e^{i\rho} \mathfrak{a} + \mathfrak{n}$ where \mathfrak{a} and \mathfrak{n} are the corresponding algebras in the Iwasawa decomposition $D = KAN$, we can think of \mathfrak{h}_{ρ} as a twisted upper triangular subalgebra and the other, $\tilde{\tilde{\mathfrak{h}}}_{\rho}$, as lower triangular. Locally at least we can decompose,

$$D = H_{\rho} \cdot \tilde{H}_{\rho} = \tilde{H}_{\rho} \cdot H_{\rho}, \tag{4.4}$$

and because the standard Iwasawa decomposition can be modified to incorporate the twisting by ρ as in [32] we can identify $D \equiv G^{\mathbb{C}} = G \cdot \tilde{H}_{\rho} = G \cdot H_{\rho}$. Thus the cosets D/H_{ρ} and D/\tilde{H}_{ρ} can be identified with G and so $g \in G$ can serve as field variables on either of the two dual models. To extract the sigma models one needs to specify projectors \mathcal{P} and $\tilde{\mathcal{P}}$ such that,¹⁰

$$\text{Im}\mathcal{P} = \mathfrak{h}_{\rho}, \quad \text{Ker}\mathcal{P} = (1 + \mathcal{E})\mathfrak{d}, \quad \text{Im}\tilde{\mathcal{P}} = \tilde{\tilde{\mathfrak{h}}}_{\rho}, \quad \text{Ker}\tilde{\mathcal{P}} = (1 + \mathcal{E})\mathfrak{d}. \tag{4.5}$$

Explicitly if we let (making use of the definition of \mathcal{E} in eqs. (3.7,3.8) of [32]),

$$w = e^{-i\rho} + i \cosh(p) + i e^{-i\rho} \sinh(p) = w_1 + i w_2, \quad x = \frac{w_1}{w_2}, \tag{4.6}$$

and define,

$$\mathcal{O} = \mathcal{R} - \tan \frac{\rho}{2} (\mathcal{R}^2 + 1), \quad \tilde{\mathcal{O}} = \mathcal{R} - \cot \frac{\rho}{2} (\mathcal{R}^2 + 1), \tag{4.7}$$

then,

$$\mathcal{P}(g^{-1}dg) = (\mathcal{O} - i)(\mathcal{O} + x)^{-1} g^{-1}dg, \quad \tilde{\mathcal{P}}(g^{-1}dg) = (\tilde{\mathcal{O}} + i)(\tilde{\mathcal{O}} - x)^{-1} g^{-1}dg. \tag{4.8}$$

Equipped with all of this we can now simply specify the non-linear sigma models obtained after integrating out the auxiliary fields from the \mathcal{E} models. They read,

$$\begin{aligned} S &= S_{WZW,k}^{\mathfrak{d}}[g] + \frac{k}{\pi} \int d\sigma d\tau \left(\mathcal{P}(g^{-1}\partial_+g), g^{-1}\partial_-g \right)_{\mathfrak{d}}, \\ \tilde{S} &= S_{WZW,k}^{\mathfrak{d}}[g] + \frac{k}{\pi} \int d\sigma d\tau \left(\tilde{\mathcal{P}}(g^{-1}\partial_+g), g^{-1}\partial_-g \right)_{\mathfrak{d}}, \end{aligned} \tag{4.9}$$

where we emphasise that the deformed inner product on $\mathfrak{g}^{\mathbb{C}}$ of eq. (4.1) is used to define the WZW models and that the term depending on the projectors has coefficient -2 times

¹⁰There is a slight simplification here of the general formulas of [32] since $g \in G$ the adjoint action ad_g commutes in this case with the idempotent \mathcal{E} .

that of the kinetic term of the WZW model. Using $\mathcal{R}^3 = -\mathcal{R}$ it was established in [32] that the first of these actions matches the general model in eq. (2.2) with parameters α , β and γ obeying the integrable locus relation. What of the Poisson-Lie dual theory? After some tedious trigonometry and using the relations eq. (4.2) together with the definition of the inner product eq. (4.1) one finds the action \tilde{S} is also of the form of eq. (2.2) but the T-duality acts on the parameters as,

$$\begin{aligned} \alpha &\rightarrow \tilde{\alpha} = \frac{k^2}{\alpha}, \\ \beta &\rightarrow \tilde{\beta} = -\beta, \\ \gamma &\rightarrow \tilde{\gamma} = \frac{k^2 + \alpha\gamma - \alpha^2}{\alpha} = -\frac{\beta^2}{\gamma}. \end{aligned} \tag{4.10}$$

This is a truly elegant result; recall that $\frac{1}{k}$ plays the role of α' so that these Poisson-Lie T-duality rules really do resemble the radial inversion of abelian T-duality. Being canonically equivalent it must be the case that the T-dual model is also integrable, and indeed one sees that $\tilde{\alpha}, \tilde{\beta}, \tilde{\gamma}$ also sit on the integrable locus; this serves as a check of the T-duality rules.

We can see that the WZW point is rather special; it is the self-dual point of the duality transformation.¹¹ As remarked earlier in the RG portrait figure 1 there are two regions that corresponding to a real action, shaded in green and for which $\Theta^2 > 0$. The Poisson-Lie duality action simply maps the region for $\alpha < k$ one-to-one with that of $\alpha > k$; these two regions of course touch at the self-dual WZW fixed point.

The action of this T-duality on the charge algebra is also of note. It follows immediately that the RG invariant combination is transformed as,

$$\Theta \rightarrow \tilde{\Theta} = \frac{k^2}{\Theta}. \tag{4.11}$$

Then we see that the quantum group parameter $q = \exp\left[\frac{8\pi\Theta}{k^2+\Theta^2}\right]$ is invariant under T-duality. However recall that the affine tower of charges (at least in the $\mathfrak{su}(2)$ where it has been established explicitly) differs from the standard affine quantum group by a multiplicative factor between gradations of $-\frac{k+i\Theta}{k-i\Theta}$. This factor undergoes an S-transformation, i.e it is mapped to negative its inverse. This illustrates that whilst the T-duality rules look quite trivial, at the level of charges the canonical transformation that maps the two T-dual theories can have quite an involved action.

5 The supersymmetric YB-WZ model

This section falls a bit outside the main line of the paper but is motivated by the following observation. It is clear from the previous discussion that starting from a generic $d = 2$ non-linear σ -model and requiring (classical) integrability, imposes severe restrictions on the target manifold and its metric and torsion 3-form. However another way to restrict the allowed background geometries is by requiring the existence of extended worldsheet supersymmetries. Indeed asking that the non-linear σ -model exhibits $N > (1, 1)$ supersymmetry

¹¹Self-duality under PL of WZW models (with no deformations) was exhibited already in [55].

introduces additional geometric structure which only exists for particular background geometries. A hitherto unexplored terrain is the eventual relationship between integrable models on the one hand and extended supersymmetry on the other (however see [56] for some early work in this direction).

In this section we explore the possibility of having $N > (1, 1)$ supersymmetry in the YB-WZ models studied in this paper. This is an interesting point in itself because if one thinks about the potential use of these integrable models as backgrounds for type II superstrings in the NS worldsheet formulation then the existence of an $N = (2, 2)$ supersymmetric extension is necessary as well. As we will see, the integrable deformations of the WZW-model studied in this paper do generically not allow for an extended supersymmetry.

Given is a non-linear sigma model with target manifold \mathcal{M} endowed with a metric G and a closed 3-form H (the torsion). Locally we write $H = dB$. Passing to an $N = (1, 1)$ supersymmetric extension of the model does not require any further geometric structure. Indeed the action for the $N = (1, 1)$ supersymmetric non-linear sigma model written in $N = (1, 1)$ superspace is remarkably similar to the non-supersymmetric one,¹²

$$\mathcal{S} = \int d^2\sigma d^2\theta D_+ X^\mu (G_{\mu\nu} + B_{\mu\nu}) D_- X^\nu, \tag{5.1}$$

where X^μ are some local coordinates on the target manifold.

However asking for more supersymmetry does introduce additional geometrical structure. E.g. $N = (2, 2)$ supersymmetry requires the existence of two complex structures \mathcal{J}_+ and \mathcal{J}_- which are endomorphisms of the tangent space $T\mathcal{M}$ and which are such that $(\mathcal{M}, G, H, \mathcal{J}_\pm)$ is a bihermitian structure [57, 58], i.e. \mathcal{M} is even-dimensional and the complex structures \mathcal{J}_\pm satisfy,

1. $\mathcal{J}_\pm^2 = -\mathbf{1}$,
2. $[X, Y] + \mathcal{J}_\pm [\mathcal{J}_\pm X, Y] + \mathcal{J}_\pm [X, \mathcal{J}_\pm Y] - [\mathcal{J}_\pm X, \mathcal{J}_\pm Y] = 0$ for all $X, Y \in T\mathcal{M}$, which is the integrability condition for the complex structures,
3. $G(\mathcal{J}_\pm X, Y) = -G(X, \mathcal{J}_\pm Y)$ for all $X, Y \in T\mathcal{M}$, so G is a hermitian metric with respect to both complex structures,
4. $\nabla^{(+)} \mathcal{J}_+ = \nabla^{(-)} \mathcal{J}_- = 0$ with $\nabla^{(\pm)}$ covariant derivatives which use the Bismut connections:

$$\Gamma^{(\pm)} = \{ \} \pm \frac{1}{2} G^{-1} H, \tag{5.2}$$

such that in a local coordinate bases,

$$\nabla_\rho \mathcal{J}_{\pm\nu}^\mu = \pm \frac{1}{2} \left(G^{\kappa\lambda} H_{\lambda\rho\nu} \mathcal{J}_{\pm\kappa}^\mu - G^{\mu\lambda} H_{\lambda\rho\kappa} \mathcal{J}_{\pm\nu}^\kappa \right), \tag{5.3}$$

where the covariant derivative ∇ in the above is taken with the Christoffel symbol as connection. This condition is equivalent to the requirement that the exterior derivative of the two-forms $\omega_\pm(X, Y) = -G(X, \mathcal{J}_\pm Y)$ are given by:

$$d\omega_\pm(X, Y, Z) = \mp H(\mathcal{J}_\pm X, \mathcal{J}_\pm Y, \mathcal{J}_\pm Z). \tag{5.4}$$

¹²A brief summary of our superspace conventions can be found in appendix A.

Using the covariant constancy of the complex structure one can rewrite the integrability condition (condition 2) as,

$$H(X, \mathcal{J}_\pm Y, \mathcal{J}_\pm Z) + H(Y, \mathcal{J}_\pm Z, \mathcal{J}_\pm X) + H(Z, \mathcal{J}_\pm X, \mathcal{J}_\pm Y) = H(X, Y, Z). \quad (5.5)$$

Note that demanding $N = (2, 0)$ or $N = (2, 1)$ instead of $N = (2, 2)$ supersymmetry only requires the existence of \mathcal{J}_+ satisfying the above conditions.

We now rewrite these conditions for the deformed models studied in this paper. Since at the level of the action the deformation preserves the left acting G symmetry while it breaks the right acting G symmetry (to its Cartan subgroup), the geometry and the $\mathcal{N} = (2, 2)$ conditions are most naturally presented in the basis of left-invariant one-forms u^A . Given the deformed metric G_{AB} eq. (3.3) and the torsion H_{ABC} eq. (3.4), we find that the above conditions for $\mathcal{N} = (2, 2)$ supersymmetry translate in this basis to the following:

1. The first condition is simply,

$$\mathcal{J}_\pm^A{}_C \mathcal{J}_\pm^C{}_B = -\delta_B^A. \quad (5.6)$$

2. The second condition (using the form in eq. (5.5)) results in:

$$3\mathcal{J}_\pm^D{}_{[A} \mathcal{J}_\pm^E{}_B H_{C]DE} = H_{ABC}, \quad (5.7)$$

where H_{ABC} is given in eq. (3.4).

3. The third condition yields, $G_{AB} = \mathcal{J}_\pm^C{}_A \mathcal{J}_\pm^D{}_B G_{CD}$ or using eq. (3.3):

$$\mathcal{J}_\pm^C{}_A \kappa_{CB} = -\mathcal{J}_\pm^C{}_B \kappa_{CA} - \frac{\gamma}{\alpha} (\mathcal{J}_\pm^C{}_B \mathcal{R}_{CA}^2 + \mathcal{J}_\pm^C{}_A \mathcal{R}_{CB}^2). \quad (5.8)$$

4. After a little bit of work, the covariant constancy of the complex structures (the fourth condition), translates to,

$$u_C{}^\mu \partial_\mu \mathcal{J}_\pm^A{}_B = \mathcal{J}_\pm^A{}_D M_\pm^D{}_{CB} - M_\pm^A{}_{CD} \mathcal{J}_\pm^D{}_B, \quad (5.9)$$

where,

$$M_\pm^A{}_{BC} = \Gamma_{BC}^A \pm \frac{1}{2} G^{AD} H_{DBC}, \quad (5.10)$$

and where the spin connection Γ_{BC}^A is given by eq. (D.7). Eq. (5.9) implies an integrability condition,

$$\mathcal{J}_\pm^A{}_E R_\pm^E{}_{BCD} = R_\pm^A{}_{ECD} \mathcal{J}_\pm^E{}_B, \quad (5.11)$$

where the curvature tensors R_\pm are given by,

$$R_\pm^A{}_{BCD} = M_\pm^E{}_{DB} M_\pm^A{}_{CE} - M_\pm^E{}_{CB} M_\pm^A{}_{DE} - F_{CD}{}^E M_\pm^A{}_{EB}. \quad (5.12)$$

The integrability condition eq. (5.11) is the requirement that the complex structures commute with the generators of the holonomy group defined by the connections in eq. (5.10).

While the first three conditions are given by algebraic equations eqs. (5.6)–(5.7), which can be analyzed in a way similar to what was done in [59, 60], the last one, eq. (5.9), is involved. However, the integrability conditions for the latter are algebraic again and can be explicitly analyzed.

In [59, 60] these conditions were analyzed for the undeformed case, $\alpha = |k|$, $\beta = \gamma = 0$, *i.e.* the standard WZW model and it was found that on any even-dimensional group manifolds there exist solutions to the above equations. Let us briefly review those results. In the undeformed case the connections in eq. (5.10) are simply,

$$M_{+BC}^A = 0, \quad M_{-BC}^A = F_{BC}^A. \quad (5.13)$$

With this one verifies that the curvature tensors in eq. (5.12) vanish (reflecting the fact group manifolds are parallelizable), either trivially or by virtue of the Jacobi identities, and as a consequence the integrability conditions, eq. (5.11), are automatically satisfied. Turning then to eq. (5.9) one finds that \mathcal{J}_{+B}^A is constant while \mathcal{J}_{-B}^A satisfies,

$$u_C^\mu \partial_\mu \mathcal{J}_{-B}^A = \mathcal{J}_{-D}^A F_{CB}^D - F_{CD}^A \mathcal{J}_{-B}^D. \quad (5.14)$$

In order to analyze the latter one introduces a group element in the adjoint representation,

$$S^A{}_B = v_\mu^A u_B^\mu, \quad (5.15)$$

which can easily be shown to satisfy,

$$u_C^\mu \partial_\mu S^A{}_B = F_{CB}^D S^A{}_D. \quad (5.16)$$

Using this and eq. (5.14) one shows that $S^A{}_C \mathcal{J}_{-D}^C (S^{-1})^D{}_B$ (which is \mathcal{J}_- in the right invariant frame) is constant as well. In this way the remaining conditions for $N = (2, 2)$ supersymmetry, eq. (5.6)–(5.8), all reduce to algebraic equations on the Lie algebra which were solved in [59, 60]. The result is remarkably simple: any complex structure pulled back to the Lie algebra is almost completely equivalent to a choice for a Cartan decomposition. Indeed the complex structure acts diagonally on generators corresponding to positive (negative roots) with eigenvalue $+i$ ($-i$). It maps the CSA to itself so that it squares to minus one and so that the Cartan-Killing metric restricted to the CSA is hermitian.

In the deformed case the integrability conditions eq. (5.11) become non-trivial and need to be investigated first. While in principle this can be done for general groups (resulting in not particularly illuminating complex expressions) we limit ourselves in this paper to a detailed analysis of the simplest case: $SU(2) \times U(1)$. A more systematic analysis of the relation extended supersymmetry and integrability in general is currently underway and will be reported on elsewhere.

For $SU(2) \times U(1)$ the β deformation is a total derivative and can be ignored in the present analysis. We choose a basis for the Lie algebra where $t_0 = (\sigma_3 + i\sigma_0)/2$, $t_{\bar{0}} = (\sigma_3 - i\sigma_0)/2$, $t_1 = (\sigma_1 + i\sigma_2)/2$ and $t_{\bar{1}} = (\sigma_1 - i\sigma_2)/2$. In this basis the non-vanishing components of the Cartan-Killing metric are given by $\kappa_{0\bar{0}} = \kappa_{1\bar{1}} = 1$ and those of \mathcal{R} by $\mathcal{R}^1{}_1 = -\mathcal{R}^{\bar{1}}{}_{\bar{1}} = i$. The non-vanishing components of the deformed metric in the left invariant frame, eq. (3.3),

are $G_{0\bar{0}} = \alpha$ and $G_{1\bar{1}} = \alpha - \gamma$. For the torsion, eq. (3.4), we get $H_{01\bar{1}} = H_{\bar{0}1\bar{1}} = ik$. The hermiticity condition eq. (5.8) and the integrability condition eq. (5.11) are both linear in the complex structures and as a consequence are easily analyzed. The hermiticity condition eliminates 10 of the 16 components of each complex structure. A straightforward but somewhat tedious calculation shows the following result for the integrability condition:

1. It is identically satisfied without any further conditions if $\alpha = |k|$ and $\gamma = 0$. This is just the undeformed $SU(2) \times U(1)$ WZW model known to be $N = (2, 2)$ supersymmetric (in fact it is even $N = (4, 4)$ supersymmetric).
2. It is satisfied if $\alpha = |k|$ and only $\mathcal{J}_{\pm 0}^0 = -\mathcal{J}_{\pm 0}^{\bar{0}}$ and $\mathcal{J}_{\pm 1}^1 = -\mathcal{J}_{\pm 1}^{\bar{1}}$ are non-vanishing.
3. Otherwise, for generic values of α, γ and k it has *no* solutions.

So we can conclude that in general the deformed $SU(2) \times U(1)$ YB-WZ model does not allow for an $N = (2, 2)$ supersymmetric extension. Remains of course case 2 in the above.

From now on we take $\alpha = |k|$. Checking eq. (5.14) one finds that only a vanishing \mathcal{J}_- is consistent with eqs. (5.6) and (5.7) while \mathcal{J}_+ is constant and its non-vanishing components are given by e.g. $\mathcal{J}_{+0}^0 = -\mathcal{J}_{+0}^{\bar{0}} = \mathcal{J}_{+1}^1 = -\mathcal{J}_{+1}^{\bar{1}} = i$. This choice for \mathcal{J}_+ also satisfies eqs. (5.6) and (5.7). So we conclude that the model is indeed $N = (2, 1)$ or $N = (2, 0)$ supersymmetric but does not allow for $N = (2, 2)$ supersymmetry.

To end this section we formulate this model in $N = (2, 1)$ superspace thereby making the $N = (2, 1)$ supersymmetry explicit. In general one starts with a set of $N = (2, 1)$ superfields z^α and $z^{\bar{\alpha}}$ satisfying the constraints $\hat{D}_+ z^\alpha = +i D_+ z^\alpha$ and $\hat{D}_+ z^{\bar{\alpha}} = -i D_+ z^{\bar{\alpha}}$ which are a consequence of the fact that the non-vanishing components of the complex structure \mathcal{J}_+ are $\mathcal{J}_{+\beta}^\alpha = +i \delta_\beta^\alpha$ and $\mathcal{J}_{+\bar{\beta}}^{\bar{\alpha}} = -i \delta_{\bar{\beta}}^{\bar{\alpha}}$. The action is expressed in terms of a vector on the target manifold ($iV_\alpha, -iV_{\bar{\alpha}}$),

$$\mathcal{S} = \frac{1}{2} \int d^2\sigma d^2\theta d\hat{\theta}^+ \left(iV_\alpha D_- z^\alpha - iV_{\bar{\alpha}} D_- z^{\bar{\alpha}} \right). \quad (5.17)$$

Passing to $N = (1, 1)$ superspace,

$$\begin{aligned} \mathcal{S} = \int d^2\sigma d^2\theta & \left(G_{\alpha\bar{\beta}} (D_+ z^\alpha D_- z^{\bar{\beta}} + D_+ z^{\bar{\beta}} D_- z^\alpha) + \right. \\ & \left. + B_{\alpha\bar{\beta}} (D_+ z^\alpha D_- z^{\bar{\beta}} - D_+ z^{\bar{\beta}} D_- z^\alpha) \right), \end{aligned} \quad (5.18)$$

one identifies the metric,

$$G_{\alpha\bar{\beta}} = G_{\bar{\beta}\alpha} = \frac{1}{2} \left(\partial_\alpha V_{\bar{\beta}} + \partial_{\bar{\beta}} V_\alpha \right), \quad (5.19)$$

and the Kalb-Ramond 2-form,

$$B_{\alpha\bar{\beta}} = -B_{\bar{\beta}\alpha} = \frac{1}{2} \left(\partial_\alpha V_{\bar{\beta}} - \partial_{\bar{\beta}} V_\alpha \right). \quad (5.20)$$

Now let us apply this to the deformed $SU(2) \times U(1)$ model where $\alpha = |k|$. The group element $g \in SU(2) \times U(1)$ is parameterized in a standard way by,

$$g = e^{\frac{i}{2}\rho} \begin{pmatrix} e^{\frac{i}{2}(\varphi_1 + \varphi_2)} \cos \frac{\psi}{2} & e^{\frac{i}{2}(\varphi_1 - \varphi_2)} \sin \frac{\psi}{2} \\ -e^{-\frac{i}{2}(\varphi_1 - \varphi_2)} \sin \frac{\psi}{2} & e^{-\frac{i}{2}(\varphi_1 + \varphi_2)} \cos \frac{\psi}{2} \end{pmatrix}, \quad (5.21)$$

where,

$$0 \leq \psi \leq \pi, \quad \varphi_1 \in \mathbb{R} \bmod 2\pi, \quad \varphi_2, \rho \in \mathbb{R} \bmod 4\pi. \quad (5.22)$$

We introduce complex coordinates $z^\alpha = (z, w)$ and $\bar{z}^{\bar{\alpha}} = (\bar{z}, \bar{w})$ with $\alpha, \bar{\alpha} = \{1, 2\}$ such that \mathcal{J}_+ acts as $+i$ on dz and dw . The complex structure in this case is exactly the same as the one studied originally in [61, 62] (for a more detailed treatment see [63, 64]), so we can use the results obtained there to write the group element in terms of the complex coordinates as,

$$g = (z\bar{z} + w\bar{w})^{-\frac{1}{2}(1+i)} \begin{pmatrix} \bar{w} & z \\ -\bar{z} & w \end{pmatrix}, \quad (5.23)$$

where the complex coordinates are related to the original coordinates as,

$$z = e^{-\frac{1}{2}\rho} e^{\frac{i}{2}(\varphi_1 - \varphi_2)} \sin \frac{\psi}{2}, \quad w = e^{-\frac{1}{2}\rho} e^{-\frac{i}{2}(\varphi_1 + \varphi_2)} \cos \frac{\psi}{2}. \quad (5.24)$$

Note that in the undeformed case, which allows for $N = (2, 2)$ supersymmetry, z and w are the chiral and the twisted chiral $N = (2, 2)$ superfield resp. [61, 62]. In the undeformed case we can readily derive the $N = (2, 1)$ vector V_z and V_w appearing in the action eq. (5.17) as it directly descends from the generalized $N = (2, 2)$ Kähler potential K obtained in [61, 62],

$$K(z, \bar{z}, w, \bar{w}) = -k \left(\frac{1}{2} (\ln w\bar{w})^2 + Li_2 \left(-\frac{z\bar{z}}{w\bar{w}} \right) \right), \quad (5.25)$$

from which we get,

$$\begin{aligned} V_z^0 &= +\partial_z K = \frac{k}{z} \ln \left(1 + \frac{z\bar{z}}{w\bar{w}} \right), \\ V_w^0 &= -\partial_w K = \frac{k}{w} \ln(z\bar{z} + w\bar{w}), \end{aligned} \quad (5.26)$$

where the upper index 0 on V points to the fact that we are dealing with the undeformed case $\alpha = |k|$ and $\gamma = 0$.

In order to extend this to the deformed case, i.e. $\gamma \neq 0$, we first rewrite the deformed geometry in terms of complex coordinates,

$$\begin{aligned} ds^2 &= \frac{k}{z\bar{z} + w\bar{w}} (dz d\bar{z} + dw d\bar{w}) - \frac{\gamma}{(z\bar{z} + w\bar{w})^2} (w dz - z dw) (\bar{w} d\bar{z} - \bar{z} d\bar{w}), \\ H &= \frac{k}{(z\bar{z} + w\bar{w})^2} (dz \wedge d\bar{z} \wedge (\bar{w} dw - w d\bar{w}) + dw \wedge d\bar{w} \wedge (\bar{z} dz - z d\bar{z})), \end{aligned} \quad (5.27)$$

where we put $\alpha = k$. From the expression for the torsion one gets the Kalb-Ramond 2-form as well,

$$B = \frac{k}{z\bar{z} + w\bar{w}} \left(\frac{\bar{z}}{\bar{w}} dz \wedge d\bar{w} - \frac{z}{w} dw \wedge d\bar{z} \right). \quad (5.28)$$

From this we obtain V_z and V_w ,

$$V_z = V_z^0 + \frac{\gamma}{z} \frac{w\bar{w}}{z\bar{z} + w\bar{w}}, \quad V_w = V_w^0 + \frac{\gamma}{w} \frac{z\bar{z}}{z\bar{z} + w\bar{w}}, \quad (5.29)$$

where V_z^0 and V_w^0 were given in eq. (5.26). Using eqs. (5.19) and (5.20) one verifies that eq. (5.29) indeed reproduces eq. (5.27) and (5.28). Combining eq. (5.29) with eq. (5.17) gives the action of the deformed theory explicitly in $N = (2, 1)$ superspace.

Concluding: as the generic $SU(2) \times U(1)$ YB-WZ model does not allow for $N = (2, 2)$ supersymmetry, it looks highly improbable that deformed models for other groups would allow for $N = (2, 2)$ supersymmetry. Even when only requiring $N = (2, 0)$ or $N = (2, 1)$ supersymmetry, one finds that this is only possible for specific values of the deformation parameters. However, it is important to note that the above derivation is based on the canonical form of the \mathcal{R} -matrix. There is still an $GL(2, \mathbb{C})$ freedom on the CSA directions of \mathcal{R} which, together with the possibility of going beyond a single Yang-Baxter to a bi-Yang-Baxter deformation, could still reveal extended supersymmetry (but since these geometries are more complicated it would seem unlikely that they are more amenable to supersymmetries).

6 Summary, conclusions and outlook

In this paper we investigated various properties of the Yang-Baxter deformation of the Principal Chiral model with a Wess-Zumino term introduced in [26].

As the undeformed model, the WZW model, exhibits rather unique features at the quantum level, we made a one-loop renormalisation group analysis of this class of models. For general groups and for generic values of the deformation parameters, the RG flow drives the theory outside the classical sigma model ansatz given in eq. (3.3) and (3.4). However, when the classical integrability condition is invoked, the renormalisation does remain within the sigma model ansatz and moreover the integrability condition is preserved along the RG flow. The fact that a very quantum property — the RG equations — are sensitive to the consideration of classical integrability is rather suggestive. It is therefore natural to conjecture that these models are quantum mechanically integrable. However, the non-ultralocal property of such theories precludes a direct application of the Quantum Inverse Scattering method. It would be very interesting to examine how the alleviation approach, used in the context of the related λ -models [65], might be applied here in order to unravel the quantum S-matrix.

Another interesting aspect is that the WZW model is the IR fixed point; in comparison the integrable λ -deformed WZW has the CFT situated as an UV fixed point. This model then seems closer in spirit to the irrelevant double trace integrable deformations of 2d CFTs constructed recently in [66]. Recently λ type deformations have been studied in the context of $G_k \times G_l / G_{k+l}$ coset theories [67]; curiously there the CFT is recovered as an IR fixed point in the same way as we have here.

An unanticipated feature of this class of models is that when restricting to simply laced groups but staying outside of the integrable locus, we found a second fixed point of the one-loop β -functions which is UV with respect to the IR WZW model. Around this fixed point, the curvatures of the target space geometry are small leading us to anticipate that the existence of this fixed point is robust to higher loops. However, at this fixed point a number of the currents have wrong sign kinetic terms. A conservative view would be to discard this as non-physical but this then begs the question of the UV completion

of the deformation we are considering. Tentatively we might suppose that the fixed point corresponds to a non-unitary CFT and that we have an exotic RG flow from this in the UV to the WZW in the IR. Comparable flows have been discovered in the context of minimal models. Needless to say it would be interesting to examine this more robustly. A technique that might help here could be to rephrase the entire discussion of these theories in terms of the free field representations of WZW models.

An obvious exercise which remains to be done is an RG analysis of the integrable models introduced in [27] that incorporate both bi-Yang-Baxter deformations and TST transformations. We expect this to be significantly more involved than the analysis performed in the current paper as the deformations in [27] destroy both the left and right acting group symmetry rendering the choice of a good basis to calculate the β -functions non-trivial.

An appealing feature of the landscape of η , Yang-Baxter and λ deformations is that they provide tractable examples of sigma models that are Poisson-Lie T-dualisable. The theories considered here also share this feature; in fact the Poisson-Lie duality (which normally results in quite convoluted geometries) has a remarkably simple form. It results in a set of “Buscher rules” that resemble Abelian T-duality in that coupling constants are simply inverted. We see quite explicitly the compability of Poisson-Lie duality and RG flow and in particular we find that the self-dual point of the duality and the fixed point of RG are coincident. At this self-dual point the symmetries are enhanced and the theory becomes the WZW CFT. With the understanding that the Heisenberg anti-ferromagnetic $XXX_{\frac{k}{2}}$ chain has a gapless regime in the same universality class as the $SU(2)_k$ WZW model [68] an intriguing question is whether this PL duality can also be given an interpretation in spin-chains.

Finally we studied the possibility of supersymmetrising these models. As for any non-linear sigma model in two dimensions an $N = (1, 1)$ supersymmetric extension is always possible. Going beyond $N = (1, 1)$ requires extra geometric structure, in particular every additional supersymmetry requires the existence of a complex structure satisfying various properties outlined in section 5 of this paper. Compared to the undeformed WZW model these conditions turn out to be rather involved. We solved them explicitly in the simplest non-trivial example: $SU(2) \times U(1)$. For generic values of the deformation parameters no supersymmetry beyond $N = (1, 1)$ is allowed. For the particular case where the deformation parameter α , defined in eq. (2.2), satisfies $\alpha = |k|$ with k the level of the WZ term an $N = (2, 1)$ extension is still possible while $N = (2, 2)$ is forbidden. We provided the manifest supersymmetric formulation of this model in $N = (2, 1)$ superspace.

The above analysis showed no obvious connection between integrability and the existence of extended supersymmetries (perhaps this is not so surprising, see e.g. [56]). A useful exercise in this context would be the following. All bi-hermitian complex surfaces have been classified [69, 70]. Those with the topology of $SU(2) \times U(1)$ are the primary Hopf surfaces. A detailed analysis of the $N = (2, 2)$ superspace formulations of those models combined with their integrability properties would be most interesting, in particular a characterization of the notion of integrability directly in $N = (2, 2)$ superspace would be quite exciting. In view of the results obtained in the current paper we expect that if a

connection between extended supersymmetry and integrability can be obtained it would probably not fall in the class of the models introduced in [26], however other possibilities remain, e.g. the models developed in [27] and through the inclusion of an action on the Cartan in the \mathcal{R} -matrix. We will come back to this issue in a future publication.

A Conventions

Let us establish our conventions. In this article we consider only semi-simple Lie groups G . For the corresponding Lie algebra \mathfrak{g} we pick a basis of Hermitian generators,

$$[T_A, T_B] = i F_{AB}{}^C T_C, \tag{A.1}$$

where $F_{AB}{}^C$ are the structure constants which satisfy the Jacobi identity:

$$F_{AB}{}^D F_{DC}{}^E + F_{CA}{}^D F_{DB}{}^E + F_{BC}{}^D F_{DA}{}^E = 0. \tag{A.2}$$

We denote by $\langle \cdot, \cdot \rangle : \mathfrak{g} \times \mathfrak{g} \rightarrow \mathbb{R}$ the ad-invariant Cartan-Killing form on \mathfrak{g} whose components are $\langle T_A, T_B \rangle = \frac{1}{x_R} \text{Tr}(T_A T_B) = \kappa_{AB}$ (with x_R the index of the representation R). In particular one gets for the adjoint representation,

$$F_{AC}{}^D F_{BD}{}^C = -c_G \kappa_{AB}, \tag{A.3}$$

with $c_G = 2h^\vee$ where h^\vee is the dual Coxeter number of the group.

Going now to a Cartan-Weyl basis where we call the generators in the Cartan subalgebra (CSA) H_m , the generators corresponding to positive (negative) roots T_a ($T_{\bar{a}}$), where we have $[H_m, T_a] = a_m T_a$ and $[H_m, T_{\bar{a}}] = -a_m T_{\bar{a}}$. Using this one immediately gets from eq. (A.3),

$$\kappa_{mn} = \frac{1}{h^\vee} \sum_a a_m a_n, \tag{A.4}$$

where the sum runs over the positive roots. With this we define the length squared of a root \vec{a} by¹³ $\vec{a} \cdot \vec{a} = a_m \kappa^{mn} a_n$. With our choice for the normalization of the Cartan-Killing

¹³ κ^{mn} is the inverse of κ_{mn} .

form the length squared of the long roots is always 2 and for the non-simply laced groups the length squared of the short roots is either 1 or 1/3.

We define left-invariant forms $u = -iu^A T_A = g^{-1} dg$ which thus obey $du^A = -\frac{1}{2} F_{BC}^A u^B \wedge u^C$ whilst right-invariant forms $v = -iv^A T_A = dg g^{-1}$ obey $dv^A = +\frac{1}{2} F_{BC}^A v^B \wedge v^C$. The Wess-Zumino-Witten action [13] is,

$$S = -\frac{k}{2\pi} \int_{\Sigma} d\sigma d\tau \langle g^{-1} \partial_+ g, g^{-1} \partial_- g \rangle + \frac{k}{24\pi} \int_{M_3} \langle \bar{g}^{-1} d\bar{g}, [\bar{g}^{-1} d\bar{g}, \bar{g}^{-1} d\bar{g}] \rangle, \quad (\text{A.5})$$

in which $g : \Sigma \rightarrow G$ and with \bar{g} the extension of g into M_3 such that $\partial M_3 = \Sigma$. We adopt light-cone coordinates $\sigma^{\pm} = \tau \pm \sigma$. For compact G , and demanding that the action is insensitive to the choice of action, requires $k \in \mathbb{Z}$.

In section 5 we deal with non-linear sigma models in $N = (1, 1)$ and $N = (2, 1)$ superspace. Let us briefly review some of the notations appearing there and refer to e.g. [63, 64] for more details. Denoting for this section the bosonic worldsheet light-cone coordinates by,

$$\sigma^{\ddagger} = \tau + \sigma, \quad \sigma^{\bar{}} = \tau - \sigma, \quad (\text{A.6})$$

and the $N = (1, 1)$ (real) fermionic coordinates by θ^+ and θ^- , we introduce the fermionic derivatives which satisfy,

$$D_{\ddagger}^2 = -\frac{i}{2} \partial_{\ddagger}, \quad D_{\bar{}}^2 = -\frac{i}{2} \partial_{\bar{}}, \quad \{D_+, D_-\} = 0. \quad (\text{A.7})$$

The $N = (1, 1)$ integration measure is given by,

$$\int d^2\sigma d^2\theta = \int d\tau d\sigma D_+ D_-. \quad (\text{A.8})$$

Passing from $N = (1, 1)$ to $N = (2, 1)$ superspace requires the introduction of one more real fermionic coordinates $\hat{\theta}^+$ where the corresponding fermionic derivative satisfies,

$$\hat{D}_{\ddagger}^2 = -\frac{i}{2} \partial_{\ddagger}, \quad (\text{A.9})$$

and all other — except for (A.7) — (anti-)commutators do vanish. The $N = (2, 1)$ integration measure is,

$$\int d^2\sigma d^2\theta d\hat{\theta}^+ = \int d\tau d\sigma D_+ D_- \hat{D}_+. \quad (\text{A.10})$$

B Charges in SU(2)

In this appendix we review the construction [35] of charges satisfying a quantum group algebra for the case of $\mathfrak{g} = \mathfrak{su}(2)$ paying rather careful attention to the normalisation of canonical momenta so as to obtain the quantum group parameters expressed in terms of RG invariant quantities.

In this appendix we use $\mathfrak{su}(2)$ generators $[T^{\pm}, T^3] = iT^{\pm}$, $[T^+, T^-] = -iT^3$ and define components of the left invariant one-forms via $g^{-1} dg \equiv u_+ T^+ + u_- T^- + u_3 T^3$.

To orientate ourselves we begin with the Lagrangian eq. (2.2) specialised to the case of the η -deformation, i.e. $\alpha = \frac{1}{\tau}$, $\beta = \frac{\eta}{1+\eta^2} \frac{1}{\tau}$, $\gamma = \frac{\eta^2}{1+\eta^2} \frac{1}{\tau}$ with $k = 0$ incorporating some of the key points of [3, 41]. Let us define some at first sight non-obvious currents,

$$j_{\pm} = -\frac{1}{2} \frac{\eta}{1+\eta^2} \frac{1}{\Sigma} (\eta u_{\sigma\pm} \pm i u_{\tau\pm}), \quad j_3 = \frac{\eta}{2\Sigma} u_{\tau 3}, \quad (\text{B.1})$$

in which $\Sigma = 4\pi\tau\eta$. These have simple Poisson brackets,

$$\begin{aligned} \{j_3(\sigma_1), j_3(\sigma_2)\} &= 0, \\ \{j_{\pm}(\sigma_1), j_3(\sigma_2)\} &= \pm i j_{\pm}(\sigma_2) \delta(\sigma_1 - \sigma_2), \\ \{j_{\pm}(\sigma_1), j_{\mp}(\sigma_2)\} &= \mp i j_3(\sigma_2) \delta(\sigma_1 - \sigma_2). \end{aligned} \quad (\text{B.2})$$

That these are indeed the correct objects to work with becomes evident if we look at the Lax connection of eq. (2.9). Recall that the path-ordered exponential integral of the spatial component of the Lax defines conserved charges. Expanding around particular values of the spectral parameter gives expressions for the charges. In particular if we expand the gauge transformed Lax $\mathcal{L}^g(z) = g^{-1} \mathcal{L}_{\sigma}(z) g - g^{-1} \partial_{\sigma} g$ around certain points $z = \pm i\eta$ — these correspond to poles in the twist function of the Maillet r/s kernels — we find that these currents occur naturally as,

$$\mathcal{L}^g(z = \mp i\eta) = 4\Sigma j_{\pm} T^{\pm} \pm 2i\Sigma j_3 T^3. \quad (\text{B.3})$$

Using the fact that the Cartan element can be factored in the path ordered exponential occurring in the monodromy matrix [71] one is led to construct (non-local) currents,

$$\begin{aligned} \tilde{\mathfrak{J}}_+(\sigma, \tau) &= j_+(\sigma, \tau) \exp \left[-2\Sigma \int_{\sigma}^{\infty} j_3(\hat{\sigma}, \tau) d\hat{\sigma} \right], \\ \tilde{\mathfrak{J}}_-(\sigma, \tau) &= j_-(\sigma, \tau) \exp \left[2\Sigma \int_{-\infty}^{\sigma} j_3(\hat{\sigma}, \tau) d\hat{\sigma} \right], \\ \tilde{\mathfrak{J}}_3(\sigma, \tau) &= j_3(\sigma, \tau). \end{aligned} \quad (\text{B.4})$$

The equations of motion imply $\partial_{\tau} \tilde{\mathfrak{J}} = \partial_{\sigma} \tilde{\mathfrak{J}}$ for some $\tilde{\mathfrak{J}}$ whose explicit form is not important to us and thus that the charges $\mathfrak{Q} = \int_{-\infty}^{\infty} \tilde{\mathfrak{J}} d\sigma$ are conserved subject to standard boundary fall off. The Poisson brackets give,

$$\{\tilde{\mathfrak{J}}_+(\sigma_1), \tilde{\mathfrak{J}}_-(\sigma_2)\} = \frac{i}{4\Sigma} \delta(\sigma_1 - \sigma_2) \partial_{\sigma_2} \exp \left[-2\Sigma \left(\int_{\sigma_2}^{\infty} - \int_{-\infty}^{\sigma_2} \right) j_3(\hat{\sigma}) d\hat{\sigma} \right], \quad (\text{B.5})$$

where we note that “cross terms” involving the non-local exponentials cancel. Thus one finds that, with suitable normalisation,

$$\{\mathfrak{Q}_+, \mathfrak{Q}_-\} = i \frac{q^{\mathfrak{Q}_3} - q^{-\mathfrak{Q}_3}}{q - q^{-1}}, \quad \{\mathfrak{Q}_{\pm}, \mathfrak{Q}_3\} = \pm i \mathfrak{Q}_{\pm}, \quad q = e^{2\Sigma}. \quad (\text{B.6})$$

Now we turn to the full theory including the WZ term. For this case we have the definitions,

$$j_{\pm} = -\frac{k \mp i\Theta}{8\pi(\alpha^2 + \Theta^2)} ((\pm i\alpha^2 + k\Theta)u_{\sigma\pm} + \alpha(\pm ik + \Theta)u_{\tau\pm}), \quad j_3 = \frac{1}{8\pi} (k u_{\sigma 3} + \alpha u_{\tau 3}), \quad (\text{B.7})$$

which obey a non-ultralocal algebra,

$$\begin{aligned} \{j_3(\sigma_1), j_3(\sigma_2)\} &= -\frac{k}{4\pi} \partial_{\sigma_1} \delta(\sigma_1 - \sigma_2), \\ \{j_{\pm}(\sigma_1), j_3(\sigma_2)\} &= \pm i j_{\pm}(\sigma_2) \delta(\sigma_1 - \sigma_2), \\ \{j_{\pm}(\sigma_1), j_{\mp}(\sigma_2)\} &= \mp i j_3(\sigma_2) \delta(\sigma_1 - \sigma_2) - \frac{k}{4\pi} \partial_{\sigma_1} \delta(\sigma_1 - \sigma_2), \end{aligned} \tag{B.8}$$

and from which we can build in the same way as above *mutatis mutandis* (non-local) conserved currents as,

$$\begin{aligned} \mathfrak{J}_+(\sigma, \tau) &= j_+(\sigma, \tau) \exp \left[\frac{8\pi}{\Theta - ik} \int_{\sigma}^{\infty} j_3(\hat{\sigma}, \tau) d\hat{\sigma} \right], \\ \mathfrak{J}_-(\sigma, \tau) &= j_-(\sigma, \tau) \exp \left[-\frac{8\pi}{\Theta + ik} \int_{-\infty}^{\sigma} j_3(\hat{\sigma}, \tau) d\hat{\sigma} \right], \\ \mathfrak{J}_3(\sigma, \tau) &= j_3(\sigma, \tau). \end{aligned} \tag{B.9}$$

At the WZW fixed point ($\alpha = |k|, \Theta = 0$) these currents just reduce to the currents generating the right acting affine $\mathfrak{su}(2)$. As with the case above these currents appear in the gauge transformed Lax expanded around the poles of its twist function, i.e.,

$$\mathcal{L}^g \left(z = \frac{\mp ik\Theta + \alpha^2}{k\alpha + \mp i\Theta\alpha} \right) = \frac{16\pi\Theta}{k^2 + \Theta^2} j_{\pm} T^{\pm} + \frac{8\pi}{k \mp i\Theta} j_3 T^3. \tag{B.10}$$

For completeness we make the identification with the parameters γ_+ and γ_- used in the analysis of [35]:

$$\gamma_+ = \frac{8i\pi}{k - i\Theta}, \quad \gamma_- = -\frac{8\pi i}{k + i\Theta}, \tag{B.11}$$

such that,

$$\frac{\gamma_-}{\gamma_+} = -\frac{k - i\Theta}{k + i\Theta}, \quad \Delta = \frac{\gamma^+ + \gamma^-}{2} = \frac{-8\pi\Theta}{\Theta^2 + k^2}. \tag{B.12}$$

Even though the currents have a non-ultra-local algebra, the charge algebra is not ambiguous [35] (there is no order of limits problem in regulating the spatial integrals) and the commutator of charges (up to overall normalisations of \mathcal{Q}^{\pm}) still obeys eq. (B.6) with $q = e^{-\Delta}$.

C Properties of \mathcal{R}

We collate here a number of identities used in the massaging of the calculation of the β -functions. The strategy of deriving these identities is practically always the same: we expand the mCYBE eq. (2.1) or related versions in the generators T_A of the Lie algebra and contract two free indices with two from the structure constants F_{AB}^C or from $F_{AB}^D \mathcal{R}^C_D$.

For completeness, we repeat here the mCYBE:

$$[\mathcal{R}x, \mathcal{R}y] - \mathcal{R}([x, \mathcal{R}y] + [\mathcal{R}x, y]) = [x, y] \quad \forall x, y \in \mathfrak{g}. \tag{C.1}$$

From this we can derive a related identity,

$$[\mathcal{R}^2x, \mathcal{R}y] - [\mathcal{R}x, \mathcal{R}^2y] = \mathcal{R}([\mathcal{R}^2x, y] - [x, \mathcal{R}^2y]) + [\mathcal{R}x, y] - [x, \mathcal{R}y], \tag{C.2}$$

and using $\mathcal{R}^3 = -\mathcal{R}$ we can also derive:

$$[\mathcal{R}^2 x, \mathcal{R}^2 y] = \mathcal{R}^2 ([\mathcal{R}^2 x, y] + [x, \mathcal{R}^2 y]) + (1 + 2\mathcal{R}^2)[x, y], \quad (\text{C.3})$$

$$[\mathcal{R}^2 x, \mathcal{R} y] + [\mathcal{R} x, \mathcal{R}^2 y] = \mathcal{R} ([\mathcal{R}^2 x, y] + [x, \mathcal{R}^2 y] + 2[x, y]) + \mathcal{R}^2 ([\mathcal{R} x, y] + [x, \mathcal{R} y]), \quad (\text{C.4})$$

for all $x, y \in \mathfrak{g}$. This gives the following (non-exhaustive) list of properties of the \mathcal{R} -matrix all of which were used in the derivation of the β -functions:

$$\mathcal{R}^D{}_A \mathcal{R}^E{}_B F_{DEC} + \mathcal{R}^D{}_B \mathcal{R}^E{}_C F_{DEA} + \mathcal{R}^D{}_C \mathcal{R}^E{}_A F_{DEB} - F_{ABC} = 0, \quad (\text{C.5})$$

$$(\mathcal{R}^2)^D{}_A \mathcal{R}^E{}_B F_{DE}{}^C + (\mathcal{R}^2)^D{}_A \mathcal{R}^C{}_E F_{BD}{}^E + \mathcal{R}^D{}_A F_{BD}{}^C + (A \leftrightarrow B) = 0, \quad (\text{C.6})$$

$$(\mathcal{R}^2)^D{}_A (\mathcal{R}^2)^E{}_B F_{DEC} - (\mathcal{R}^2)^D{}_C (\mathcal{R}^2)^E{}_A F_{DEB} - (\mathcal{R}^2)^D{}_B (\mathcal{R}^2)^E{}_C F_{DEA} - 2(\mathcal{R}^2)^E{}_C F_{ABE} - F_{ABC} = 0, \quad (\text{C.7})$$

$$\mathcal{R}^C{}_E \mathcal{R}^F{}_D F_{CA}{}^D F_{FB}{}^E + 2\mathcal{R}^C{}_E \mathcal{R}^F{}_B F_{CA}{}^D F_{DF}{}^E - c_G \kappa_{AB} = 0, \quad (\text{C.8})$$

$$(\mathcal{R}^2)^D{}_A \mathcal{R}^E{}_F F_{DE}{}^C F_{CB}{}^F = \mathcal{R}^C{}_D F_{AE}{}^D F_{CB}{}^E, \quad (\text{C.9})$$

$$(\mathcal{R}^2)^E{}_C \mathcal{R}^F{}_A F_{EF}{}^D F_{DB}{}^C + (\mathcal{R}^2)^E{}_C \mathcal{R}^F{}_D F_{AE}{}^D F_{FB}{}^C + \mathcal{R}^C{}_D F_{AE}{}^D F_{CB}{}^E + c_G \mathcal{R}_{AB} = 0, \quad (\text{C.10})$$

$$(\mathcal{R}^2)^D{}_F \mathcal{R}^C{}_E F_{CB}{}^F F_{AD}{}^E - (\mathcal{R}^2)^D{}_F \mathcal{R}^C{}_A F_{EB}{}^F F_{CD}{}^E + \mathcal{R}^C{}_D F_{AE}{}^D F_{CB}{}^E + c_G \mathcal{R}_{AB} = 0, \quad (\text{C.11})$$

$$(\mathcal{R}^2)^D{}_F (\mathcal{R}^2)^E{}_C F_{DA}{}^C F_{BE}{}^F + 2(\mathcal{R}^2)^E{}_C F_{DA}{}^C F_{BE}{}^D + c_G \kappa_{AB} = 0, \quad (\text{C.12})$$

$$\mathcal{R}^C{}_A \mathcal{R}^D{}_B F_{CD}{}^B = 0. \quad (\text{C.21})$$

D Geometry in the non-orthonormal frame

Consider a general Riemannian target manifold \mathcal{M} with local coordinates x^μ and endowed with a curved metric G . We work in a frame formalism $\hat{e}_A = e_A^\mu \partial_\mu$ where the metric is constant but non-orthonormal:

$$G_{\mu\nu}(x) = e^A{}_\mu(x) G_{AB} e^B{}_\nu(x). \quad (\text{D.1})$$

Requiring the spin-connection to be metric-compatible and torsion-free gives the following connection coefficients:

$$\Gamma_{BC}^A = \frac{1}{2}G^{AE} (\Omega_{EB}{}^D G_{DC} + \Omega_{EC}{}^D G_{DB}) + \frac{1}{2}\Omega_{BC}{}^A, \quad (\text{D.2})$$

where $\Omega_{AB}{}^C$ are the anholonomy coefficients determined by,

$$[\hat{e}_A, \hat{e}_B] = \Omega_{AB}{}^C \hat{e}_C, \quad \Omega_{AB}{}^C = e_A{}^\mu e_B{}^\nu (\partial_\nu e^C{}_\mu - \partial_\mu e^C{}_\nu). \quad (\text{D.3})$$

In our case, the target manifold is a Lie manifold G endowed with a deformed geometry. Introducing left-invariant one-forms $u = g^{-1}dg = -iu_\nu^A T_A dx^\nu$ which satisfy,

$$du^A = -\frac{1}{2}F_{BC}{}^A u^B \wedge u^C, \quad (\text{D.4})$$

we go to the frames $\hat{e}_A = u_A^\mu \partial_\mu$. The deformed geometry in this frame is given by the constant non-orthonormal metric eq. (3.3) and by the torsion eq. (3.4),

$$G_{AB} = \alpha \kappa_{AB} + \gamma \mathcal{R}_{AB}^2, \quad H_{ABC} = 3\beta F_{[AB}{}^D \mathcal{R}_{C]D} - k F_{ABC}. \quad (\text{D.5})$$

The inverse metric is then (using $\mathcal{R}^3 = -\mathcal{R}$):

$$G^{AB} = \frac{1}{\alpha} \kappa^{AB} + \frac{\gamma}{\alpha(\gamma - \alpha)} (\mathcal{R}^2)^{AB}. \quad (\text{D.6})$$

For the spin-connection coefficients we find from eq. (D.4) that $\Omega_{AB}{}^B = F_{AB}{}^C$ and thus,

$$\Gamma_{BC}^A = \frac{1}{2}G^{AE} (F_{EB}{}^D G_{DC} + F_{EC}{}^D G_{DB}) + \frac{1}{2}F_{BC}{}^A. \quad (\text{D.7})$$

Noting that the spin-connections are constant, the Riemann tensor can be calculated from,

$$R^A{}_{BCD} = \Gamma_{DB}^E \Gamma_{CE}^A - \Gamma_{CB}^E \Gamma_{DE}^A - \Omega_{CD}{}^E \Gamma_{EB}^A, \quad (\text{D.8})$$

and the Ricci tensor from,

$$R_{AB} = R^C{}_{ACB} = -\Gamma_{CA}^E \Gamma_{BE}^C - F_{CB}{}^E \Gamma_{EA}^C. \quad (\text{D.9})$$

With the β -functions in mind we end this appendix with a set of useful expressions which are found by plugging in the expressions of the metric eq. (3.3) and the torsion eq. (3.4) and by making use of the properties of the \mathcal{R} -matrix listed in appendix C:

- The spin-connection:

$$\Gamma_{BC}^A = \frac{1}{2} \frac{\gamma}{\alpha - \gamma} (F_{BD}{}^A (\mathcal{R}^2)^D{}_C + F_{CD}{}^A (\mathcal{R}^2)^D{}_B) + \frac{1}{2} F_{BC}{}^A. \quad (\text{D.10})$$

- The Ricci tensor:

$$\begin{aligned} R_{AB} &= \frac{c_G}{4} \left(1 + \left(\frac{\gamma}{\gamma - \alpha} \right)^2 \right) \kappa_{AB} - \frac{c_G}{4} \left(1 - \left(\frac{\alpha}{\gamma - \alpha} \right)^2 \right) \mathcal{R}_{AB}^2 \\ &\quad + \frac{1}{2} \left(\frac{\gamma}{\alpha - \gamma} \right) F_{AD}{}^C F_{BC}{}^E (\mathcal{R}^2)^D{}_E. \end{aligned} \quad (\text{D.11})$$

- The Ricci curvature:

$$R = R_{AB}G^{AB} = -\frac{c_G}{4} \left(\frac{1}{(\gamma - \alpha)} D + \frac{\gamma}{(\gamma - \alpha)^2} l \right), \quad (\text{D.12})$$

where D is the dimension and l is the rank of the Lie algebra \mathfrak{g} . Hence, we have $\text{Tr}(\mathcal{R}^2) = -(D - l)$.

- Expressions from the torsion tensor:

$$\begin{aligned} H_{AB}^2 &= H_{ACD}H_{BEF}G^{CE}G^{DF} \\ &= c_G \left(\frac{\alpha k^2 - 2(\gamma k^2 + \alpha\beta^2)}{\alpha(\gamma - \alpha)^2} \right) \kappa_{AB} - c_G \frac{\beta^2}{(\gamma - \alpha)^2} \mathcal{R}_{AB}^2 \\ &\quad + \left(\frac{2(\gamma k^2 + \alpha\beta^2)}{\alpha(\gamma - \alpha)^2} \right) (\mathcal{R}^2)^D{}_E F_{BC}{}^E F_{AD}{}^C, \end{aligned} \quad (\text{D.13})$$

$$H^2 = -c_G \left(\frac{k^2 + \beta^2}{(\gamma - \alpha)^3} D - \frac{3(\gamma k^2 + \alpha\beta^2)}{\alpha(\gamma - \alpha)^3} l \right), \quad (\text{D.14})$$

$$\begin{aligned} \nabla_C H^C{}_{AB} &= G^{DE} (\Gamma_{DA}^C H_{EBC} - \Gamma_{DB}^C H_{EAC}) \\ &= c_G \frac{\beta}{\gamma - \alpha} \mathcal{R}_{AB} + \frac{2\beta}{\gamma - \alpha} \mathcal{R}^D{}_E F_{AD}{}^C F_{BC}{}^E. \end{aligned} \quad (\text{D.15})$$

ABSTRACT: We clarify the relation between various approaches to the manifestly T-duality symmetric string. We explain in detail how the PST covariant doubled string arises from an unusual gauge fixing. We pay careful attention to the role of “spectator” fields in this process and also show how the T-duality invariant doubled dilaton emerges naturally. We extend these ideas to non-Abelian T-duality and show they give rise to the duality invariant formalism based on the semi-Abelian Drinfeld Double. We then develop the $\mathcal{N} = (0, 1)$ supersymmetric duality invariant formalism.

1 Introduction

A central theme in recent years has been to understand the ways in which dualities of string and M-theory may be promoted to manifest symmetries and indeed the extent to which they may be used to determine the structure of the underlying theory.

The idea of a T-duality invariant worldsheet description, *the doubled worldsheet (DWS)*, of strings goes back to pioneering work of Duff [1] and Tseytlin [2, 3]. The study of this approach was reignited following the proposal of Hull [4, 5] to use such a formalism to define strings in a class of non-geometric backgrounds known as T-folds. Parallel to this has been the development of a spacetime T-duality invariant theory, often now dubbed *double field theory (DFT)*, whose origins date to the seminal works of Tseytlin [2, 3] and Siegel [6, 7]. This approach was derived from the perspective of closed string field theory on a torus by Hull and Zwiebach [8]. These ideas have also been explored in the context of M-theory [9, 10] where *exceptional field theory (EFT)* seeks to promote the U-duality

group to a manifest symmetry of a spacetime action and in the E_{11} program of West [11] and collaborators.¹

A common theme of the *doubled worldsheet*, *double field theory* and *exceptional field theory* is that in order to make the duality act as a linearly realised symmetry, the dimensionality of spacetime is augmented by the introduction of additional coordinates. For instance, in the case of T-duality of strings on a d -dimensional torus, we have a $2d$ -dimensional extended spacetime consisting of d -regular coordinates x^i and d -dual coordinates \tilde{x}_i . Just as position is conjugate to momenta one can think of these extra coordinates as conjugate to winding of the string. For strings in a curved background, the components of the background metric g_{ij} and NS two-form fields b_{ij} in the internal toroidal directions are united into a *generalised metric*,

$$\mathcal{H}_{IJ} = \begin{pmatrix} g - b g^{-1} b & -b g^{-1} \\ g^{-1} b & g^{-1} \end{pmatrix}, \tag{1.1}$$

on the doubled space parametrised by coordinates $\mathbb{X}^I = \{x^i, \tilde{x}_i\}$. The T-duality group, which is $O(d, d; \mathbb{Z})$ in this case, acts on this *generalised metric* as,

$$\mathcal{H} \rightarrow \mathcal{H}' = \mathcal{O}^T \mathcal{H} \mathcal{O}, \tag{1.2}$$

where the group element preserves the inner product, $\mathcal{O}^T \eta \mathcal{O} = \eta$, given in this basis by,

$$\eta_{IJ} = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}. \tag{1.3}$$

From the generalised metric we see that the doubled space is equipped with an almost product structure $\mathcal{S} = \eta \mathcal{H}$ such that $\mathcal{S}^2 = \mathbf{1}$ which one can think of as giving rise to a “chiral structure” specified by the projection operators,

$$P_{\pm} = \frac{1}{2} (\mathbf{1} \pm \mathcal{S}). \tag{1.4}$$

This doubled space is also equipped with a natural symplectic product Ω given in this basis as,

$$\Omega_{IJ} = \begin{pmatrix} 0 & \mathbf{1} \\ -\mathbf{1} & 0 \end{pmatrix}. \tag{1.5}$$

The existence of the objects \mathcal{S} , η and Ω are central to the recent proposal of Born geometries [15, 16].

In all of these duality symmetric approaches, there is a price to pay; action principles based on the doubled or extended spacetimes require supplementary constraints. In *DFT* and *EFT* gauge invariance of the theory requires a constraint, also known as the section condition, that essentially declares the field content of the theory to depend on only a

¹Our focus in this note will be on the worldsheet rather than spacetime so for further introduction to the *DFT* and *EFT* we refer the reader to the review articles [12–14].

physical spacetime’s worth of coordinates.² In the case of *DWS*, the worldsheet bosons are required to obey a chirality constraint meaning that of the $2d$ bosons \mathbb{X}^I exactly half are left-movers and half are right-movers and thereby give the correct contribution to the physical central charge. In this note we will be focussed on the variety of ways in which the chirality constraint of *DWS* has been handled.

To explain this let us momentarily restrict ourselves to a simple case; a doubled torus T^{2d} with coordinates \mathbb{X}^I and a generalised metric \mathcal{H} possibly depending on some other “spectator” coordinates y parametrising a base manifold over which the doubled torus is trivially fibered with vanishing connection. In this situation the constraints are given in terms of the chiral projections by,

$$(P_+)^I{}_J \partial_- \mathbb{X}^J = 0, \quad (P_-)^I{}_J \partial_+ \mathbb{X}^J = 0. \quad (1.6)$$

Chiral scalars are notoriously tricky objects to describe, the main reason is that these constraints are first order differential equations and in the terminology of Dirac second class constraints and can not be imposed easily with Lagrange multipliers. One approach is to simply consider a non-linear σ -model in the doubled spacetime,

$$S_{\text{Hull}} = \frac{1}{2} \int d^2 \sigma \partial_+ \mathbb{X}^I \mathcal{H}_{IJ} \partial_- \mathbb{X}^J + \dots, \quad (1.7)$$

in which, and in the following, the ellipsis indicate terms depending on the spectators and also a topological term involving Ω_{IJ} both of which we shall detail later. One can then implement the constraints supplementary to the action for instance by using Dirac brackets and then performing canonical quantisation [27] or by holomorphic factorisation of the resulting partition function [28, 29]. Whilst this is certainly a viable route, one should very much like to have an action principle from which eq. (1.6) follows. Without introducing extra field content this is possible only at the expense of sacrificing manifest Lorentz invariance leading to the action pioneered by Tseytlin [2, 3],

$$S_{\text{Tseytlin}} = \frac{1}{4} \int d^2 \sigma - \partial_\sigma \mathbb{X}^I \mathcal{H}_{IJ} \partial_\sigma \mathbb{X}^J + \partial_\sigma \mathbb{X}^I \eta_{IJ} \partial_\tau \mathbb{X}^J + \dots, \quad (1.8)$$

which essentially employs a Floreanini-Jackiw [30] construction for chiral bosons. The equations of motion that follow from eq. (1.8) may be integrated and using a gauge invariance of the form $\delta X^I = f^I(\tau)$ give rise to the desired chirality constraints of eq. (1.6). Despite its apparent non-covariance one can still employ some conventional field theory techniques, for instance one-loop beta functions of this action have been calculated [31, 32] and shown to give rise to background field equations for \mathcal{H} which are indeed compatible with the equations that follow from *DFT* in the present context (other attempts to make more precise the linkage between *DFT* and the worldsheet theory by allowing \mathcal{H} to depend on the internal coordinates are found in [33, 34] and [35]). However multi-loop calculations are at best very difficult without Lorentz covariance.

²Upon solving this section condition for type II DFT [17] globally, one recovers the generalised geometry [18, 19] reformulation of supergravity of [20, 21]. Ways in which the section condition can be consistently relaxed are of great interest and connect to gauged supergravities see [22–26].

A further approach is to include extra fields so as to furnish the action with a gauge redundancy which promotes the second class constraint to a first class one. This is the spirit of the Pasti-Sorokin-Tonin (PST) approach to chiral fields³ [36]. In the present context this leads to a doubled action,

$$S_{\text{PST}} = \frac{1}{2} \int d^2\sigma \partial_{\pm}\mathbb{X}^I \mathcal{H}_{IJ} \partial_{\pm}\mathbb{X}^J - \frac{\partial_{\pm}f}{\partial_{\pm}f} (P_{+}\partial_{\pm}\mathbb{X})^I \eta_{IJ} (P_{+}\partial_{\pm}\mathbb{X})^J + \frac{\partial_{\pm}f}{\partial_{\pm}f} (P_{-}\partial_{\pm}\mathbb{X})^I \eta_{IJ} (P_{-}\partial_{\pm}\mathbb{X})^J + \dots \quad (1.9)$$

The symmetries of this action are,

$$1) \quad \delta\mathbb{X}^I = \Lambda^I(f), \quad \delta f = 0, \quad (1.10)$$

$$2) \quad \delta\mathbb{X}^I = \frac{\epsilon}{\partial_{\pm}f} (P_{-}\partial_{\pm}\mathbb{X})^I + \frac{\epsilon}{\partial_{\pm}f} (P_{+}\partial_{\pm}\mathbb{X})^I, \quad \delta f = \epsilon. \quad (1.11)$$

Upon using the second symmetry to fix $f = f(\tau)$ one recovers the Tseytlin action eq. (1.8).

Whilst this overall picture is correct, the literature has been rather sketchy in places about many of the details concerning the derivations of the covariant forms of the doubled worldsheet and in particular has omitted a careful treatment of spectator fields (i.e. exactly the terms in ellipsis in the above discussion). In the following we will resolve many of these outstanding issues and by giving the complete derivation of the covariant bosonic doubled formalism achieved by adopting an unusual gauge fixing in a Buscher procedure. A version of this idea was suggested in [37] wherein an axial gauge fixing gives rise to the non-covariant action eq. (1.8) and more recently explored in [38, 39] wherein covariant gauge fixing choices were adopted (though those are not directly relevant to the present discussion). We further this approach by making direct the linkage to the PST form of the action and will then be able to clarify some surprising features concerning the origin of the PST symmetries. These ideas will then be generalised to the case of non-Abelian T-dualities [40] and we will recover a covariant version of the Poisson-Lie duality symmetric action of Klimčík and Ševera [41, 42].

This work arose out of an ongoing attempt to better understand the supersymmetric doubled formalism. It is quite clear in this case how to generalise the chirality constraints to $\mathcal{N} = 1$ supersymmetry; one promotes partial derivatives to super covariant derivatives acting on superfields,

$$(P_{+})^I{}_J D_{-}\mathbb{X}^J = 0, \quad (P_{-})^I{}_J D_{+}\mathbb{X}^J = 0. \quad (1.12)$$

Previous work in the literature has followed the route of imposing the constraints by hand either via Dirac brackets as in [27] or via holomorphic factorisation of a partition function [43]. However the implementation of these constraints at the level of the action has rarely been considered; there is no known covariant formalism in the style of eq. (1.9)

³A different approach based upon gauging the the symmetries generated by the constraints was followed in [5] however at the cost of losing manifest $O(d, d; \mathbb{Z})$ invariance. This approach can be extended to superspace (at least to $\mathcal{N} = (1, 1)$) and higher genus worldsheets.

and even a non-covariant Tseytlin style action has only been considered for the case of a constant generalised metric i.e. assuming no dependence on spectator coordinates. Naive attempts to generalise this appear to fail badly and addressing this short coming seems essential for the doubled worldsheet to have a life in superstring theory.

Here we take a step in this direction by carefully analysing the simplest supersymmetric model, i.e. the one which exhibits an $\mathcal{N} = (0, 1)$ supersymmetry on the worldsheet. It turns out that even a first order formulation comes accompanied by external constraints. These extra constraints are similar in nature to nilpotency constraints on superfields, so at the level of the components of the superfields they are algebraic and, as a consequence, they can simply be imposed using Lagrange multipliers. We do give both the PST and the Tseytlin like description of the $\mathcal{N} = (0, 1)$ system. Note that a Hamiltonian perspective was given in [44] in which only bosonic degrees of freedom are doubled making supersymmetry less evident; here we will instead work in superspace.

2 Bosonic abelian doubled string

2.1 Deriving the covariant doubled string

Our starting point is some compact D -dimensional manifold \mathcal{M} endowed with a metric g and a closed 3-form H . Locally we introduce the Kalb-Ramond 2-form b : $H = db$. Choosing local coordinates X^A , $A \in \{1, \dots, D\}$, the non-linear σ -model Lagrange density is given by,

$$\mathcal{L} = \partial_{\neq} X^A (g_{AB} + b_{AB}) \partial_{=} X^B. \tag{2.1}$$

We now assume the existence of d isometries ($d \leq D$) and introduce adapted coordinates x^i , $i \in \{1, \dots, d\}$, such that the background fields g and b *do not depend on* x . The spectator coordinates are called y^α , $\alpha \in \{1, \dots, D-d\}$. In an obvious matrix notation the Lagrange density becomes,

$$\mathcal{L} = \partial_{\neq} x^T E \partial_{=} x + \partial_{\neq} x^T M \partial_{=} y + \partial_{\neq} y^T N \partial_{=} x + \partial_{\neq} y^T K \partial_{=} y. \tag{2.2}$$

A special role is accorded to $E_{ij} = g_{ij} + b_{ij}$. We denote the inverse of g_{ij} (g) by g^{ij} (g^{-1}): $g_{ik} g^{kj} = \delta_i^j$ ($g g^{-1} = g^{-1} g = \mathbf{1}$). We introduce ‘‘connections’’ \mathcal{B} and $\tilde{\mathcal{B}}$,

$$\begin{aligned} \mathcal{B}^i &= g^{ij} g_{j\beta} \partial y^\beta, \\ \tilde{\mathcal{B}}_i &= b_{i\beta} \partial y^\beta - b_{ij} g^{jk} g_{k\beta} \partial y^\beta, \end{aligned} \tag{2.3}$$

which are adapted coordinate representations of (pull backs of) one-forms detailed in [5] that are horizontal and invariant with respect to the Killing vectors generating the isometry. With these we may rewrite eq. (2.2) as,

$$\mathcal{L} = \nabla_{\neq} x^T E \nabla_{=} x + \partial_{\neq} x^T \tilde{\mathcal{B}}_{=} - \partial_{=} x^T \tilde{\mathcal{B}}_{\neq} - \mathcal{B}_{\neq}^T E \mathcal{B}_{=} + \partial_{\neq} y^T K \partial_{=} y, \tag{2.4}$$

where,

$$\nabla x = \partial x + \mathcal{B}. \tag{2.5}$$

In order to obtain the T-dual model we gauge the isometries,

$$x \rightarrow x' = x + \zeta, \quad y \rightarrow y' = y. \quad (2.6)$$

For this we introduce $2d$ gauge fields A_{\pm} and A_{\pm}' transforming as,

$$A_{\pm} \rightarrow A_{\pm}' = A_{\pm} - \partial_{\pm} \zeta, \quad A_{\pm}' \rightarrow A_{\pm} = A_{\pm}' + \partial_{\pm} \zeta, \quad (2.7)$$

together with d Lagrange multipliers \tilde{x} which are inert under the gauge transformations. The gauge invariant Lagrange density is then,⁴

$$\begin{aligned} \mathcal{L}_{\text{gauged}} = & (\nabla_{\pm} x + A_{\pm})^T E (\nabla_{\pm} x + A_{\pm}) + (\partial_{\pm} x + A_{\pm})^T \tilde{\mathcal{B}}_{\pm} - (\partial_{\pm} x + A_{\pm})^T \tilde{\mathcal{B}}_{\pm} \\ & - \mathcal{B}_{\pm}^T E \mathcal{B}_{\pm} + \partial_{\pm} y^T K \partial_{\pm} y + \tilde{x}^T (\partial_{\pm} A_{\pm} - \partial_{\pm} A_{\pm}'). \end{aligned} \quad (2.8)$$

Integrating over the Lagrange multipliers sets the field strengths to zero, so we can gauge away the gauge fields and we recover the original model. However making the gauge choice $x = 0$, integrating by parts on the Lagrange multiplier term and integrating out the gauge fields yields the dual model,

$$\tilde{\mathcal{L}}_{\text{dual}} = \nabla_{\pm} \tilde{x}^T \tilde{E} \nabla_{\pm} \tilde{x} + \partial_{\pm} \tilde{x}^T \tilde{\mathcal{B}}_{\pm} - \partial_{\pm} \tilde{x}^T \tilde{\mathcal{B}}_{\pm} - \tilde{\mathcal{B}}_{\pm}^T \tilde{E} \tilde{\mathcal{B}}_{\pm} + \partial_{\pm} y^T \tilde{K} \partial_{\pm} y, \quad (2.9)$$

with,

$$\nabla \tilde{x} = \partial \tilde{x} + \tilde{\mathcal{B}}. \quad (2.10)$$

The dual background fields are given by the Buscher rules [46, 47],

$$\tilde{E} = E^{-1}, \quad \tilde{M} = E^{-1} M, \quad \tilde{N} = -N E^{-1}, \quad \tilde{K} = K - N E^{-1} M, \quad (2.11)$$

together with a shift in the dilaton that is seen when the dualisation procedure is carried out in a path integral.

Let us now turn to the manifest T-dual invariant or doubled formulation of the model. In fact our starting point, the gauged Lagrange density eq. (2.8) is already “doubled” as both the original coordinates x and the dual coordinates \tilde{x} appear. This was suggested in [37] (see also [48] for a detailed development) where it was shown that by making the non-Lorentz covariant gauge choice $A_{\pm} = A_{\pm}' \equiv A$ and subsequently integrating out A one recovers Tseytlin’s non-Lorentz covariant doubled formulation [2, 3]. This is very reminiscent of the Floreanini-Jackiw formulation of a chiral boson [30]. Just as the Floreanini-Jackiw formalism can be covariantized [36, 49] we expect the same for Tseytlin’s action. In the next we show how by making a judicious gauge choice in eq. (2.8) one indeed obtains a Lorentz invariant doubled worldsheet formulation.

Starting from the gauge invariant Lagrange density in eq. (2.8) we impose the gauge fixing condition,

$$\partial_{\pm} f A_{\pm} = \partial_{\pm} f A_{\pm}', \quad (2.12)$$

⁴Note that in order to avoid nontrivial holonomies around non-contractible loops, \tilde{x} should satisfy appropriate periodicity conditions. In addition, a surface term $\partial_{\pm}(\tilde{x}^T A_{\pm}) - \partial_{\pm}(\tilde{x}^T A_{\pm}')$ should be added to eq. (2.8) [45] which is important to keep in mind as we treat boundary contributions in what follows.

where f is some scalar field. In writing the gauge fixing choice as in eq. (2.12) we are emphasising that the function f should be suitably chosen so as to have nowhere vanishing derivatives — we will discuss this requirement further in the discussion section. Making a coordinate transformation,

$$\sigma^\ddagger \rightarrow \hat{\sigma}^\ddagger = \sigma^\ddagger, \quad \sigma^\bar{=} \rightarrow \hat{\sigma}^\bar{=} = f, \quad (2.13)$$

the above gauge choice simplifies to $\hat{A}_\ddagger = 0$. From this we immediately identify the residual gauge symmetry. It is given by eqs. (2.6) and (2.7) where the gauge parameter ξ is of the form $\xi = \xi(f(\sigma^\ddagger, \sigma^\bar{=}))$. A full and detailed discussion of the residual symmetries will be given in section 2.2. In addition to this, one verifies that the Lagrange density eq. (2.8) is invariant under,

$$\tilde{x} \rightarrow \tilde{x}' = \tilde{x} + \tilde{\xi}(f), \quad (2.14)$$

as well.

Now the strategy is clear. We adopt this gauge choice and parameterize the gauge fields as,

$$A_\ddagger = A \partial_\ddagger f \quad A_\bar{=} = A \partial_\bar{=} f, \quad (2.15)$$

where A is a $d \times 1$ column matrix of scalar fields. Implementing this gauge fixing in eq. (2.8) and eliminating A through its equations of motion,

$$A = -\frac{1}{2\partial_\bar{=} f} g^{-1} \mathcal{J}_\bar{=} - \frac{1}{2\partial_\ddagger f} g^{-1} \mathcal{J}_\ddagger, \quad (2.16)$$

where,

$$\mathcal{J}_\bar{=} = E \nabla_\bar{=} x + \nabla_\bar{=} \tilde{x}, \quad \mathcal{J}_\ddagger = E^T \nabla_\ddagger x - \nabla_\ddagger \tilde{x}, \quad (2.17)$$

yields, after a little manipulation, the desired covariant doubled Lagrange density,⁵

$$\begin{aligned} \mathcal{L}_{\text{doubled}} = & \frac{1}{2} \nabla_\ddagger \mathbb{X}^T \mathcal{H} \nabla_\bar{=} \mathbb{X} - \frac{1}{2} \partial_\ddagger \mathbb{X}^T \Omega \partial_\bar{=} \mathbb{X} - \frac{1}{2} \frac{\partial_\bar{=} f}{\partial_\ddagger f} \nabla_\ddagger \mathbb{X}^T \mathcal{H} P_- \nabla_\ddagger \mathbb{X} \\ & - \frac{1}{2} \frac{\partial_\ddagger f}{\partial_\bar{=} f} \nabla_\bar{=} \mathbb{X}^T \mathcal{H} P_+ \nabla_\bar{=} \mathbb{X} + \frac{1}{2} \partial_\ddagger \mathbb{X}^T \eta \mathbb{B}_\bar{=} - \frac{1}{2} \partial_\bar{=} \mathbb{X}^T \eta \mathbb{B}_\ddagger + \partial_\ddagger y^T \hat{K} \partial_\bar{=} y, \end{aligned} \quad (2.18)$$

where,

$$\mathbb{B} = \begin{pmatrix} \mathcal{B} \\ \tilde{\mathcal{B}} \end{pmatrix}, \quad \nabla \mathbb{X} = \partial \mathbb{X} + \mathbb{B}. \quad (2.19)$$

This action is now (almost) manifestly invariant under global $O(d, d; \mathbb{R})$ transformations acting as,

$$\mathcal{H} \rightarrow \mathcal{H}' = \mathcal{O}^T \mathcal{H} \mathcal{O}, \quad \mathbb{X} \rightarrow \mathcal{O}^{-1} \mathbb{X}, \quad \mathbb{B} \rightarrow \mathcal{O}^{-1} \mathbb{B}. \quad (2.20)$$

⁵Note that a Lagrange density somewhat similar to this one has been obtained in the context of heterotic strings compactified on a Narain torus [53].

This invariance is further reduced to $O(d, d; \mathbb{Z})$ by demanding that the periodicities of the coordinates \mathbb{X} are preserved [4, 8].

Note that other than the initial integration by parts on the Lagrange multiplier term (and, see footnote 4, in a careful gauging any boundary terms from this are canceled by a boundary contribution), we have not discarded any total derivatives in this manipulation and the topological term, $\partial_{\pm} \mathbb{X}^T \Omega \partial_{\pm} \mathbb{X}$, appears automatically. One might be tempted to ignore such a piece however this term is vital for instance in getting a correct factorisation of the partition function and in [5] this topological term ensures invariance under certain large gauge transformations that are used to define the quantum theory (as originally emphasized in [54]). We will see later that when generalised to non-Abelian T-duality it will no longer remain topological and rather play the role of a potential for a WZ term. Strictly speaking this topological term spoils the invariance of the action under $O(d, d; \mathbb{Z})$ unless $\mathcal{O}^T \Omega \mathcal{O} = \Omega$. Evidently the $GL(d, \mathbb{Z})$ subgroup of the duality group preserves Ω , but for the remaining components of $O(d, d; \mathbb{Z})$, namely B-field shifts and Buscher dualities, one needs to exercise more care. Properly normalised this topological term [5] evaluates to the sum of products of winding numbers around canonically dual cycles and in a fixed winding sector evaluates to $\pi \mathbb{Z}$ contributing a sign in the path integral. B-field shifts have the effect of adding $2\pi \mathbb{Z}$ to this contribution and thus leave the path integral invariant. For T-dualities that simply swap n coordinates the coefficient of the topological term is multiplied by $(-1)^n$ and again the path integral is invariant.

The Lagrange density governing the spectator coordinates is altered as well — a fact often ignored in the literature. Indeed the $O(d, d; \mathbb{Z})$ non-invariant background field K is replaced by \hat{K} which is invariant and explicitly given by,

$$\hat{K} = K - \frac{1}{2} N g^{-1} M - \frac{1}{4} M^T g^{-1} M - \frac{1}{4} N g^{-1} N^T. \tag{2.21}$$

The action of parity is slightly non-standard. Since parity acts as $\mathcal{P} : \{\sigma^{\pm}, \sigma^{\mp}\} \rightarrow \{\sigma^{\mp}, \sigma^{\pm}\}$ leaving the one-form gauge connection $A_{\mu} dx^{\mu}$ invariant, we require that $\mathcal{P} : \{x, \tilde{x}\} \rightarrow \{x, -\tilde{x}\}$ for the gauged Lagrangian to have definite parity. In terms of the doubled space we have $\mathcal{P} : \mathbb{X}^I \rightarrow \mathcal{P}^I{}_J \mathbb{X}^J$ with $\mathcal{P}^I{}_J = -(\Omega \eta)^I{}_J$. In addition, for the term $E_{ij} \partial_{\pm} x^i \partial_{\pm} x^j$ to have definite parity we should also insist that $\mathcal{P} : b_{ij} \rightarrow -b_{ij}$ which implies that the generalised metric must transform as $\mathcal{P} : \mathcal{H} \rightarrow \mathcal{P} \cdot \mathcal{H} \cdot \mathcal{P}$. Making use of the identity $\mathcal{P} \cdot \eta \cdot \mathcal{P} = -\eta$ we see $\mathcal{P} : (P_{+} \partial_{-} \mathbb{X})^I \rightarrow (\mathcal{P} \cdot P_{-} \partial_{+} X)^I$ and thus both the Tseytlin and PST actions have definite parity.

2.2 Gauge symmetries and the origin of PST symmetry

In this section we investigate the symmetries of the manifest $O(d, d; \mathbb{Z})$ invariant Lagrange density. Upon gauge fixing the original gauge symmetry eqs. (2.6) and (2.7) and passing to the second order formalism, the residual gauge symmetry extended by the symmetry eq. (2.14) is given by,

$$\mathbb{X} \rightarrow \mathbb{X}' = \mathbb{X} + \Lambda(f), \quad f \rightarrow f' = f, \tag{2.22}$$

where $\Lambda(f)$ is a $2d \times 1$ column matrix of arbitrary functions of f . This explains the origin of the first of the symmetries of eq. (1.10). However the appearance of the PST symmetry which acts as,

$$\begin{aligned} \delta f &= \varepsilon, \\ \delta \mathbb{X} &= \frac{\varepsilon}{\partial_{\mp} f} P_{-} \nabla_{\mp} \mathbb{X} + \frac{\varepsilon}{\partial_{=} f} P_{+} \nabla_{=} \mathbb{X}, \end{aligned} \quad (2.23)$$

in the second order formulation eq. (2.18) is quite mysterious. It looks as if it is unrelated to the original gauge symmetry eqs. (2.6) and (2.7). In the remainder we explain how the PST symmetry originates from the gauged σ -model in eq. (2.8).

Given an infinitesimal vector, ξ^{μ} , $\mu \in \{\mp, =\}$, we introduce the variations,

$$\begin{aligned} \delta A_{\mu} &= \mathcal{L}_{\xi} A_{\mu} = \partial_{\mu}(\xi^{\nu} A_{\nu}) + \xi^{\nu} F_{\nu\mu}, \\ \delta x &= -\xi^{\mu} A_{\mu}, \\ \delta \tilde{x} &= -\xi^{\mp}(\mathcal{J}_{\mp} + E^T A_{\mp}) + \xi^{=}(\mathcal{J}_{=} + EA_{=}), \end{aligned} \quad (2.24)$$

where $F_{\mu\nu} = \partial_{\mu} A_{\nu} - \partial_{\nu} A_{\mu}$, \mathcal{L}_{ξ} is the Lie derivative along ξ and \mathcal{J} was given in eq. (2.17). One easily verifies that the gauged σ -model in eq. (2.8) is invariant under these transformations. This is not so surprising as these transformations can be rewritten as,

$$\begin{aligned} \delta x &= -\xi^{\mu} A_{\mu}, \\ \delta A_{\mp} &= \partial_{\mp}(\xi^{\mu} A_{\mu}) - \xi^{=} \frac{\delta \mathcal{S}}{\delta \tilde{x}}, \\ \delta A_{=} &= \partial_{=}(\xi^{\mu} A_{\mu}) + \xi^{\mp} \frac{\delta \mathcal{S}}{\delta \tilde{x}}, \\ \delta \tilde{x} &= -\xi^{\mp} \frac{\delta \mathcal{S}}{\delta A_{=}} + \xi^{=} \frac{\delta \mathcal{S}}{\delta A_{\mp}}, \end{aligned} \quad (2.25)$$

where we introduced the action $\mathcal{S} = \int d^2\sigma \mathcal{L}_{\text{gauged}}$. So one sees that this is not a new symmetry: it is a combination of a (field dependent) gauge transformation eqs. (2.6), (2.7) with parameter $\zeta = -\xi^{\mu} A_{\mu}$ and a (trivial) equations of motion symmetry.

However the situation changes when making the gauge choice $A_{\mp} = \partial_{\mp} f A$, $A_{=} = \partial_{=} f A$. The residual gauge symmetry is now,

$$x \rightarrow x' = x + \varepsilon(f), \quad f \rightarrow f' = f, \quad A \rightarrow A' = A - \frac{d\varepsilon(f)}{df}, \quad (2.26)$$

and the symmetries in eq. (2.25) survive provided we assign the following transformation rules to A and f ,

$$\begin{aligned} \delta f &= \xi^{\mu} \partial_{\mu} f, \\ \delta A &= \xi^{\mu} \partial_{\mu} A. \end{aligned} \quad (2.27)$$

Introducing the parameters ε and \varkappa ,

$$\varepsilon \equiv \xi^{\mp} \partial_{\mp} f + \xi^{=} \partial_{=} f, \quad \varkappa \equiv \xi^{\mp} \partial_{\mp} f - \xi^{=} \partial_{=} f, \quad (2.28)$$

one rewrites the transformation rules as,

$$\begin{aligned}
 \delta f &= \varepsilon, \\
 \delta x &= -\varepsilon A, \\
 \delta \tilde{x} &= \frac{\varepsilon}{2} \left(-\frac{\mathcal{J}_\oplus}{\partial_\oplus f} + \frac{\mathcal{J}_\ominus}{\partial_\ominus f} + 2b A \right) - \frac{\varkappa}{2\partial_\oplus f \partial_\ominus f} \frac{\delta \mathcal{S}}{\delta A}, \\
 \delta A &= \frac{\varepsilon}{2} \left(\frac{\partial_\oplus A}{\partial_\oplus f} + \frac{\partial_\ominus A}{\partial_\ominus f} \right) + \frac{\varkappa}{2\partial_\oplus f \partial_\ominus f} \frac{\delta \mathcal{S}}{\delta \tilde{x}}.
 \end{aligned} \tag{2.29}$$

So one sees that the symmetry parameterized by ε corresponds to a genuine gauge symmetry while the one parameterized by \varkappa is a trivial equations of motion symmetry. Eliminating A through its equations of motion, eq. (2.16) the \varkappa dependent term in $\delta \tilde{x}$ drops out and the transformations rules for x , \tilde{x} and f exactly reduce to the PST transformations in eq. (2.23).

Concluding: we initially had $2d$ gauge fields and d abelian gauge symmetries. Imposing the gauge choice $\partial_\oplus f A_\ominus = \partial_\ominus f A_\oplus$ eliminates half of the gauge fields but introduces one new degree of freedom f leaving one unfixed gauge symmetry which appears as the PST gauge symmetry in the way outlined above. The PST symmetry acts as a shift on f allowing it to be used to put $f = \tau$ which leads to the Tseytlin doubled formulation.

2.3 Equations of motion in the PST doubled formalism

We can now see how the desired chirality constraints, eq. (1.6), follow as equations of motion in this approach. For a single chiral boson a clear explanation of this was provided in [55] and we adapt this to the doubled string taking into account the twisted nature of the constraints.

The equations of motion that follows from a variation in \mathbb{X} of the doubled action (2.18) can be expressed as,

$$0 = \partial_\oplus \left(\mathcal{H} P_+ \nabla_\ominus \mathbb{X} - \frac{\partial_\ominus f}{\partial_\oplus f} P_- \nabla_\oplus \mathbb{X} \right) + \partial_\ominus \left(\mathcal{H} P_- \nabla_\oplus \mathbb{X} - \frac{\partial_\oplus f}{\partial_\ominus f} P_+ \nabla_\ominus \mathbb{X} \right). \tag{2.30}$$

Introducing a one-form with components,

$$v_\oplus = \frac{\partial_\oplus f}{\sqrt{\partial_\oplus f \partial_\ominus f}}, \quad v_\ominus = \frac{\partial_\ominus f}{\sqrt{\partial_\oplus f \partial_\ominus f}}, \tag{2.31}$$

allows the equations of motion to be recast as,

$$0 = d(v\Lambda), \quad \Lambda = v_\oplus \mathcal{H} P_+ \nabla_\ominus \mathbb{X} - v_\ominus \mathcal{H} P_- \nabla_\oplus \mathbb{X}. \tag{2.32}$$

The homogenous solution $\Lambda = 0$ corresponds exactly, after making use of the chiral projectors P_\pm , to the chirality constraint,

$$P_+ \nabla_\ominus \mathbb{X} = 0, \quad P_- \nabla_\oplus \mathbb{X} = 0, \tag{2.33}$$

i.e. the covariant version of eq. (1.6) that incorporates the connection. There is also an inhomogeneous solution of the form $\Lambda_I = \Gamma_I(f) \sqrt{\partial_\oplus f \partial_\ominus f}$ since then $v\Lambda = df\Gamma(f)$ is

trivially closed. However this is a pure gauge piece; under the residual gauge symmetry $\delta\mathbb{X} = \mathbb{T}(f)$ we have,

$$\begin{aligned}\delta\Lambda &= \frac{1}{\sqrt{\partial_{\pm}f\partial_{\mp}f}} (\partial_{\pm}f\mathcal{H}P_{+}\partial_{\mp}\mathbb{T} - \partial_{\mp}f\mathcal{H}P_{-}\partial_{\pm}\mathbb{T}) \\ &= \sqrt{\partial_{\pm}f\partial_{\mp}f} (\mathcal{H}P_{+} - \mathcal{H}P_{-})\mathbb{T}' = \sqrt{\partial_{\pm}f\partial_{\mp}f}\eta\mathbb{T}',\end{aligned}\tag{2.34}$$

which is of the correct form to be gauged away with $\Gamma_I(f) = \eta\mathbb{T}'$.

Performing the variation with respect to f yields an equation of motion,

$$\begin{aligned}0 &= \partial_{\pm} \left[\frac{1}{\partial_{\mp}f} (P_{+}\nabla_{\mp}\mathbb{X})^T \mathcal{H}(P_{+}\nabla_{\mp}\mathbb{X}) - \frac{\partial_{\mp}f}{(\partial_{\pm}f)^2} (P_{-}\nabla_{\pm}\mathbb{X})^T \mathcal{H}(P_{-}\nabla_{\pm}\mathbb{X}) \right] \\ &\quad - \partial_{\mp} \left[\frac{\partial_{\pm}f}{(\partial_{\mp}f)^2} (P_{+}\nabla_{\mp}\mathbb{X})^T \mathcal{H}(P_{+}\nabla_{\mp}\mathbb{X}) - \frac{1}{\partial_{\pm}f} (P_{-}\nabla_{\pm}\mathbb{X})^T \mathcal{H}(P_{-}\nabla_{\pm}\mathbb{X}) \right].\end{aligned}\tag{2.35}$$

Here the projectors P_{\pm} come in handy to show that this equation can be recast as

$$0 = d \left(v \frac{\Lambda^T \eta \Lambda}{\sqrt{\partial_{\pm}f\partial_{\mp}f}} \right),\tag{2.36}$$

and hence follows as a consequence of the field equation for \mathbb{X} . That this does not give rise to extra dynamical equations is a manifestation of the PST gauge symmetry.

2.4 Gauge fixing and the dilaton

In our above derivations we introduced a gauge fixing condition,

$$0 = \partial_{\pm}f A_{=} - \partial_{\mp}f A_{\pm}.\tag{2.37}$$

Let us consider how this should be done in a path integral. We begin with the ill-defined,

$$Z = \int [d\mathbb{X}][dA_{\pm}][dA_{=}] e^{-i \int \mathcal{L}[A_{\pm}, A_{=}, \mathbb{X}]},\tag{2.38}$$

and insert the gauge fixing condition and Jacobian,

$$Z = \int [d\mathbb{X}][dA_{\pm}][dA_{=}] \delta(\partial_{\pm}f A_{=} - \partial_{\mp}f A_{\pm}) \det(\partial_{\pm}f\partial_{\mp} - \partial_{\mp}f\partial_{\pm}) e^{-i \int \mathcal{L}[A_{\pm}, A_{=}, \mathbb{X}]}. \tag{2.39}$$

At this stage the function f should not be considered dynamical but rather it is a fixed background object that defines a gauge fixing. The delta function restricts the path integral and since this is just an algebraic equation one can solve it by replacing $A_{=}$ with $A_{\pm} \frac{\partial_{\mp}f}{\partial_{\pm}f}$. Hence,

$$\begin{aligned}Z[f] &= \int [d\mathbb{X}][dA_{\pm}][dA_{=}] \frac{1}{\partial_{\pm}f} \delta \left(A_{=} - \frac{\partial_{\mp}f}{\partial_{\pm}f} A_{\pm} \right) \det(\partial_{\pm}f\partial_{\mp} - \partial_{\mp}f\partial_{\pm}) e^{-i \int \mathcal{L}[A_{\pm}, A_{=}, \mathbb{X}]} \\ &= \int [d\mathbb{X}][dA_{\pm}] \frac{1}{\partial_{\pm}f} \det(\partial_{\pm}f\partial_{\mp} - \partial_{\mp}f\partial_{\pm}) e^{-i \int \mathcal{L}[A_{\pm}, A_{\pm} \frac{\partial_{\mp}f}{\partial_{\pm}f}, \mathbb{X}]} \\ &= \int [d\mathbb{X}][dA][db][dc] e^{-i \int \mathcal{L}[A, \mathbb{X}; f] + \mathcal{L}_{gh}[b, c; f]},\end{aligned}\tag{2.40}$$

in which we made the final change of variables $A_{\pm} = A\partial_{\pm}f$ and the ghost Lagrangian is given by

$$\mathcal{L}_{gh} = \partial_{\pm}f b \partial_{=}c - \partial_{=}f b \partial_{\pm}c . \tag{2.41}$$

The PST symmetry, which extends to the ghost sector as,

$$\begin{aligned} \delta f &= \varepsilon , \\ \delta \mathbb{X} &= \frac{\varepsilon}{\partial_{\pm}f} P_{-} \nabla_{\pm} \mathbb{X} + \frac{\varepsilon}{\partial_{=}f} P_{+} \nabla_{=} \mathbb{X} , \\ \delta b &= \frac{1}{2} \varepsilon \left(\frac{\partial_{\pm}b}{\partial_{\pm}f} - \frac{\partial_{=}b}{\partial_{=}f} \right) , \\ \delta c &= \frac{1}{2} \varepsilon \left(\frac{\partial_{\pm}c}{\partial_{\pm}f} - \frac{\partial_{=}c}{\partial_{=}f} \right) , \end{aligned} \tag{2.42}$$

can now be re-interpreted as saying nothing more than $Z[f]$ does not depend on the gauge fixing choice. We can then simply choose to integrate over choices of the gauge fixing function f in much the same way as one averages over gauge choices to obtain R_{ξ} gauge in QED. That is we can consider,

$$Z = \frac{1}{\text{vol}_{\text{PST}}} \int [df] Z[f] , \tag{2.43}$$

in which we divide by the volume of the PST group. Since the PST symmetry acts a simple shift on f , it can be fixed without the need for further ghost terms.

To progress to the doubled formalism we now need to integrate out the gauge fields A in this path integral. As is well known, under T-duality, the dilaton receives a shift which in the Buscher procedure can be attributed to the determinant that comes from the Gaussian integral over the gauge fields. A useful mnemonic to obtain the correct shift is that the string frame supergravity measure $\sqrt{|g|}e^{-2\phi}$ should be invariant. For $g \rightarrow g^{-1}$ this means that T-dual dilaton is given by

$$\phi' = \phi - \frac{1}{2} \ln \det g . \tag{2.44}$$

On the other hand a T-duality invariant ‘‘doubled dilaton’’ is given by

$$\Phi = \phi - \frac{1}{4} \ln \det g . \tag{2.45}$$

We can see that in the above derivation it is this doubled dilaton that emerges automatically in the covariant doubled formalism for elementary reasons; whereas in a tradition Buscher procedure one integrates out *two* components of a gauge field in the Gaussian term $A_{\pm}gA_{\pm}$ giving essentially a factor of $\det(g)^{-1}$, in the covariant fixing we have a Gaussian term $AgA\partial_{\pm}f\partial_{=}f$ and we integrate over a *single* mode, A , giving rise to a determinant factor $\det(g)^{-\frac{1}{2}} \times (\partial_{\pm}f\partial_{=}f)^{-\frac{d}{2}}$. The determinant of the metric enters with half the power and thus will give rise to a Fradkin Tseytlin coupling of to the doubled dilaton eq. (2.45). Note that even if we begin with a non-flat geometry in which the normal dilaton is constant the doubled dilaton will not be.

2.5 A comment on chiral gauging

In the derivation above we started with the usual string σ -model and performed an unusual gauge fixing in a Buscher procedure to obtain the manifestly Lorentz covariant doubled sigma model whose equations of motion imply chirality conditions. One might wish to adopt a different tactic namely to begin with a *doubled* sigma-model from the outset and invoke the constraints via a gauging procedure. In a previous paper, [49], two of the present authors emphasized that PST style actions for (supersymmetric) chiral bosons can be obtained by gauging a chiral (super)-conformal symmetry and by then specifying a Beltrami parametrisation for the corresponding gauge field. This approach also works in the current case although in a rather surprising way which we will now illustrate (suppressing spectators for simplicity).

We start with a Hull style σ -model on the doubled space,

$$S_{Hull} = \frac{1}{2} \int d^2\sigma \mathcal{H}_{IJ}(y) \partial_{\mp} \mathbb{X}^I \partial_{\pm} \mathbb{X}^J + \dots, \quad (2.46)$$

in which the ellipses indicate spectator terms that will play no role in what follows. We want to furnish the action with a gauge invariance,

$$\delta \mathbb{X} = \varepsilon^{\mp} P_{-} \partial_{\mp} \mathbb{X} + \varepsilon^{\pm} P_{+} \partial_{\pm} \mathbb{X}, \quad (2.47)$$

such that only the field configurations obeying the constraint eq. (1.6) are physical. *A priori* the gauge parameters ε^{\pm} correspond to independent symmetries however as we shall soon see gauge invariance will force them to be related. It is curious that in the ungauged action that this putative symmetry does not correspond to a rigid invariance (unless $\partial_y \mathcal{H} = 0$); this is one of the features that makes the following gauging procedure rather atypical. We proceed by introducing gauge fields $h_{\mp\mp}$ and $h_{\pm\pm}$ (not to be confused with the usual worldsheet metric components) with the usual conformal transformation rules,

$$\begin{aligned} \delta h_{\mp\mp} &= \partial_{\mp} \varepsilon^{\pm} + \varepsilon^{\pm} \partial_{\pm} h_{\mp\mp} - \partial_{\pm} \varepsilon^{\mp} h_{\mp\mp}, \\ \delta h_{\pm\pm} &= \partial_{\pm} \varepsilon^{\mp} + \varepsilon^{\mp} \partial_{\mp} h_{\pm\pm} - \partial_{\mp} \varepsilon^{\pm} h_{\pm\pm}, \end{aligned} \quad (2.48)$$

and “covariant” derivatives,

$$\nabla_{\mp}^h \mathbb{X}^I = \partial_{\mp} \mathbb{X}^I - h_{\mp\mp} (P_{+} \partial_{\pm} \mathbb{X})^I, \quad \nabla_{\pm}^h \mathbb{X}^I = \partial_{\pm} \mathbb{X}^I - h_{\pm\pm} (P_{-} \partial_{\mp} \mathbb{X})^I. \quad (2.49)$$

In fact, though their structure is informed by the usual conformal covariant derivative, these derivatives are not at all covariant as e.g. $\delta \nabla_{\pm}^h \mathbb{X} |_{\nabla_{\pm}^h \mathbb{X} = 0} \neq 0$. That these derivatives are not actually covariant makes the fact that the following construction works even more surprising. We continue regardless of this and consider the “gauged” action,

$$S_{\text{gauged}} = \frac{1}{2} \int d^2\sigma \mathcal{H}_{IJ} \nabla_{\mp}^h \mathbb{X}^I \nabla_{\pm}^h \mathbb{X}^J + \dots. \quad (2.50)$$

Performing a gauge variation, integrating by parts all terms containing $\partial_{\mp\mp} \mathbb{X}$ and $\partial_{\pm\pm} \mathbb{X}$ and making use of the identities obeyed by the projectors eq. (A.13) results in a variation

of the Lagrange density,

$$\begin{aligned} \frac{1}{2} \delta \mathcal{L}_{\text{gauged}} = & -\varepsilon^\dagger \partial_\mp \mathcal{H}_{IJ} (P_- \partial_\mp \mathbb{X})^I \partial_- \mathbb{X}^J + 2\varepsilon^\dagger h_{==} \eta_{IJ} (P_- \partial_\mp P_+ \partial_- \mathbb{X})^I \partial_\mp \mathbb{X}^J \\ & - \varepsilon^\dagger \partial_- \mathcal{H}_{IJ} \partial_\mp \mathbb{X}^I (P_+ \partial_- \mathbb{X})^J - 2\varepsilon^\dagger h_{\mp\mp} \eta_{IJ} \partial_- \mathbb{X}^I (P_+ \partial_- P_- \partial_\mp) \mathbb{X}^J \end{aligned} \quad (2.51)$$

To cancel this we see that the gauge variation parameters are not independent and one must enforce,

$$h_{\mp\mp} h_{==} = 1, \quad \varepsilon^\dagger h_{\mp\mp} = \varepsilon^\dagger, \quad \varepsilon^\dagger h_{==} = \varepsilon^\dagger. \quad (2.52)$$

It is easy to see that these are consistent with the gauge transformations rules. With these identifications and the definitions of the projectors we find that indeed action eq. (2.50) is gauge invariant. Solving the first of these relations with a Beltrami parametrisation

$$h_{\mp\mp} = \frac{\partial_\mp f}{\partial_- f}, \quad h_{==} = \frac{\partial_- f}{\partial_\mp f}. \quad (2.53)$$

and noting that the quadratic term in gauge fields vanishes by virtue of $(P_+)^T \mathcal{H} P_- = 0$, one immediately recovers from eq. (2.50) the Lorentz covariant action PST action of eq. (1.9).

3 Application to non-abelian T-duality

Let us now consider the generalisation of these ideas to a non-Abelian group⁶ of isometries, and for clarity we ignore spectator fields first and then give the result with their inclusion after. Let us consider a σ -model on a d -dimensional group space G specified by the Lagrange density,

$$\mathcal{L} = L_\mp^a E_{ab} L_+^b, \quad (3.1)$$

in which E_{ab} is a constant (or possibly spectator dependant) matrix and the L^a are the pull back to the worldsheet of the left invariant Maurer-Cartan forms for a group element $g \in G$ with conventions,

$$L^a = -i \delta^{ab} \text{Tr} T_b g^{-1} dg, \quad dL^a = \frac{1}{2} f^a{}_{bc} L^b \wedge L^c, \quad [T_a, T_b] = i f_{ab}{}^c T_c, \quad \text{Tr} T_a T_b = \delta_{ab}. \quad (3.2)$$

This σ -model has a global G_L invariance that we can gauge by introducing a connection one-form $A = i A^a T_a$ in the algebra of G which minimally couples through the introduction of covariant derivatives,

$$\partial g \rightarrow Dg = \partial g - Ag. \quad (3.3)$$

The connection has a field strength,

$$F_{\mp=} = \partial_\mp A_- - \partial_- A_\mp - [A_\mp, A_-]. \quad (3.4)$$

⁶In this work we restrict our attention to the cases in which the structure constants of the group dualised are traceless; this is to avoid the occurrence of a mixed gravitational-gauge anomaly when coupled to a curved background which upon dualisation can give rise to a Weyl anomaly i.e. a dual background that does not obey the (super)gravity equations. For discussion of this and related issues see [50–52].

We see then that the gauging replaces the Maurer-Cartan forms with,

$$L^a \rightarrow L^a - A^a D_{ab}, \quad D_{ab} = \text{Tr}(T_a g T_b g^{-1}), \quad (3.5)$$

in which we have defined the adjoint action D_{ab} which obeys $D.D^T = \mathbf{1}$. Then the action is invariant under the G_L local transformations,

$$g \rightarrow h^{-1}g, \quad A \rightarrow h^{-1}Ah - h^{-1}\partial h. \quad (3.6)$$

In addition we introduce a Lagrange multiplier term $\text{Tr} v F_{\pm} =$ to enforce a flat connection which is gauge invariant provided the Lagrange multipliers transforms in the adjoint,

$$v \rightarrow h^{-1}vh. \quad (3.7)$$

After integration by parts of the Lagrange multiplier term one finds a gauged Lagrange density,

$$\begin{aligned} \mathcal{L}_{\text{gauged}} = & L_{\pm}^T E L_{\pm} - A_{\pm}^T D E L_{\pm} - L_{\pm}^T E D^T A_{\pm} + A_{\pm} D E D^T A_{\pm} \\ & + A_{\pm}^T \partial_{\pm} v - A_{\pm}^T \partial_{\pm} v + A_{\pm} F A_{\pm}, \end{aligned} \quad (3.8)$$

in which $F_{ab} = -i f_{ab}^c v_c$. Obtaining the non-Abelian T-dual is then achieved by gauge fixing g to the identity and integrating out the gauge fields to yield,

$$\mathcal{L}_{\text{dual}} = \partial_{\pm} v^T (E + F)^{-1} \partial_{\pm} v. \quad (3.9)$$

Now we invoke the covariant gauge fixing choice,

$$A_{\pm}^a = A^a \partial_{\pm} f, \quad A_{\pm}^a = A^a \partial_{\pm} f, \quad (3.10)$$

and integrate out the field A . Since the non-Abelian term in the field strength $[A_{\pm}, A_{\pm}]$ vanishes in this gauge the manipulations are actually quite similar to the Abelian case described earlier.

If we define,

$$\mathbb{L}^A = \begin{pmatrix} L^a \\ \tilde{L}_a \end{pmatrix}, \quad \tilde{L}_a = D_{ba}(g) \partial v^b, \quad (3.11)$$

then one finds a doubled action,

$$\mathcal{L} = \frac{1}{2} \mathbb{L}_{\pm}^T \mathcal{H} \mathbb{L}_{\pm} - \frac{1}{2} \mathbb{L}_{\pm}^T \Omega \mathbb{L}_{\pm} - \frac{1}{2} \frac{\partial_{\pm} f}{\partial_{\pm} f} \mathbb{L}_{\pm}^T (\mathcal{H} P_{-}) \mathbb{L}_{\pm} - \frac{1}{2} \frac{\partial_{\pm} f}{\partial_{\pm} f} \mathbb{L}_{\pm}^T (\mathcal{H} P_{+}) \mathbb{L}_{\pm}. \quad (3.12)$$

Notice that the pull back of $\Omega_{AB} \mathbb{L}^A \wedge \mathbb{L}^B = 2L^a \wedge \tilde{L}_a$ which entered the action as a purely topological term in the Abelian case is no-longer topological, instead it serves as a Kalb-Ramond potential. Since,

$$d\tilde{L}_a = d(D_{ba} \partial v^b) = f_{ab}^c L^b \wedge \tilde{L}_c, \quad (3.13)$$

this implies a three-form flux

$$H = d(L^a \wedge \tilde{L}_a) = -\frac{1}{2} f_{bc}^a L^b \wedge L^c \wedge \tilde{L}_a. \quad (3.14)$$

It is quite straightforward to extend these considerations to include a fibration and spectator coordinates. Starting with the Lagrangian,

$$\mathcal{L} = L_{\mp}^T E L_{=} + L_{\mp}^T M \partial_{=} y + \partial_{\mp} y^T N L_{=} + \partial_{\mp} y^T K \partial_{=} y, \quad (3.15)$$

in which E, M, N, K may have arbitrary dependence on the coordinates y , and repeating the above procedure yields the doubled action,

$$\begin{aligned} \mathcal{L} = & \frac{1}{2} \mathbb{L}_{\mp}^{\nabla T} \mathcal{H} \mathbb{L}_{=}^{\nabla} - \frac{1}{2} \mathbb{L}_{\mp}^T \Omega \mathbb{L}_{=} - \frac{1}{2} \frac{\partial_{=} f}{\partial_{\mp} f} \mathbb{L}_{\mp}^{\nabla T} (\mathcal{H} P_{-}) \mathbb{L}_{\mp}^{\nabla} - \frac{1}{2} \frac{\partial_{\mp} f}{\partial_{=} f} \mathbb{L}_{=}^{\nabla T} (\mathcal{H} P_{+}) \mathbb{L}_{=}^{\nabla} \\ & + \frac{1}{2} \mathbb{L}_{\mp}^T \eta \mathbb{B}_{=} - \frac{1}{2} \mathbb{B}_{\mp}^T \eta \mathbb{L}_{=} + \hat{K}_{\mu\nu} \partial_{\mp} y^{\mu} \partial_{=} y^{\nu}, \end{aligned} \quad (3.16)$$

in which we defined,

$$\mathbb{L}^{\nabla} = \mathbb{L} + \mathbb{B}, \quad P_{+} \mathbb{B} = \begin{pmatrix} g^{-1} M \\ E^T g^{-1} M \end{pmatrix}, \quad P_{-} \mathbb{B} = \begin{pmatrix} g^{-1} N^T \\ -E g^{-1} N^T \end{pmatrix}, \quad (3.17)$$

and the modified Lagrangian on the base involves \hat{K} defined as in the Abelian case in eq. (2.21).

3.1 Relation to Poisson Lie doubled formalism

There is an existing formulation for a non-Abelian T-duality double formalism, which in fact also accommodates a further generalisation known as Poisson Lie T-duality [41, 42]. The result we obtained in eq. (3.12) can be understood in this context. To do so we remind the reader of a little technology — the Drinfeld double [62].

The Drinfeld double \mathcal{D} is a Lie algebra that can be decomposed as the sum of two sub algebras $\mathcal{D} = \mathcal{G} \oplus \tilde{\mathcal{G}}$ that are maximally isotropic with respect to an inner product $\langle \cdot | \cdot \rangle$. If T_a are the generators of \mathcal{G} and \tilde{T}^a those of $\tilde{\mathcal{G}}$, then the generators of the double $\mathbb{T}_A = \{T_a, \tilde{T}^a\}$ obey $\eta_{AB} = \langle \mathbb{T}_A | \mathbb{T}_B \rangle$ i.e.,

$$\langle T_a | T_b \rangle = \langle \tilde{T}^a | \tilde{T}^b \rangle = 0, \quad \langle T_a | \tilde{T}^b \rangle = \delta_a^b. \quad (3.18)$$

The structure constants of the double $[\mathbb{T}_A, \mathbb{T}_B] = i F_{AB}^C \mathbb{T}_C$ decompose as,

$$[T_a, T_b] = i f_{ab}^c T_c, \quad [\tilde{T}^a, \tilde{T}^b] = i \tilde{f}^{ab}_c \tilde{T}^c, \quad [T_a, \tilde{T}^b] = i \tilde{f}^{bc}_a T_c - i f_{ac}^b \tilde{T}^c, \quad (3.19)$$

and the Jacobi identity places further constraints on the admissible choices of \mathcal{G} and $\tilde{\mathcal{G}}$. We also need to define some matrices for $g \in G$ the group of \mathcal{G} ,

$$g^{-1} T_a g = a_a^b T_b, \quad g^{-1} \tilde{T}^a g = b^{ab} T_b + (a^{-1})_b^a \tilde{T}^b, \quad \Pi^{ab} = b^{ca} a_c^b, \quad (3.20)$$

and tilde analogues, $\tilde{a}, \tilde{b}, \tilde{\Pi}$, for $\tilde{g} \in \tilde{G}$. The statement of Poisson-Lie T-duality then is the equivalence between the two σ -models,

$$S = \int d^2 \sigma (E^{-1} + \Pi)_{ab}^{-1} L_{\mp}^a L_{=}^b, \quad \tilde{S} = \int d^2 \sigma [(E + \tilde{\Pi})^{-1}]^{ab} \tilde{L}_{\mp a} \tilde{L}_{=}^b, \quad (3.21)$$

where L and \check{L} refer to the left-invariant one-forms of G and \check{G} respectively (a háček is used to distinguish \check{L} from \tilde{L} introduced above).

If $G = \check{G} = U(1)^d$ we have an Abelian double and the dual pairs of σ -models correspond to Abelian T-duals. If \mathcal{G} is the algebra of some d -dimensional non-Abelian Lie group and $\check{\mathcal{G}} = u(1)^d$, the double is said to be semi-Abelian and the two dual models in eq. (3.21) reduce exactly to non-Abelian T-dual related actions of eq. (3.1) and eq. (3.9). The case where neither \check{G} nor G are Abelian corresponds to a dualisation of non-isometric σ -models and has recently found new applications in the context of the relation between certain classes of integrable models in two dimensions known as η and λ deformations.⁷

That the actions in eq. (3.21) are dual was established in [41, 42] by constructing an action on the Drinfeld double given by,

$$S_{\text{PLT}} = \frac{1}{2} \int_{\Sigma} \langle l^{-1} \partial_{\sigma} l | l^{-1} \partial_{\tau} l \rangle + \frac{1}{12} \int_{M_3} \langle l^{-1} dl | [l^{-1} dl, l^{-1} dl] \rangle - \frac{1}{2} \int_{\Sigma} \langle l^{-1} \partial_{\sigma} l | \mathcal{H} | l^{-1} \partial_{\sigma} l \rangle, \quad (3.22)$$

in which l is group element of the Drinfeld double, $\mathcal{H}_{AB} = \langle \mathbb{T}_A | \mathcal{H} | \mathbb{T}_B \rangle$ is just the $O(d, d)$ coset generalised metric and M_3 is a suitable three-manifold whose boundary is the worldsheet Σ . This action can be thought of as deforming the chiral WZW model of Sonnenschein [56] and is essentially a doubled action in a Tseytlin style non-covariant gauge. Parametrising $l = \tilde{g}g$ with $\tilde{g} \in \check{G}$ and $g \in G$ and integrating out \tilde{g} will give the action S of eq. (3.21) and doing the converse with $l = g\tilde{g}$ gives the dual action \tilde{S} .

There also exists a PST version of the doubled action eq. (3.22) given by [57],⁸

$$\begin{aligned} S_{\text{PLT-PST}} = & \frac{1}{2} \int_{\Sigma} \langle l^{-1} \partial_{\pm} l | \mathcal{H} | l^{-1} \partial_{\pm} l \rangle + \frac{1}{12} \int_{M_3} \langle l^{-1} dl | [l^{-1} dl, l^{-1} dl] \rangle \\ & - \frac{1}{2} \int_{\Sigma} \frac{\partial_{\pm} f}{\partial_{\pm} f} \langle l^{-1} \partial_{\pm} l | \mathcal{H} P_{\pm} | l^{-1} \partial_{\pm} l \rangle + \frac{1}{2} \int_{\Sigma} \frac{\partial_{\pm} f}{\partial_{\pm} f} \langle l^{-1} \partial_{\pm} l | \mathcal{H} P_{\mp} | l^{-1} \partial_{\pm} l \rangle. \end{aligned} \quad (3.23)$$

Let us now restrict our attention to the semi-Abelian double appropriate for non-Abelian T-duality. The first thing to note is that if we express the group element on the double as $l = \tilde{g}g$ then,

$$l^{-1} dl = g^{-1} \tilde{g}^{-1} d\tilde{g}g + g^{-1} dg = idv_a g^{-1} \tilde{T}^a g + g^{-1} dg = ia^{-1}(g)_b^a dv_a \tilde{T}^b + iL^a T_a, \quad (3.24)$$

in which we parametrised $\tilde{g} = \exp(iv_a \tilde{T}^a)$. However since $a^{-1}(g)$ is no more than the adjoint action, $D^T(g)$, we see that,

$$l^{-1} dl = i\check{L}_a \tilde{T}^a + iL^a T_a = i\mathbb{L}^A \mathbb{T}_A \quad (3.25)$$

coinciding with the definition in eq. (3.11). One can now see that all the terms involving \mathcal{H} in (3.12) directly match those in eq. (3.23). All that remains is to understand the WZ term for which we observe,

$$\langle l^{-1} dl | [l^{-1} dl, l^{-1} dl] \rangle = F_{AB}{}^C \eta_{CD} \mathbb{L}^A \wedge \mathbb{L}^B \wedge \mathbb{L}^C = 3f_{ab}{}^c L^a \wedge L^b \wedge \check{L}_c \quad (3.26)$$

⁷For a brief summary of this direction the reader may consult [63] and references within.

⁸To the best of our knowledge this has not appeared in the literature and we are grateful to K. Sfetsos for sharing his notes in which it was derived.

which is in agreement with eq. (3.14), thus confirming what started off as a topological term in the Abelian doubled theory is precisely what is needed as a potential for the WZ in the non-Abelian doubled theory.

To close this section let us finally note that actions of this style have been used in [64–67] to describe strings whose doubled target space is a twisted torus and have been conjectured to give a world sheet description of $\mathcal{N} = 4$ electrically gauged supergravities. The works [64, 65] have the chirality constraint as supplementary to the action and those of [66, 67] use the Tseytlin style formulation. It will be of interest to make more precise the linkage between the spacetime violation of section condition leading to gauged supergravities as in [23–26] and the generalised notions of Poisson-Lie duality whose worldsheet generalised metric has dependence on both coordinates and their duals.

4 Towards the supersymmetric doubled string

A supersymmetric first order manifest T-dual invariant worldsheet formulation is still lacking. Even a non-covariant Tseytlin type description has not been given yet. We provide here a first step by constructing the simplest model which has an $\mathcal{N} = (0, 1)$ worldsheet supersymmetry. While extremely simple it already exhibits all subtleties which also occur in models with more supersymmetry. We will keep supersymmetry manifest by working in $\mathcal{N} = (0, 1)$ superspace (conventions can be found at the beginning of appendix A).

4.1 The covariant formulation

For simplicity we restrict ourselves to a trivial bundle structure. All results can rather straightforwardly be generalized to a non-trivial bundle structure. The starting point is the Lagrange density,

$$\mathcal{L} = 2i \partial_{\mp} x E D_{-} x + \mathcal{L}_S(y), \tag{4.1}$$

where x is a set of adapted coordinates such that the background field $E = E(y)$ depends only on the spectator coordinates y whose dynamics is governed by \mathcal{L}_S . In order to gauge the isometries $x \rightarrow x + \varepsilon$ we introduce gauge fields A_{\mp} and A_{-} and using Lagrange multipliers \tilde{x} we impose flatness. The gauged σ -model is given by,⁹

$$\mathcal{L} = 2i \partial_{\mp} x E D_{-} x + 2i A_{\mp} E A_{-} + 2i A_{\mp} \mathcal{J}_{-} + 2i \mathcal{J}_{\mp} A_{-} + \mathcal{L}_S(y), \tag{4.2}$$

where,

$$\mathcal{J}_{\mp} = E^T \partial_{\mp} x - \partial_{\mp} \tilde{x}, \quad \mathcal{J}_{-} = E D_{-} x + D_{-} \tilde{x}. \tag{4.3}$$

Integrating over \tilde{x} gives the original model back. Motivated by the non-supersymmetric case we impose the gauge choice,

$$A_{\mp} = \partial_{\mp} f A, \quad A_{-} = D_{-} f A, \tag{4.4}$$

⁹Note that we could as well have introduced the full $\mathcal{N} = (0, 1)$ gauge multiplet which consists of A_{\mp} , A_{-} and A_{+} . Introducing Lagrange multipliers which constrain all fieldstrengths $F_{\mp+}$, $F_{\mp-}$, F_{+-} and F_{--} to zero, one finds that upon making a field redefinition on \tilde{x} this reduces to the current case.

where f is an arbitrary function and A is a set of $d\mathcal{N} = (0,1)$ scalar superfields. The Lagrange density becomes so,

$$\mathcal{L} = 2i \partial_{\pm} x E D_- x + 2i \partial_{\pm} f D_- f A g A + 2i A (\partial_{\pm} f \mathcal{J}_- + D_- f \mathcal{J}_{\pm}) + \mathcal{L}_S(y). \quad (4.5)$$

The residual gauge invariance is given by,

$$x \rightarrow x + \varepsilon(f), \quad A \rightarrow A - \partial_f \varepsilon(f), \quad f \rightarrow f. \quad (4.6)$$

In addition the action is invariant under,

$$\tilde{x} \rightarrow \tilde{x} + \tilde{\varepsilon}(f), \quad (4.7)$$

as well. The equations of motion for A are given by,

$$D_- f A = -\frac{1}{2} g^{-1} \mathcal{J}_- - \frac{1}{2} \frac{D_- f}{\partial_{\pm} f} g^{-1} \mathcal{J}_{\pm}, \quad (4.8)$$

which, because of the fermionic nature of $D_- f$, *cannot* directly be solved for A . However one notes that by multiplying the equations of motion by $D_- f$ one obtains the constraint,

$$D_- f \mathcal{J}_- = 0. \quad (4.9)$$

Acting with D_- on this one gets,

$$\mathcal{J}_- = 2i \frac{D_- f}{\partial_{\pm} f} D_- \mathcal{J}_-. \quad (4.10)$$

Despite appearances, eq. (4.9) is an algebraic constraint on the components of the superfields. Indeed writing the superspace components of x and \tilde{x} , $x = x + i\theta^- \psi_-$ and $\tilde{x} = \tilde{x} + i\theta^- \tilde{\psi}_-$, one readily verifies using eq. (4.10) that the constraint can be solved for half of the component fields ψ and $\tilde{\psi}$. As such this constraint can simply be imposed using Lagrange multipliers. This is very reminiscent of the nilpotent superfield constraints ([58, 59]; a systematic treatment and review of nilpotent superfields can be found in [60]). Using this in the equations of motion eq. (4.8) one solves for A ,

$$A = -\frac{1}{2} \frac{1}{\partial_{\pm} f} g^{-1} \mathcal{J}_{\pm} - \frac{i}{\partial_{\pm} f} g^{-1} D_- \mathcal{J}_- + D_- f (\dots), \quad (4.11)$$

where the terms following $D_- f$ remain undetermined but they will not play any role in what follows. Using this to eliminate A in the first order Lagrange density eq. (4.5) one gets,

$$\begin{aligned} \mathcal{L} = & 2i \partial_{\pm} x E D_- x - i \mathcal{J}_{\pm} g^{-1} \mathcal{J}_- - \frac{i}{2} \frac{D_- f}{\partial_{\pm} f} \mathcal{J}_{\pm} g^{-1} \mathcal{J}_{\pm} \\ & + \frac{\partial_{\pm} f}{\partial_{\pm} f} \mathcal{J}_- g^{-1} D_- \mathcal{J}_- + \mathcal{L}_S(y), \end{aligned} \quad (4.12)$$

together with the constraint given in eq. (4.9). Repeatedly using eqs. (4.9) and (4.10), one rewrites this as,

$$\begin{aligned} \mathcal{L} = & 2 \frac{\partial_{\pm} f}{\partial_{\pm} f} \left(D_- - \frac{D_- f}{\partial_{\pm} f} \partial_{\pm} \right) \mathbb{X} \eta P_+ D_- (P_+ D_- \mathbb{X}) - i \left(D_- - \frac{D_- f}{\partial_{\pm} f} \partial_{\pm} \right) \mathbb{X} \eta P_- \partial_{\pm} \mathbb{X} \\ & + 2i \frac{D_- f}{\partial_{\pm} f} \Psi_+ \eta P_+ D_- \mathbb{X} + \mathcal{L}_S(y), \end{aligned} \quad (4.13)$$

where the topological term has been dropped. The Lagrange multiplier Ψ_+ , which transforms under $O(d, d; \mathbb{Z})$ in the same way as \mathbb{X} , enforces the constraint,

$$\mu_- \equiv D_- f P_+ D_- \mathbb{X} = 0, \quad (4.14)$$

which is equivalent to the constraint in eq. (4.9). Note that because of the presence of the projection operator P_+ only d components of the Lagrange multiplier Ψ_+ effectively appear in the lagrangian.

The covariant action has two classes of symmetries,

The residual gauge symmetry Even after we gauge fixed the gauged non-linear σ -model there is a residual gauge invariance left:

$$\begin{aligned} f &\rightarrow f \\ \mathbb{X} &\rightarrow \mathbb{X} + \Lambda(f) \\ \Psi_+ &\rightarrow \Psi_+ - \frac{i}{2} D_- S \partial_{\mp} \Lambda, \end{aligned} \quad (4.15)$$

where $\Lambda(f)$ is a $2d \times 1$ column matrix of arbitrary functions of f .

The PST symmetry As the gauge fixing function f was randomly chosen, we expect that it can be shifted in an arbitrary way which is the origin of the PST symmetry. To see this first consider the action defined by eq. (4.13) in the absence of the Lagrange multiplier term. After some significant effort one determines that under the variation,

$$\begin{aligned} \delta f &= \varepsilon \\ \delta \mathbb{X} &= \frac{\varepsilon}{\partial_{\mp} f} P_- \partial_{\mp} \mathbb{X} + \frac{2i\varepsilon}{\partial_- f} P_+ D_- (P_+ D_- \mathbb{X}) - \frac{2i\varepsilon}{\partial_- f} D_- f P_+ D_- \left(\frac{1}{\partial_{\mp} f} P_- \partial_{\mp} \mathbb{X} \right), \end{aligned} \quad (4.16)$$

one produces only terms that are proportional to the constraint μ defined in eq. (4.14) or derivatives thereof. Moreover, this property is shared by the variation of the constraint itself. As a result, one is then guaranteed a transformation of the Lagrange multiplier that renders the whole Lagrangian (4.13) invariant. For pedagogical purpose we illustrate this in the simplest case of constant background fields in the appendix.

4.2 The Tseytlin formulation

We now pass to a Lorentz non-covariant gauge for the PST symmetry in order to recover a Tseytlin like formulation. Choosing $f = f(\tau)$ [49] we get that the Lagrange density eq. (4.13) becomes,

$$\begin{aligned} \mathcal{L} &= -\frac{i}{2} \hat{D} \mathbb{X} \eta \partial_{\tau} \mathbb{X} + \frac{i}{2} \hat{D} \mathbb{X} \mathcal{H} \partial_{\sigma} \mathbb{X} + \hat{D} \mathbb{X} \eta P_+ D_- S D_- \mathbb{X} \\ &\quad + \theta^- \Psi_+ \eta P_+ D_- \mathbb{X} + \mathcal{L}_S(y), \end{aligned} \quad (4.17)$$

where,

$$\hat{D} \equiv D_- + \frac{i}{2} \theta^- \partial_{\mp} = \partial_- + \frac{i}{2} \theta^- \partial_{\sigma}, \quad \hat{D}^2 = \frac{i}{2} \partial_{\sigma}, \quad \theta^- D_- = \theta^- \hat{D}. \quad (4.18)$$

The equations of motion for Ψ_+ and \mathbb{X} read,

$$\begin{aligned} \theta^- P_+ D_- \mathbb{X} = \theta^- P_+ \hat{D} \mathbb{X} = 0, \\ \hat{D} \left(\partial_\tau \mathbb{X} - S \partial_\sigma \mathbb{X} + i \hat{D} S \hat{D} \mathbb{X} + i P_+ D_- S D_- \mathbb{X} \right. \\ \left. - i D_- S P_+ \hat{D} \mathbb{X} + \theta^- P_+ \Psi_+ \right) = 0. \end{aligned} \quad (4.19)$$

The second of these equations immediately implies,

$$\partial_\tau \mathbb{X} - S \partial_\sigma \mathbb{X} + i \hat{D} S \hat{D} \mathbb{X} + i P_+ D_- S D_- \mathbb{X} - i D_- S P_+ \hat{D} \mathbb{X} + \theta^- P_+ \Psi_+ = F(\tau), \quad (4.20)$$

with $F(\tau)$ an arbitrary function of τ . Using the residual gauge invariance, eq. (4.15), which assumes now the form,

$$\begin{aligned} \mathbb{X} &\rightarrow \mathbb{X} + \Lambda(\tau) \\ \Psi_+ &\rightarrow \Psi_+ - \frac{i}{4} D_- S \partial_\tau \Lambda(\tau), \end{aligned} \quad (4.21)$$

this function can be put to zero leaving us with,

$$\partial_\tau \mathbb{X} - S \partial_\sigma \mathbb{X} + i \hat{D} S \hat{D} \mathbb{X} + i P_+ D_- S D_- \mathbb{X} - i D_- S P_+ \hat{D} \mathbb{X} + \theta^- P_+ \Psi_+ = 0. \quad (4.22)$$

The first equation in eq. (4.19) implies,

$$P_+ \hat{D} \mathbb{X} = \theta^- P_+ \hat{D} (P_+ \hat{D} \mathbb{X}). \quad (4.23)$$

Acting with P_- on eq. (4.22) and using eq. (4.23) one obtains,

$$P_- \partial_+ \mathbb{X} = 0. \quad (4.24)$$

Acting with P_+ on eq. (4.22) allows one to solve for $\theta^- P_+ \Psi_+$. However multiplying this equation with θ^- gives,

$$\theta^- P_+ D_- (P_+ D_- \mathbb{X}) = 0. \quad (4.25)$$

From the first equation in eq. (4.19) one also gets,

$$P_+ D_- \mathbb{X} = \theta^- P_+ D_- (P_+ D_- \mathbb{X}) \quad (4.26)$$

which combined with eq. (4.25) gives,

$$P_+ D_- \mathbb{X} = 0. \quad (4.27)$$

So the equations of motion of the model in the Tseytlin gauge indeed reproduce the constraints eqs. (4.24) and (4.27) as expected.

4.3 Component form

For convenience we now give the results expanded into components as defined by the superfield expansion $\mathbb{X} = \mathbb{X} + i\theta^-\Xi_-$. We use that $D_-\hat{D}|_{\theta=0} = \frac{i}{2}\partial_\sigma$ to find that the lagrangian can be expressed as,

$$D_-\mathcal{L}|_{\theta=0} = \frac{1}{4}\partial_\sigma\mathbb{X}\eta\partial_\tau\mathbb{X} - \frac{1}{4}\partial_\sigma\mathbb{X}\mathcal{H}\partial_\sigma\mathbb{X} - i\Xi_-\eta(\partial_\pm\Xi_- + iD_-S\partial_\sigma\mathbb{X}) + \frac{1}{2}\Xi_-\eta D_-SD_-S\Xi_- + i\Psi_+\eta P_+\Xi_- . \quad (4.28)$$

Here, and in the following component expressions, we adopt the implicit notation that $D_-S \equiv D_-S|_{\theta=0}$ and $\mathbb{X} \equiv \mathbb{X}|_{\theta=0}$. Note the presence of a four-fermi interaction term that would have been hard to guess from the bosonic case; this term will prove essential in what follows. As above, the variation with respect to the Lagrange multiplier enforces,

$$P_+\Xi_- = 0 . \quad (4.29)$$

The variation with respect to \mathbb{X} gives an equation of motion that is a total ∂_σ derivative which, using the residual gauge redundancy, can be integrated to yield,

$$P_+(\partial_-\mathbb{X} - D_-S\Xi_-) = 0 , \quad P_-\partial_\pm\mathbb{X} = 0 . \quad (4.30)$$

The variation with respect to the fermion is more intricate and yields,

$$2\partial_\pm\Xi_- + iD_-S\partial_\sigma\mathbb{X} + iD_-SD_-S\Xi_- + P_+\Psi_+ = 0 . \quad (4.31)$$

The P_+ projection of this equation fixes the Lagrange multiplier however the P_- projection provides a fermion equation of motion,

$$\begin{aligned} 0 &= P_-\left(\partial_\pm\Xi_- + \frac{i}{2}D_-S\partial_\sigma\mathbb{X} + \frac{i}{2}D_-SP_+D_-S\Xi_-\right) \\ &= P_-\left(\partial_\pm\Xi_- + \frac{i}{2}D_-S\partial_\sigma\mathbb{X} + \frac{i}{2}D_-S\partial_-\mathbb{X}\right) \\ &= P_-\left(\partial_\pm\Xi_- + \frac{i}{2}D_-S\partial_\pm\mathbb{X}\right) , \end{aligned} \quad (4.32)$$

in which we used that $P_-D_-S = D_-SP_+$ and the equation of motion eq. (4.30) to pass to the final line. Together the equations (4.29), (4.30), and (4.32) are exactly the component content of the superspace equations,

$$P_+D_-\mathbb{X} = P_-\partial_\pm\mathbb{X} = 0 . \quad (4.33)$$

5 Discussion and open problems

In this paper we have clarified many missing details in the construct of the manifestly T-duality symmetric worldsheet theory and shown how such a formulation can be obtained through a novel gauge fixing choice. This procedure allowed us to make the generalisation to

the supersymmetric case in the most minimal, but still non-trivial, extension to $\mathcal{N} = (0, 1)$ supersymmetry. The essential reason for the complexity comes from having in the theory chiral bosons whose chirality is mis-aligned with that of the supersymmetry.

The natural next direction here is to extend this work to both $\mathcal{N} = (1, 1)$ and $\mathcal{N} = (2, 2)$ supersymmetry. The $\mathcal{N} = (1, 1)$ case is already under study and will directly follow from the techniques outlined within. The $\mathcal{N} = (2, 2)$ remains less obvious but should be an exciting arena to make a direct link to Hitchin’s generalised geometry. Initial results in this direction have recently been reported by one of us [61]. It will also be of interest to consider spacetime supersymmetry generalising the result of [68] to curved backgrounds.

Our discussion has been local in nature and there are sensitive issues, even in the bosonic theory, that will have to be addressed if the derivation used is to be implemented in full Polyakov sum over genus at the quantum level. At first sight our gauge fixing choice $\partial_{\pm} f A_{\pm} = \partial_{\mp} f A_{\mp}$ looks to require the introduction of a globally defined exact form $u = df$. In fact this is too strong, as is known from previous studies of the PST formalism [69] it is sufficient to work with a closed form $du = 0$. Put another way [70], the residual gauge invariance is sufficient to eliminate cohomological contributions that come from integrating the equation of motion to produce the constraint. However one still requires in the manipulations that f has nowhere vanishing first derivatives so as to allow such terms to appear in the denominator of fractions in a PST approach. Since this necessitates the existence of a nowhere vanishing vector field, it is not obvious how to extend from \mathbb{R}^2 to a compact Riemann surfaces of non-vanishing Euler character. The appearance of the function f was via a gauge fixing, the interpretation here is that the gauge fixing choice adopted can not be globally extended and is only locally well defined. A possible resolution is to find a suitable global fixing or to work patchwise. Understanding this will be an interesting topic for further investigation

This formulation may have great utility; by calculating the β -functions in a perhaps naive manner one could hope to find background field equations for the generalised metric which relate to the target space formulation of *DFT*. Whilst the non-covariant Tseytlin style action allows for such progress to be made at 1-loop order [31–33], it is very hard to extend this to higher loops — the non-Lorentz invariant structure makes the regularisation of Feynman diagrams taxing at best. Using the covariant formulation may alleviate some of this trouble. Optimistically we hope that the techniques in this paper could prove to be a valuable starting point for the calculation of duality covariant corrections to *DFT*.

Acknowledgments

This work is supported in part by the Belgian Federal Science Policy Office through the Interuniversity Attraction Pole P7/37, and in part by the “FWO-Vlaanderen” through the project G020714N and a postdoctoral fellowship, and by the Vrije Universiteit Brussel through the Strategic Research Program “High-Energy Physics”. We are grateful to J.P. Ang, David Berman, Chris Blair and Martin Roček and for numerous illuminating discussions, and to K. Sfetsos for discussions and sharing with us his work on the PST formulation of Poisson-Lie duality. We would like to thank the Simons Center for Geometry

and Physics for providing a stimulating environment during the conference “Generalized Geometry and T-dualities” while part of this work was finalized.

A Conventions

Throughout the paper we use worldsheet lightcone coordinates,

$$\sigma^{\pm} = \tau + \sigma, \quad \sigma^{\mp} = \tau - \sigma. \tag{A.1}$$

In $N = (0, 1)$ superspace this is extended by adding one one-component real fermionic coordinate θ^- . The fermionic derivative D_- satisfies,

$$D_-^2 = -\frac{i}{2} \partial_- . \tag{A.2}$$

The T-duality group $O(d, d; \mathbb{Z})$ plays a central role. In the present context $\mathcal{O} \in O(d, d; \mathbb{Z})$ is a $2d \times 2d$ matrix with integer entries satisfying,

$$\mathcal{O}^T \eta \mathcal{O} = \eta, \tag{A.3}$$

where,

$$\eta = \begin{pmatrix} 0 & \mathbf{1} \\ \mathbf{1} & 0 \end{pmatrix}. \tag{A.4}$$

In the current paper we use adapted coordinates x^i and their T-duals \tilde{x}_i , $i \in \{1, \dots, d\}$ together with spectator coordinates y^μ , $\mu \in \{1, \dots, D - d\}$. We write the adapted coordinates together with the dual ones into a single $O(d, d; \mathbb{Z})$ multiplet,

$$\mathbb{X} = \begin{pmatrix} x \\ \tilde{x} \end{pmatrix}, \tag{A.5}$$

which transforms under the action of $\mathcal{O} \in O(d, d; \mathbb{Z})$ as,

$$\mathbb{X} \rightarrow \mathbb{X}' = \mathcal{O}^{-1} \mathbb{X}. \tag{A.6}$$

Writing $\mathcal{O} \in O(d, d; \mathbb{Z})$ as,

$$\mathcal{O} = \begin{pmatrix} A & B \\ C & D \end{pmatrix}, \tag{A.7}$$

the background fields $E_{ij}(y) = g_{ij}(y) + b_{ij}(y)$ transform non-linearly,

$$E \rightarrow E' = (EB + D)^{-1}(EA + C), \tag{A.8}$$

however, the *generalised metric* \mathcal{H} ,

$$\mathcal{H} = \begin{pmatrix} 1 & -b \\ 0 & 1 \end{pmatrix} \begin{pmatrix} g & 0 \\ 0 & g^{-1} \end{pmatrix} \begin{pmatrix} 1 & 0 \\ b & 1 \end{pmatrix} = \begin{pmatrix} g - b g^{-1} b & -b g^{-1} \\ g^{-1} b & g^{-1} \end{pmatrix}, \tag{A.9}$$

transforms linearly,

$$\mathcal{H} \rightarrow \mathcal{H}' = \mathcal{O}^T \mathcal{H} \mathcal{O}. \quad (\text{A.10})$$

From \mathcal{H} we construct an almost product structure S ,

$$S = \eta \mathcal{H}, \quad (\text{A.11})$$

such that $S^2 = +\mathbf{1}$. Using this we introduce the orthogonal projection operators P_+ and P_- ,

$$P_{\pm} = \frac{1}{2} (\mathbf{1} \pm S). \quad (\text{A.12})$$

Some often used identities include,

$$\mathcal{H} P_{\pm} = P_{\pm}^T \mathcal{H} = \pm \eta \mathcal{H}, \quad P_{\pm} \partial_y S = \partial_y S P_{\mp}. \quad (\text{A.13})$$

B PST symmetry in the $\mathcal{N} = (0, 1)$ case

We assume constant background fields and for notation convenience define,

$$\sigma = \frac{1}{\partial_- f} P_+ \partial_- \mathbb{X}, \quad \rho = \frac{1}{\partial_+ f} P_- \partial_+ \mathbb{X}. \quad (\text{B.1})$$

In terms of these quantities we can recast the Lagrangian as,

$$\mathcal{L} = -i \partial_+ f D_- X \eta (\sigma + \rho) + i D_- f \partial_+ \mathbb{X} \eta (\sigma + \rho) + i \Psi_{\mp\mp} \eta \mu_-, \quad (\text{B.2})$$

where we have defined $\Psi_{\mp\mp} \partial_- f = 2\Psi_{\mp}$ and in which the constraint, and its derivative are given by,

$$\mu_- = D_- f P_+ D_- \mathbb{X}, \quad \nu_- = \frac{2i}{\partial_- f} D_- \mu_- = P_+ D_- X - \sigma D_- f. \quad (\text{B.3})$$

The PST transformations in the case of constant backgrounds reduce to,

$$\delta f = \varepsilon, \quad \delta \mathbb{X} = \varepsilon (\sigma + \rho), \quad (\text{B.4})$$

which exactly replicate those already seen in the bosonic $\mathcal{N} = (0, 0)$ case. Under these transformation one finds,

$$\delta \mu_- = D_- (\varepsilon \nu_-), \quad (\text{B.5})$$

and the variation of the Lagrangian reads,

$$\delta \mathcal{L} = i \delta \Psi_{\mp\mp} \eta \mu_- + \Lambda_{\mp} \eta \nu_- - \Lambda_{\mp\mp} \eta \partial_- \nu_-, \quad (\text{B.6})$$

in which we defined

$$\begin{aligned} \Lambda_{\mp} &= i \varepsilon \left(D_- \Psi_{\mp\mp} - \frac{\partial_+ f}{\partial_- f} \partial_- \sigma + \partial_+ \sigma \right), \\ \Lambda_{\mp\mp} &= -i \varepsilon \left(\frac{\partial_+ f}{\partial_- f} \sigma - \frac{\partial_+ \mathbb{X}}{\partial_- f} \right). \end{aligned} \quad (\text{B.7})$$

Then invariance of the action is recovered with,

$$\delta\Psi_{\pm\pm} = D_- \left(\frac{2\Lambda_{\pm}}{\partial_- f} \right) + D_- \left(\frac{2}{\partial_- f} \partial_- \Lambda_{\pm\pm} \right). \quad (\text{B.8})$$

One could choose other rewritings of the action by adding on terms proportional to the constraint, but due to eq. (B.5) the transformation rule of the Lagrange multiplier can be modified to ensure the resulting action still possesses the PST symmetry.
