The Cherenkov light from charged particles is tracked through the ice to the DOMs (Lundberg et al. 2007; Chirkin 2013c, and from work by C. Kopper in 2011⁵⁵) taking into account the Antarctic ice properties (Ackermann et al. 2006; Aartsen et al. 2013b; Chirkin 2013a). Finally, the detector response and data acquisition are simulated. The same simulation chain is used for atmospheric muons which are simulated with CORSIKA (Heck et al. 1998). Both neutrino simulation and atmospheric muon simulation can be weighted to different fluxes.

The event selection for IC59 is identical to Aartsen et al. (2014c) and covers the up-going zenith range 90° – 180° . For the later seasons the zenith range has been enlarged to additionally cover angles between 85° and 90° as in Aartsen et al. (2015c) where the overburden by the Antarctic ice sheet is still more than 12 km of water equivalent. Additionally, the separation of mis-reconstructed atmospheric muons and well reconstructed neutrino-induced muons has been improved by using boosted decision trees (BDTs). For IC2011 and later, the AdaBoost algorithm (Freund & Schapire 1997) implemented in Pedregosa et al. (2011) has been used. Due to filter and processing changes after the first complete detector season a separate BDT has been trained for IC2011 and the data are treated separately as for the seasons IC59 and IC79.

For the optimization of the BDT we use simulations of up-going muon neutrinos following an E^{-2} spectrum which produce a muon via a charged-current interaction. In addition, to define the signal for the BDT, only simulated events with directions reconstructed to better than 5° are used. The background is defined by atmospheric muons from cosmic-ray air showers that have been mis-reconstructed as up-going. The simulation is weighted to the cosmic-ray model in Gaisser (2012). The features used in the training of the BDT are characteristics of the event topology and parameters evaluating the quality of the reconstructions. These parameters have been selected requiring good agreement between experimental and

Figure 2. Exposure. Top: individual contributions to the total exposure from the different detector configurations. Bottom: total exposure for different zenith regions for the combined data set. Note that the exposure is based on the sum of the effective areas of ν_μ and $\bar{\nu}_\mu$. Therefore, the total number of events is obtained by integrating the product of exposure and averaged neutrino flux $\Phi_{(\nu_\mu + \bar{\nu}_\mu)/2}$ over the neutrino energy and solid angle.

simulated data. The threshold of the BDT classifier is chosen by considering the neutrino selection efficiency and the purity. In order to model the atmospheric background using simulation a high purity is required, rejecting nearly all atmospheric muons. The chosen threshold results in a purity which is better than 99.7%. The remaining background clusters at low energies and is strongly dominated by atmospheric neutrinos. Thus, it cannot affect the analysis and therefore does not have to be taken into account as a separate template in the likelihood fit. The performance estimates are based on 10-fold cross validation (Narsky & Porter 2013) and a separate validation set. Additionally, a fit of the data has been performed excluding events from above the horizon between 85° and 90° . Since the fit results remain nearly unaffected we conclude that the fit is not biased by any unaccounted high-energy muons.

Figure 2 shows the total exposure for the different detector configurations and for the full data set for different ranges in cosine zenith. The total number of events as well as the total

Table 1
Summary of the Data Selection

Season	$\theta_{\min} - \theta_{\max}$ (deg)	t_{live} (days)	N_{event}
IC59	90–180	348.1	21, 411
IC79	85–180	310.0	36, 880
IC2011	85–180	342.1	71, 191
IC2012–2014	85–180	1059.8	222, 812

Note. The table gives the number of events and the effective live time for each data set used.

live time categorized by season are summarized in Table 1. For the best-fit astrophysical flux (see Section 4.2) the expected number of astrophysical muon neutrinos included in these data is approximately 500.

3. ANALYSIS METHOD

3.1. Likelihood Method

The experimental and simulated data are binned in two observables sensitive to distinguish between signal and background: reconstructed muon energy and cosine of the zenith angle. These bins are analyzed by a maximum likelihood approach. The expectation in each bin is a function of the signal and nuisance parameters. The likelihood used in this analysis is given by Chirkin (2013b) and is the same as used in Aartsen et al. (2014c). The likelihood per bin is

$$\mathcal{L}_i = \left(\frac{\mu_i}{s_i/n_s} \right)^{s_i} \cdot \left(\frac{\mu_i}{d_i} \right)^{d_i}, \quad (1)$$

where n_s defines the ratio of the live times for simulation and experimental data, d_i is the number of events in the data, s_i the number of simulated events, and μ_i the expectation in bin i . With this likelihood the expectation μ_i is optimized based on the knowledge of the statistics of the simulated and experimental data set. Unlike a Poisson likelihood, we account for the finite statistics of simulated data which becomes relevant for small bin contents in a multi-dimensional parameter space. In the limit of infinite statistics of simulated data this likelihood converges to a saturated Poisson likelihood. A version of Equation (1), modified for weighted events according to Chirkin (2013b), is used in the analysis.

The per-bin expectation is given by

$$\begin{aligned} \mu_i(\boldsymbol{\theta}; \boldsymbol{\xi}) = & \mu_i^{\text{conv.}}(\boldsymbol{\xi}) \\ & + \mu_i^{\text{prompt}}(\Phi_{\text{prompt}}; \Delta\gamma_{\text{CR}}, \lambda_{\text{CR}}, \boldsymbol{\xi}_{\text{det}}) \\ & + \mu_i^{\text{astro.}}(\Phi_{\text{astro}}, \gamma_{\text{astro}}; \boldsymbol{\xi}_{\text{det}}), \end{aligned}$$

which depends on the signal $\boldsymbol{\theta}$ and nuisance parameters $\boldsymbol{\xi}$ (see Table 2). Here, $\boldsymbol{\xi}_{\text{det}}$ corresponds to the parameters taking into account the neutrino detection uncertainties (see Section 3.2.1). In this analysis, the signal parameters consist of the astrophysical flux parameters and the prompt flux parameter. The astrophysical flux model used here is a single power-law flux described by two parameters: the normalization Φ_{astro} at 100 TeV neutrino energy and the spectral index γ_{astro} :

$$\Phi_{\nu+\bar{\nu}} = \Phi_{\text{astro}} \cdot \left(\frac{E}{100 \text{ TeV}} \right)^{-\gamma_{\text{astro}}}. \quad (2)$$

Table 2
Nuisance Parameters

	IC59	IC79	IC2011	IC2012-2014	scaling	Best Fit (68% C.L.)
<i>Flux properties:</i>						
Conventional flux Φ_{conv}	1.028	1.047	1.184	1.194	relative	0.998 ± 0.003
Kaon-pion ratio K/π	1.310	1.514	1.002	1.032	relative	0.977 ± 0.027
Cosmic-ray spectral index $\Delta_{\gamma_{\text{CR}}}$	-0.049	-0.049	-0.061	0.012	absolute	$0.008^{+0.004}_{-0.023}$
Cosmic-ray model λ_{CR}	1.0 (H3p)	1.0 (H3p)	1.0 (H3p)	1.0 (H3p)	absolute	0.0–0.5
Optical efficiency ϵ_{opt}	1.011	0.974	1.042	1.056	relative	1.002 ± 0.002
<i>Optical ice properties:</i>						
Scattering length λ_{scat}	1.027	1.014	relative	0.999 ± 0.005
Absorption length λ_{abs}	1.000	1.047	relative	1.001 ± 0.004
Absorption/scattering length $\lambda_{\text{abs/scat}}$...	0.991	relative	1.000 ± 0.004
Ice model λ_{ice1} [SpiceMie,WHAM]	0. (SpiceMie)	SpiceMie (fixed)	absolute	$0.000 + 0.014$
Ice model λ_{ice2} [SpiceMie,SpiceLea]	0.551	SpiceLea (fixed)	absolute	0.006 ± 0.057

Note. Columns two to five show the best-fit values for each data sample individually where the fit was performed on data within a predefined background region. The background regions were defined as follows: for IC59 the muon energy loss proxy must be less than 1 GeV m^{-1} and for IC79, IC2011 and IC2012-2014 the muon energy proxy must be less than 10 TeV. These best-fit values are used as default values to define a common baseline. In the combined likelihood fit the default values are then scaled by global nuisance parameters where the best-fit values including the 68% C.L. error determined by the profile likelihood technique are shown in the last column. Column six shows if the scaling is an absolute or relative change with respect to the default values. Note that the nuisance parameters quoted here are allowed to change for each data set to absorb differences in the simulations which are caused by improvements in the simulation code and models. Thus, they do not have to reflect their real physical quantities.

The prompt neutrino flux is described by the prediction taken from Enberg et al. (2008) (ERS) where the absolute normalization Φ_{prompt} is taken as free parameter. In addition, nuisance parameters are introduced to take into account systematic uncertainties, e.g., the conventional atmospheric neutrino flux is described by the prediction taken from Honda et al. (2007) and the flux normalization Φ_{conv} is taken as a nuisance parameter. Note that the conventional and prompt neutrino flux predictions have been corrected for the knee in the cosmic-ray spectrum based on the cosmic-ray models in Hoerandel (2003) and Gaisser (2012) (see Section 3.2). The implementation of nuisance parameters is described in Section 3.2 in more detail.

The global likelihood, which is maximized, is the product of all per-bin-likelihoods $\mathcal{L} = \prod_i \mathcal{L}_i$. The significances and parameter uncertainties in this analysis are derived using the profile likelihood technique and Wilks’ theorem (Wilks 1938). The applicability of Wilks’ theorem has been tested and verified by ensemble studies.

3.2. Systematic Uncertainties

In order to account for systematic uncertainties, resulting from the imperfect background and signal modeling, continuous nuisance parameters valid for the entire energy and zenith range are introduced. The systematic uncertainties can be divided into two categories: neutrino detection uncertainties and atmospheric flux uncertainties. The former include the optical efficiency of the detector, the neutrino–nucleon cross section, the muon energy loss cross section and the optical properties of the Antarctic ice. The latter include the flux normalizations, the spectral shape and composition of the cosmic-ray spectrum in the “knee” region, the spectral index of the primary cosmic-ray spectrum, and the relative production yield of pions and kaons in the atmosphere. The implementation of these uncertainties as nuisance parameters in the likelihood function is done similar to Aartsen et al. (2014c). Main improvements with respect to previous analyses are the

parameterizations of the systematic detector effects as unbinned functions of both fit observables (S. Schoenen 2016, in preparation) using adaptive kernel density estimation and the interpolations between specific models to account for the model uncertainties. The systematic detector effects are studied by simulated data sets where the default parameters are changed within their uncertainties. In cases where no interpolation between specific models is used, the nuisance parameters are implemented by using independent correction factors $f_k(\xi_k)$. These factors scale the default per-bin expectation μ_i^0 for each flux contribution with respect to the individual nuisance parameter ξ_k :

$$\mu_i^0 \mapsto \mu_i^0 \cdot \prod_k f_k(\xi_k).$$

3.2.1. Neutrino Detection Uncertainties

Optical efficiency of the detector. The optical efficiency ϵ_{opt} takes into account all uncertainties related to the light production and detection in the detector, e.g., the number of produced Cherenkov photons, the overall optical transparency of the ice, the photon detection efficiency of the DOMs, and the shadowing of photons by detector components. Since the optical efficiency is directly connected to the brightness of an event as observed with the detector, its uncertainty results in an uncertainty on the reconstructed energy scale. The effect has been parameterized as a function of the muon energy proxy and the cosine zenith angle and is implemented as a nuisance parameter. The uncertainty on the optical efficiency is estimated to be less than 15%. Since the ice properties of the refrozen water within the drill holes differ from the bulk ice properties they are taken into account as a modification of the angular acceptance (Aartsen et al. 2013b).

Optical properties of the Antarctic ice. The probability of a Cherenkov photon to be detected by a DOM depends not only on the optical efficiency of the detector but also on the optical transparency of the Antarctic ice. The main processes are

scattering and absorption of photons on their path to the DOM. For the Antarctic ice this is modeled by depth-dependent scattering and absorption lengths. The modeling is done using measured data from calibration light sources that are integrated into the DOMs. Different models of the ice have been developed during the operation of IceCube. For this analysis the following ice models are used: *WHAM* for IC59 (based on a measurement of the optical properties of the glacial ice at the South Pole presented in Ackermann et al. 2006), *SpiceMie* for IC59, IC79 and IC2011 (Aartsen et al. 2013b), and *SpiceLea* for IC2011-2014 (Chirkin 2013a). For all available simulation data sets, the effects of the optical ice properties as a function of reconstructed energy proxy and cosine zenith are parameterized and implemented as a nuisance parameter. This is done for different ice models and each detector configuration. The parameterization is done by introducing a parameter λ_{ice} that describes a linear combination ($\lambda_{\text{ice}} \cdot M_1 + (1 - \lambda_{\text{ice}}) \cdot M_2$) between two ice models where M_1 and M_2 are the expectations per bin corresponding to the two ice models. In addition, for a given ice model the effects of different scattering lengths λ_{scat} and absorption lengths λ_{abs} on the muon energy proxy and the cosine zenith angle have been parameterized. Owing to missing simulations this could not be done for IC59. For IC79 the scattering and absorption lengths have been varied simultaneously resulting in only one effective nuisance parameter $\lambda_{\text{abs/scat}}$. From IC2011 on the scattering and absorption lengths have been varied separately. For more information see Table 2. The individual uncertainty for both quantities is estimated to be less than 10%. The scattering length mainly influences the angular resolution of the neutrino arrival direction and therefore the reconstructed zenith angle. Since the cosine zenith bin width of the analysis is relatively coarse, the effect of this uncertainty on the observable distribution is small. The absorption length mainly influences the flux normalization and the shape of the energy distribution. This effect is much larger, compared to the scattering length effect.

3.2.2. Atmospheric Flux Uncertainties

Flux normalization. The uncertainty on the normalization of the conventional atmospheric neutrino flux is implemented as a nuisance parameter Φ_{conv} that scales the flux normalization of the model by Honda et al. (2007). This model has been extrapolated to higher energy based on the method in taking into account a more realistic spectrum of cosmic rays and their composition (Illana et al. 2011; Schukraft 2013). Note that the uncertainty of this parameter is relatively large, on the order of 30%. Thus, it absorbs any kind of uncertainty which influences the global flux normalization in the fit.

Cosmic-ray model and spectral index. The composition of the cosmic rays is uncertain, in particular above the knee at an energy of about 3 PeV. Models are based on the superposition of Galactic cosmic-rays with rigidity-dependent cut-offs and an emerging extragalactic component. Since conventional and prompt atmospheric neutrinos are produced by cosmic-ray interactions within the atmosphere, the uncertainty on the cosmic-ray spectrum also affects the expectation of these neutrinos. The effect of different cosmic-ray models is parameterized by λ_{CR} as a function of the muon energy proxy and the cosine zenith angle similar to the discrete ice models. Here, a linear combination between Hoerandel (2003) and Gaisser (2012), which are the extreme cases, is used. In addition to the effects between different cosmic-ray models an

overall change in the cosmic-ray spectral index affects the expectation of atmospheric neutrinos. Therefore, a shift of the cosmic-ray spectral index $\Delta\gamma_{\text{CR}}$ is implemented as a nuisance parameter representing the uncertainty on the cosmic-ray spectral index. The uncertainty is estimated to be of the order of 4% based on differences between the aforementioned cosmic-ray models. A positive $\Delta\gamma_{\text{CR}}$ corresponds to a softer energy spectrum.

Kaon-to-pion ratio. Conventional atmospheric neutrinos are produced by decays of pions and kaons which are themselves produced in air showers. The relative contribution of kaons and pions K/π to the production of conventional atmospheric neutrinos affects their zenith angle distribution. In this analysis it is defined by the ratio of the integrated neutrino fluxes from kaon and pion decays. Using the neutrino flux parameterization from Gaisser (1990) fitted to the conventional atmospheric neutrino prediction from Honda et al. (2007) between 1 and 10 TeV, the kaon-to-pion ratio is implemented as a nuisance parameter where the uncertainty is estimated to be of the order of 10%.

Atmospheric temperature effects. The expected number of conventional atmospheric neutrinos is directly connected to the number of pion and kaon decays in the atmosphere. A denser atmosphere will increase the interaction probability for pions and kaons relative to the decay probability, which reduces the overall neutrino flux. Thus, annual temperature fluctuations influence the expectation of conventional atmospheric neutrinos. Since the prediction of conventional atmospheric neutrinos from Honda et al. (2007) is based on the standard US atmosphere, the expectation is corrected for annual temperature fluctuations. This is done using the formalism reported in Desiati et al. (2014) and data measured by the instrument AIRS installed on the *AQUA* satellite (AIRS Science Team/Joao Texeira 2013). The effect of this correction is estimated to be of the order of 2% with an uncertainty of about 0.1%.

With the goal of achieving an unbiased result for the signal parameters, we note that many nuisance parameters were deliberately chosen correlated (see Figure 3). For example, the optical detector efficiency is correlated to the Cherenkov light yield uncertainty and to the effects of the uncertainties in the muon energy loss cross sections. In cases where the effects of one uncertainty are fully absorbed by other nuisance parameters only one parameter has been implemented for better numerical stability of the fit. A list of the implemented parameters is given in Table 2. In order to obtain an unbiased result the nuisance parameters are implemented without priors which is tested to have no effect on the sensitivity for an astrophysical or prompt flux.

The fit procedure was tested by generating pseudo experiments where the input parameters were varied. The fit of the signal parameters was found to be robust and unbiased against the choice of nuisance parameters.

Since IceCube's MC simulations have evolved and improved from year to year, the default expectations for each nuisance parameter have changed for simulated data sets year by year. In order to avoid a tension in the fitted nuisance parameters induced purely by the differences of the simulations, two methods were tested: the implementation of individual nuisance parameters for each year, and the alignment of all nuisance parameters to a common baseline. We found that the two methods give similar sensitivities both for the astrophysical and the prompt flux parameters, and the

Figure 3. Correlation matrix of signal and nuisance parameters. λ_{ice1} describes the linear combination between SpiceMie (Aartsen et al. 2013b) and WHAM (Ackermann et al. 2006) for IC59, λ_{ice2} describes the linear combination between SpiceMie (Aartsen et al. 2013b) and SpiceLea (Chirkin 2013a) for IC2011. $\lambda_{\text{abs/scat}}$ describes the relative change of the ice properties for IC79 and λ_{abs} , λ_{scat} describes the relative change of the ice properties for IC2011-14.

alignment method is chosen since the time consumption for the fit is much lower. The alignment is done by fitting the nuisance parameters in a predefined background region for each year individually. The resulting best-fit values for the nuisance parameters, summarized in Table 2, define the default values for each year. In the combined likelihood fit of all six years these default values are then scaled by global nuisance parameters. The scaling can be either an absolute or relative change with respect to the aligned default values.

The flavor composition at Earth is not identical to the flavor composition at an astrophysical source due to neutrino oscillations. For a source dominated by $p\gamma/pp$ -interactions, the initial flavor ratio of 1:2:0 ($\nu_e:\nu_\mu:\nu_\tau$) is transformed to be approximately equally partitioned among the flavors (Learned & Pakvasa 1995; Athar et al. 2006). Therefore, it is necessary to take into account the muonic decay of taus originating from charged current ν_τ interactions by combining it with the astrophysical muon neutrino flux. A fit of the data with and without this contribution shows that accounting for it leads to a decrease in the astrophysical normalization of about 5% and has no effect on the spectral index. In the rest of the paper we account for the contribution of ν_τ assuming equal partitioning. The astrophysical normalization for other expected flavor compositions of astrophysical neutrino sources can be obtained by rescaling.

3.3. Parametric Unfolding

The best-fit result for the neutrino energy spectrum measured by this analysis can be used to determine for each event a neutrino energy probability density function $P(E_\nu|E_{\text{reco}}^i)$ with respect to its muon energy proxy E_{reco}^i . These functions depend on the assumption for the neutrino energy spectrum and are therefore model-dependent. In particular, for the astrophysical neutrino flux an unbroken, single power law is assumed. For the full six-year data sample the neutrino energy distribution is given by the sum over the probability density function of all events $\sum_i P(E_\nu|E_{\text{reco}}^i)$ where each function is normalized to an

event count of one. Since this approach is model-dependent it is called *parametric unfolding* in the following. Note that this method cannot replace a model-independent unfolding as done in Boerner et al. (2015) for different IceCube data samples.

4. RESULTS OF THE SPECTRAL LIKELIHOOD FIT

4.1. Fit Result

The result of the fit is presented as a set of one-dimensional projections of energy and zenith in Figure 4 separately for each contributing data sample. The experimental data are shown as black crosses, and the best-fit expectations for astrophysical and conventional atmospheric neutrinos are shown as red and blue bands, respectively. An excess of high-energy events consistent with an astrophysical signal above the atmospheric background is visible for each data sample. The overall agreement between the data and the MC of the full data set is good for all energies and zenith angles. We have tested quality of the fit based on the two-dimensional distributions using the ratio between the likelihood (Equation (1)) and the saturated likelihood as test-statistic (Olive et al. 2014). The test-statistic distribution was generated via pseudo experiments based on the best fit. The resulting p -value is 95.4%, indicating a very good agreement between data and MC. All nuisance parameters are fitted to values consistent with their uncertainty (Table 2).

Note that the data sample taken with the 79-string configuration contains roughly twice as many high-energy events above a reconstructed muon energy of 100 TeV than other years (see Figure 4). Nevertheless, the result of the fit for all years is consistent with the fits for individual years. Visual inspection and other cross checks of these events revealed no indication of any time-dependent detector effects. A dedicated analysis searching for time-dependent neutrino sources (Aartsen et al. 2015e) has found no indication of a signal. Therefore, the observations are consistent with a statistical fluctuation.

4.2. Astrophysical Flux

The best fit for the unbroken power-law model of the astrophysical flux results in

$$\Phi_{\nu+\bar{\nu}} = (0.90^{+0.30}_{-0.27}) \cdot (E_\nu/100 \text{ TeV})^{-(2.13 \pm 0.13)} \quad (3)$$

in units of $10^{-18} \text{ GeV}^{-1} \text{ cm}^{-2} \text{ sr}^{-1} \text{ s}^{-1}$. The statistical significance of this flux with respect to the atmospheric-only hypothesis is 5.6 standard deviations. The fit results are shown in Figure 5 and summarized in Table 3. The quoted errors are based on the profile likelihood using Wilks' theorem (Wilks 1938) and include both statistical and systematic uncertainties. No contribution from prompt atmospheric neutrinos is preferred by the best-fit spectrum, and an upper limit, based on the profile likelihood, is shown in Figure 5. For more information about the upper limit for prompt atmospheric neutrinos see Section 6.

The two-dimensional contours of the profile likelihood as a function of the signal parameters are shown in Figure 6. While the fitted astrophysical flux normalization is strongly correlated with the astrophysical spectral index, these astrophysical signal parameters are found to be largely independent of the prompt flux normalization.

The model assumes an unbroken power law for the astrophysical signal. We estimate that neutrinos in the

Figure 4. Distributions of the experimental data for the muon energy proxy (top) and reconstructed zenith (bottom) for each contributing data sample (left: 59-string, center-left: 79-string, center-right: 86-string (2011–2012), right: 86-string (2012–2015)). Note that IC2011 is different from the later years due to changes in the data processing. The best-fit model for astrophysical and atmospheric neutrinos is superimposed. Only statistical errors are shown.

Figure 5. Best-fit neutrino spectra for the unbroken power-law model. The width of the line corresponding to conventional atmospheric neutrinos (blue) represents the one-sigma error on the measured spectrum. The width of the line corresponding to astrophysical neutrinos (red) shows the effect of varying both of the astrophysical parameters within one-sigma of the best fit values, without accounting for correlation. The green line represents the upper limit on the prompt model (Enberg et al. 2008). The horizontal width of the red band denotes the energy range of neutrino energies which contribute 90% to the total likelihood ratio between the best-fit and the conventional atmospheric-only hypothesis. The black crosses show the unfolded spectrum published in Kopper et al. (2015).

experimental data sample with energies mainly between 194 TeV and 7.8 PeV contribute to this observation. This energy range is shown in Figure 5. It defines the central range of neutrino energies that contribute 90% to the total observed likelihood ratio between the best fit and the conventional atmospheric-only hypothesis. Note that this definition is different from Aartsen et al. (2015b, 2015c).

4.3. Multi-PeV Track-like Event

The selected data include one exceptionally high-energy muon event that is shown in Figure 7 (Schoenen & Raelde 2015). The deposited energy has been measured to (2.6 ± 0.3)

Table 3
Best-fit Parameter Values for the Unbroken Power-law Model

Parameter	Best-Fit	68% C.L.
Φ_{astro}	0.90	0.62–1.20
γ_{astro}	2.13	2.00–2.26
Φ_{prompt}	0.00	0.00–0.19

Note. Φ_{astro} is the normalization of the astrophysical neutrino flux at 100 TeV and is given in units of $10^{-18} \text{ GeV}^{-1} \text{ s}^{-1} \text{ sr}^{-1} \text{ cm}^{-2}$. Φ_{prompt} is given in units of the model in Enberg et al. (2008). The normalizations correspond to the sum of neutrinos and antineutrinos.

PeV of equivalent electromagnetic energy Aartsen et al. (2014a). Assuming the best-fit atmospheric energy spectrum from this analysis (see Figure 5) the p -value of this event being of atmospheric origin has been estimated to be less than 0.005%, strongly suggesting an astrophysical origin.

The segmented energy loss reconstruction described in Aartsen et al. (2014a) can be used to reconstruct the direction of through-going muons. This includes the timing of not only the first photon but all photons as well as the total number of photons. The reconstructed direction of the event is given in Table 4 and discussed in Section 5.1.

In order to estimate the angular uncertainty and the most likely muon and neutrino energy we have simulated events with energies according to our best-fit energy spectrum with directions varying by 1° around the best-fit direction. Additionally, the position where the muon enters the instrumented volume has been varied within 10 m. Systematic uncertainties due to the lack of knowledge of the optical ice properties are taken into account by varying the ice model parameters within their uncertainties during the simulation.

Based on these simulations we evaluate the muon energy at the point of entrance into the instrumented volume, that results in the observed deposited energy. The obtained median muon energy is (4.5 ± 1.2) PeV where the error range corresponds to 68% C.L.

Figure 6. Two-dimensional profile likelihood scans of the astrophysical parameter Φ_{astro} , γ_{astro} and the prompt normalization Φ_{prompt} in units of the model in Enberg et al. (2008). The contours at 68%, 95%, and 99% CL assuming Wilks' theorem are shown.

For the estimation of the median expected neutrino energy we have taken into account that high-energy muons arise not only from ν_{μ} charged-current interactions but also from muonic decay of charged-current ν_{τ} interactions and muonic W^{-} decays in $\bar{\nu}_e + e^{-} \rightarrow W^{-}$ interactions. Here, we assume the best-fit astrophysical spectrum and an equal flux of all flavors but include the effects of the Earth's absorption for the specific decl. of the event. Under these assumptions, we find 87.7% probability of a primary ν_{μ} , 10.9% for a primary ν_{τ} and 1.4% for a primary $\bar{\nu}_e$. The respective probability distributions of primary neutrino energy are shown in Figure 8. The expected neutrino energy depends on the primary flavor. The median expected muon neutrino energy is 8.7 PeV for the above assumptions.

The angular reconstruction uncertainty including systematic uncertainties of the Antarctic ice (see Section 3.2) can be estimated from the aforementioned dedicated simulation. Figure 9 shows the angular reconstruction uncertainty for an ensemble of events with similar deposited energy, direction and entry point into the fiducial volume. The angular reconstruction uncertainty is given by the angular distance between the true and the reconstructed muon direction. The median angular uncertainty is 0.23° and the 99% containment is 0.9° . Details of the studies of the multi-PeV track-like event are shown in L. Rädcl (2016, in preparation).

4.4. Test for a Spectral Cut-off

The default hypothesis of an unbroken power law is tested against the hypothesis of a spectral cut-off. For this, an exponential energy cut-off $E_{\nu}^{\text{cut-off}}$ is added to the astrophysical neutrino flux:

$$\Phi_{\nu+\bar{\nu}} = \Phi_{\text{astro}} \cdot \exp\left(-\frac{E_{\nu}}{E_{\nu}^{\text{cut-off}}}\right) \cdot \left(\frac{E_{\nu}}{100 \text{ TeV}}\right)^{-\gamma_{\text{astro}}}. \quad (4)$$

In the fit the spectral index γ_{astro} is highly degenerate with an exponential energy cut-off $E_{\nu}^{\text{cut-off}}$, therefore two scenarios with fixed spectral indices have been tested. For the spectral indices the benchmark model with $\gamma_{\text{astro}} = 2$ and the best-fit value $\gamma_{\text{astro}} = 2.13$ are chosen. Figure 10 shows the two-dimensional contours of the profile likelihood as a function of the signal parameters Φ_{astro} , $E_{\nu}^{\text{cut-off}}$ and Φ_{prompt} . For the benchmark model a cut-off is slightly preferred at the level of one standard deviation. This is an expected behavior as the actual best-fit spectral index is softer. Thus, fixing the spectral index to a harder spectrum will result in a slight deficit at the highest neutrino energies. When fixing the spectral index to the best-fit value for an unbroken power law, this slight preference for an exponential cut-off disappears. These results are nearly independent of the prompt flux normalization.

4.5. Unfolded Astrophysical Spectrum

The best-fit results for the neutrino energy spectrum as quoted in Table 3 and the knowledge of the connection between the reconstructed muon and true neutrino energy can be used to unfold a neutrino energy distribution for the six-year sample (see Section 3.3). The results of this parametric unfolding are shown in Figure 11 as a cumulative energy distribution of the number of neutrinos with energies greater than E_{ν} . The statistical error band is given by the square root of this number. The error band that corresponds to the uncertainty

Figure 7. Event view of the PeV track-like event recorded by IceCube on 2014 June 11. Left: top and two side views. Right: perspective view. Shown are the IceCube DOMs as black dots. The colors indicate the photon arrival time from red (early) to green (late) and the size of the sphere the amount of measured charge. Note that the scaling is nonlinear and a doubling in sphere size corresponds to one hundred times the measured charge. The blue line shows the reconstructed particle track. The reconstructed equatorial coordinates of this event are decl.=11°42' and R.A.=110°63'. This event deposited an energy of 2.6 ± 0.3 PeV within the detection volume.

on the astrophysical flux is determined by varying the astrophysical spectrum within the measured uncertainties on the astrophysical flux parameters. Based on the per-event probability density function $P(E_\nu | E_{\text{reco}}^i)$ the median neutrino energy for each event can also be calculated. Figure 12 shows the distribution of the median neutrino energies for the six-year sample.

In both distributions a clear excess above approximately 100 TeV in neutrino energy is visible, and is not compatible with the atmospheric background expectation. Although only a single event with energy greater than a PeV has been observed, we can infer from our fit and from the relation between muon energy and energy of the parent neutrino that there are most likely several neutrinos with energies above a PeV in the six-year sample.

4.6. Discussion

This analysis found an astrophysical spectral index of $\gamma = 2.13 \pm 0.13$, which is harder than previously reported measurements, see e.g., Kopper et al. (2015), Neiderhausen et al. (2015) and Aartsen et al. (2015f). We refer to these analyses in the rest of the section as starting event analysis, cascade analysis and combined analysis, respectively. Figure 13 compares the measured astrophysical neutrino flux normalization and spectral index with these results and the previous measurement using through-going muons Aartsen et al. (2015c).

While the sample used in the cascade analysis is completely statistically independent, the starting event analysis and global fit have an overlap in events. The combined fit includes three years of muon data from 2009 to 2012 based on Aartsen et al. (2014c, 2015c). The starting event analysis includes a small fraction (6%) of up-going muons that start within the detector, that are also included here. However, these three analyses are strongly dominated by independent cascade-like events of which a large fraction originates from the Southern Hemisphere. For the starting event analysis 73% of the events above 100 TeV are down-going and 93% of these are cascade-like. For the investigation of the tension in the observed energy spectrum of astrophysical neutrinos, the assumption of statistical independence is reasonably well justified but will result in a lower limit on the tension.

The combined analysis finds the smallest confidence region of the three aforementioned results. The p -value for obtaining the combined fit result and the result reported here from an unbroken powerlaw flux is 3.3σ , and is therefore in significant tension. For the discussion, it is important to highlight the systematic differences between these measurements. The threshold for the up-going muon signal is a few hundred TeV while astrophysical starting events are detected above a few times 10 TeV. It should be noted that for the overlapping energy region >200 TeV the measured fluxes for the cascade-dominated channels are in good agreement with the results reported here, as shown in Figure 5. As a conclusion, we

Notes. The horizontal lines separate the different data sets IC59, IC79, IC2011 and IC2012-2014. The signalness is defined as the ratio of the astrophysical expectation over the sum of the atmospheric and astrophysical expectations for a given energy proxy and the best-fit spectrum. The signalness decreases up to about 10% when taking into account a prompt flux at the conservative upper limit of $1.06 \times \text{ERS}$ (see Section 6). The angular errors are statistical errors only and do not include systematics.

^a These events were included in Aartsen et al. (2014c).

^b These events were included in Aartsen et al. (2015c).

^c This event is identical to Event 38 in Kopper et al. (2015).

Figure 8. Probability distribution of primary neutrino energies that could result in the observed multi-PeV track-like event. The total probabilities for the different flavors are 87.7%, 10.9% and 1.4% for ν_μ , ν_τ , and $\bar{\nu}_e$, respectively.

confirm for the Northern Hemisphere a flux of muon neutrinos that is generally consistent with the observed all flavor flux in the Southern Hemisphere, but which is in tension with the assumption of a single power law describing this and previous observations with a lower energy threshold at the same time.

It is expected that for a Galactic origin the neutrino flux should be correlated with the Galactic plane. It is generally assumed that the contribution from the Galactic plane and Galactic sources is stronger in the Southern Hemisphere, which e.g., includes the Galactic center. The measured astrophysical flux is not strongly affected by a split in right ascension (see Section 5.2), where one region includes the part of the Galactic plane which is visible in the northern sky and the other does not. This can be interpreted as an indication that the flux observed here is mostly of extragalactic origin.

The observed tension may arise either from a spectral break at lower energies for the same sources or from an additional flux component, e.g., expected from Galactic sources or the

Figure 9. Angular reconstruction uncertainty of the multi-PeV track-like event. The estimate is based on an ensemble of simulated events with similar deposited energy, direction and entry point into the fiducial volume. The simulation takes into account the ice uncertainties (see Section 3.2). Including statistical and systematic uncertainties, 50% (99%) of the events are reconstructed better than $0^\circ.23$ ($0^\circ.90$).

Galactic plane, that is sub-dominant at the high energies to which this analysis is sensitive.

Figure 14 compares the measured diffuse astrophysical muon neutrino flux to theoretical flux predictions corresponding to different source types. The measured flux is within its uncertainties slightly below the Waxman–Bahcall upper bound (Waxman 2013). Senno et al. (2016) predict a diffuse neutrino flux originating from gamma-ray bursts, which is currently not ruled out (Aartsen et al. 2015d, 2016). A flux of cosmogenic neutrinos as predicted by Kotera et al. (2010) would only contribute subdominantly to the measured astrophysical neutrino flux. Neutrino fluxes from blazars and star-forming galaxies are predicted by e.g., Murase et al. (2014) and Bechtol et al. (2015), respectively. Glüsenskamp (2016) already constrains this blazar model. These fluxes are of the same order of magnitude as the measured flux within the given uncertainty band. However, due to the small statistics at high energies we cannot differentiate if the measured astrophysical neutrino flux corresponds to a neutrino flux originating from a specific source type or if it is a combination of different source types.

5. ANALYSIS OF ARRIVAL DIRECTIONS AND SEARCH FOR ANISOTROPIES

5.1. Arrival Directions of Highest-energy Events

The multi-PeV event discussed in Section 4.3 has a high probability of being astrophysical. Therefore, it is particularly interesting to correlate such an event with potential sources.

Figure 15 shows the direction of the event with its angular uncertainty and nearby high-energy gamma-ray sources from Nolan et al. (2012), Acero et al. (2015), Wakely & Horan (2007) in a window centered around the arrival direction. The closest source is multiple degrees away which is much larger than the angular error estimate.

For events that have a muon energy proxy above 200 TeV we expect roughly twice as many events with an astrophysical origin than with an atmospheric origin, assuming the best-fit

Figure 10. Two-dimensional profile likelihood scans of the astrophysical parameters Φ_{astro} , $E_{\nu}^{\text{cut-off}}$ and the prompt normalization Φ_{prompt} in units of the model in Enberg et al. (2008). The contour lines at 68%, 90% and 95% CL assume Wilks’ theorem. For the top and middle figure the spectral index is fixed to $\gamma_{\text{astro}} = 2$, while in the bottom figure it is fixed to the best-fit value $\gamma_{\text{astro}} = 2.13$. The white dots indicate the best-fit values.

Figure 11. Cumulative distribution of the parametric unfolded neutrino energy spectrum for the six-year data sample assuming the best-fit spectrum as given by this analysis. Blue/red corresponds to the conventional atmospheric/astrophysical expectation weighted to the best-fit spectrum. Orange represents the sum of both expectations. The parametric unfolded data are shown as a hatched band where the gray band shows the statistical uncertainty and the white band additionally the effect of the uncertainties on the fitted astrophysical flux parameters.

Figure 12. Distribution of the median expected neutrino energy assuming the best-fit spectrum as given by this analysis. The black crosses corresponds to experimental data and blue/red to the conventional atmospheric/astrophysical expectation weighted to the best-fit spectrum.

spectrum. Figure 16 shows the arrival direction of these events. Most events are located relatively close to the horizon where the Earth is not yet opaque to high energy neutrinos. Table 4 summarizes the per-event information. No obvious correlation with gamma-ray sources in the catalogs of Nolan et al. (2012), Acero et al. (2015), or Wakely & Horan (2007) were found. However, event 10 is close to the extended TeV source HESS J1857+026 (Wakely & Horan 2007).

A dedicated analysis searching for clusters in the neutrino arrival directions has been performed and found no evidence for a neutrino point source (M. G. Aartsen et al. 2016, in preparation).

Figure 13. Results of different IceCube analyses measuring the astrophysical flux parameters Φ_{astro} and γ_{astro} . The contour lines show the 90% CL. The result of this analysis (IC tracks, 6yr) is shown by the red solid contour line. The contour obtained by the previous measurement using through-going muons (Aartsen et al. 2015c) (IC tracks, 2yr) is the red dashed line. In addition, the results for the most recent analysis of starting events (Kopper et al. 2015) (IC HESE, 4yr), the complementary cascade channel (Niederhausen et al. 2015) (IC cascades) and an analysis combining different IceCube results (IC combined, Aartsen et al. 2015f) are shown. The result of this analysis (red, solid) and IC combined are incompatible at 3.3σ (two-sided significance).

Figure 14. Comparison of the measured diffuse astrophysical muon neutrino flux (see Figure 5) with theoretical neutrino flux predictions corresponding to different source types (Kotera et al. 2010; Murase et al. 2014; Bechtol et al. 2015; Senno et al. 2016). Since Murase et al. 2014 predicts a lower and upper flux bound for neutrinos originating from blazars the central line between both bounds is shown. The purple line shows the Waxman–Bahcall upper bound (Waxman 2013).

5.2. Test for Anisotropies Related to the Galactic Plane

As discussed in Section 4.6 the measurement in this paper confirms the observation of an all-sky diffuse high-energy astrophysical neutrino flux. However, a tension exists between the measured spectral index of this analysis with the starting event data which originate mostly from the Southern Hemisphere. Furthermore, Neronov & Semikoz (2016) claim inconsistency of the previously published starting event data

Figure 15. Window centered around the arrival direction of the multi-PeV track-like event. The solid (dashed) black line shows the 50% (99%) error circle for the angular reconstruction. The orange line indicates the Galactic plane. Additionally, the gamma-ray sources of the catalogs Wakely & Horan (2007), Acero et al. (2015), Nolan et al. (2012) within the window are shown.

with an isotropic signal with a preference of a Galactic latitude dependency. As the comparison to the Southern Hemisphere is subject to different energy thresholds and detector systematics, we perform a simple, self-consistent test for a dominant signal from the Galactic plane.

We split the sample into two right ascension regions, one containing the main parts of the Galactic plane: $\alpha \in [0^\circ:0, 108^\circ:9) \cup [275^\circ:0, 360^\circ:0)$ and one excluding it: $\alpha \in [108^\circ:9, 275^\circ:0)$. These intervals are chosen such that the two split samples are of similar statistics, resulting in 162363 and 189931 events respectively. Both samples are fitted independently and the aforementioned systematics can be considered identical as they are equalized by the daily Earth rotation.

The fit result, shown in Figure 17, is a small but not statistically significant larger flux and softer spectrum from the region including the Galactic plane. The p -value for both results being compatible is at about 43%. In conclusion, the observed flux is not dominated by the Galactic plane. However a small, sub-dominant contribution cannot be excluded.

6. SEARCH FOR A SIGNATURE OF PROMPT ATMOSPHERIC NEUTRINOS

The expected prompt neutrino flux provides a background for the measurement of the astrophysical flux. However, a flux of prompt neutrinos is interesting by itself and can be constrained by the present analysis.

The prompt flux predicted by Enberg et al. (2008) is sub-dominant to the conventional flux at low energies and the astrophysical flux at high energies. Nevertheless, the correlation of the energy spectrum and arrival directions of neutrinos at the detector lead to a clear signature. Figure 18 shows the pulls for simulated data corresponding to six years of live time and based on the IC2012-2014 event selection. Here, signal is defined as the prompt expectation and background is the sum of the conventional and astrophysical flux. The main effect of a prompt neutrino flux on the two observables will be visible for muon energy proxy values between 1 and 100 TeV in the fairly

up-going directions. However, a large part of this signature is absorbed within the uncertainties represented by the implemented nuisance parameters (see Section 3.2).

The overall best-fit prompt normalization is zero. Figure 19 shows the best-fit prompt normalization as a function of the astrophysical normalization and spectral index. Additionally, the two-dimensional confidence contours for the astrophysical parameters are shown. In the region where our experimental data are compatible with our single power-law model, the best-fit prompt normalization does not deviate from zero. Only for strong deviations from the best-fit astrophysical spectrum is a non-zero prompt normalization fitted, but this is strongly disfavored with respect to the best fit. Such behavior is expected. If the astrophysical flux decreases, the measured high-energy events need to be explained by another component. Assuming an unbroken power-law model for the astrophysical flux, the sensitivity for the prompt neutrino flux, taking into account the systematic uncertainties, is estimated to be $1.5 \times \text{ERS}$. Note that the sensitivity (median expected upper limit in the absence of a prompt neutrino flux) on a prompt neutrino flux depends on the chosen input values for the astrophysical flux.

In the absence of an indication of a non-zero prompt contribution an upper limit is calculated. Based on the profile likelihood for the prompt normalization, the upper limit at 90% confidence level is $0.50 \times \text{ERS}$. The more stringent limit compared to the sensitivity is caused by an under-fluctuation of the conventional atmospheric and astrophysical background by about one standard deviation.

For this reason we scan the resulting limit on the prompt flux as a function of the astrophysical signal parameters.

Figure 20 shows the joint three-dimensional 90% confidence region for the prompt flux and the astrophysical parameters. It was obtained using Wilks' theorem, and is bound by the surface for which $-2\Delta \log L$ is 6.25 higher than the best-fit value. The maximum prompt flux in the three-dimensional confidence region is $1.06 \times \text{ERS}$. We take this as a conservative upper limit on the prompt flux. Further tests have shown that reasonable changes to the astrophysical hypothesis, such as the introduction of a high-energy cut-off, have only small effects on this limit.

Several more recent calculations of the prompt flux have been published: GMS (H3p) (Garzelli et al. 2015), BERSS (H3p) (Bhattacharya et al. 2015) and GRRST (H3p) (Gauld et al. 2016). Figure 21 shows multiple predictions for the prompt flux as well as the upper limit calculated here using the prediction from Enberg et al. (2008) and taking into account a more realistic cosmic-ray model (Gaisser 2012). Since nuisance parameters describing the uncertainties of the cosmic-ray model, e.g., the cosmic-ray spectral index, are implemented, the upper limit curve slightly deviates from the ERS prediction including the knee. The energy range has been calculated such that the limit increases by 10% if only neutrinos with energies in that range are taken into account. For the sensitive region which is between 9 and 69 TeV the effect of the prompt predictions is only a change in normalization and it is therefore appropriate to convert the limit obtained with the ERS prediction to the other predictions. Also, the cosmic-ray composition only changes the normalization in this energy range. The values are summarized in Table 5.

Figure 16. Arrival directions of events with a muon energy proxy above 200 TeV. Given the best-fit spectrum the ratio of astrophysical to atmospheric events is about two to one. The horizontal dashed gray line shows the applied zenith angle cut of 85° . The curved gray line indicates the Galactic plane and the dashed black line the supergalactic plane (Lahav et al. 2000). The multi-PeV track event is shown as a red dot and the energy proxy value listed in Table 4.

Figure 17. Two-dimensional profile likelihood scans of the astrophysical parameters Φ_{astro} and γ_{astro} for the two disjoint right ascension regions, one containing the Northern Hemisphere part of the Galactic plane (red) and the other not (black). The contour lines at 68% and 90% CL assume Wilks' theorem.

7. SUMMARY AND CONCLUSIONS

In this paper we have presented the result of analyzing six years of up-going muon data measured with the IceCube neutrino telescope. We measure an astrophysical flux of $\Phi_{\nu+\bar{\nu}} = (0.90^{+0.30}_{-0.27}) 10^{-18} \text{ GeV}^{-1} \text{ cm}^{-2} \text{ sr}^{-1} \text{ s}^{-1}$. $(E_\nu/100 \text{ TeV})^{-(2.13 \pm 0.13)}$ with a statistical significance of 5.6 standard deviations with respect to only being of atmospheric origin. With this result we have further established the observation of an astrophysical neutrino signal (Aartsen et al. 2013a, 2014b, 2015c) in a second, largely independent detection channel. The detection channel used here is of great interest because of the good directional reconstruction of

Figure 18. Signal over square root of background for the reconstructed muon energy vs. zenith angle corresponding to six years of IceCube data after applying the event selection for the 86-string configuration (IC2012-2014). Here, background is defined as the sum of the conventional atmospheric (Honda et al. 2007) and astrophysical ($10^{-8} \times E^{-2}$) $\nu_\mu + \bar{\nu}_\mu$ flux. The prompt atmospheric (Enberg et al. 2008) $\nu_\mu + \bar{\nu}_\mu$ flux is defined as the signal. The numbers in each bin correspond to the expected number of background events in six years.

detected muons and a large signal efficiency with an estimated number of about 500 astrophysical neutrinos included in this data sample.

The data include an exceptionally high-energy muon with $(2.6 \pm 0.3) \text{ PeV}$ deposited energy, which is the highest-energy lepton that has been reported to date.

A parametric unfolding of neutrino energies shows that the spectrum extends to about 10 PeV in neutrino energy with no significant spectral break or cut-off.

The measured hard spectral index of $\gamma = 2.13 \pm 0.13$ is in tension with complementary measurements of IceCube, which

Figure 19. Best-fit prompt normalization Φ_{prompt} in units of the model of Enberg et al. (2008) for each scan point $\Phi_{\text{astro}}, \gamma_{\text{astro}}$. Additionally, the two-dimensional contours for $\Phi_{\text{astro}}, \gamma_{\text{astro}}$ are shown.

Figure 20. 90% CL contour assuming Wilks' theorem based on a three-dimensional profile likelihood scans of the astrophysical parameters $\Phi_{\text{astro}}, \gamma_{\text{astro}}$ and the prompt normalization Φ_{prompt} in units of the model of Enberg et al. (2008).

have a lower energy threshold by about one order of magnitude and are predominantly sensitive to the Southern Hemisphere. However, the consistency of the observed fluxes at high energies may be interpreted as indication of a spectral break or additional astrophysical component at lower energy to which this analysis is not sensitive.

For the highest-energy events no correlation with known high-energy gamma-ray sources or other astrophysical objects could be identified.

By splitting the data in right ascension, we find no significant correlation with the orientation of the Galactic plane and conclude that the dominant fraction of the flux is largely all-sky and isotropic.

The present analysis is also sensitive to a flux of prompt neutrinos which are expected from the decay of heavy mesons in the atmosphere. We find no indications for such a signal. However, because the prompt flux is subdominant to the

Figure 21. Prompt atmospheric muon neutrino flux predictions shown as dashed lines (Enberg et al. 2008; Bhattacharya et al. 2015; Garzelli et al. 2015; Gauld et al. 2016) in comparison to the constraint on the prompt flux given by this analysis. The shaded area shows the uncertainty band corresponding to the prediction in Gauld et al. (2016). Besides the ERS (H3p) prediction this is the closest band to the prompt flux constraint. For better readability the uncertainty bands of the other models are not shown. The black solid line shows the neutrino energy region where the prompt neutrino flux based on the model in Enberg et al. (2008) is constrained. The black dotted line indicates the model behavior including the best-fit nuisance parameters beyond the sensitive energy range. All flux predictions are based on the cosmic-ray model from Gaisser (2012).

Table 5
Limits for Fluxes of Prompt Neutrinos for Different Predictions

Model	Flux limit
ERS (H3p)	1.06
GMS (H3p)	≈ 2.9
BERSS (H3p)	≈ 3.0
GRRST (H3p)	≈ 3.1

Note. The limits for GMS (H3p) (Garzelli et al. 2015), BERSS (H3p) (Bhattacharya et al. 2015) and GRRST (H3p) (Gauld et al. 2016) are determined by rescaling the ERS (H3p) limit with the corresponding flux ratio at 30 TeV which is well within the sensitive energy range. All flux predictions are based on the cosmic ray model from Gaisser (2012).

astrophysical and conventional atmospheric neutrino flux, the exclusion depends on the assumed astrophysical model parameters. Variations of the astrophysical flux uncertainties lead to a conservative exclusion limit of approximately at the level of the mean expected flux normalization from Enberg et al. (2008). For the first time, it is possible to constrain such a flux in this range of theoretical predictions. However, recent perturbative QCD calculations from Garzelli et al. (2015), Bhattacharya et al. (2015) and (Gauld et al. 2016) predict lower prompt neutrino fluxes which are not yet constrained by the upper limit.

ABSTRACT: We assess the impact of searches at flavor factories for new neutral resonances that couple to both photons and gluons. These are well motivated by “heavy axion” solutions of the strong CP problem and by frameworks addressing both Dark Matter and the Higgs hierarchy problem. We use LHCb public diphoton data around the B_s mass to derive the current best limit on these resonances for masses between 4.9 and 6.3 GeV. We estimate that a future LHCb dedicated search would test an axion decay constant of $O(\text{TeV})$ for axion masses in the few-to-tens of GeV, being fully complementary to the low mass ATLAS and CMS searches. We also derive the impact of BABAR searches based on Υ decays and the future Belle-II reach.

1 Introduction

The lack of new physics at the Large Hadron Collider (LHC) and the lack of direct detection signal of dark matter (DM) at present experiments make it necessary to rethink the theoretical questions in the SM from a wider viewpoint and trigger broader experimental searches for new physics (NP). In this paper we make a step in this direction by presenting a NP case for flavor factories at the intensity frontier. These are light resonances below the EW scale which are neutral under the SM gauge group and couple to both gluons and photons. We show that flavor experiments have an unexploited potential to probe these states in a complementary mass range to previously proposed low-mass resonance searches at ATLAS and CMS [1]. Pointing out these gaps in the search program at flavor facilities is now a particularly important question in view of the upcoming LHCb upgrade and the Belle II data taking.

The possibility we consider here is that the new physics scale M_{NP} lies beyond the reach of the LHC. If that is the case, NP signals might still arise from pseudo-Nambu-Goldstone bosons (pNGBs) associated to spontaneously broken approximate symmetries. These are often called axion-like particle (ALP) in the literature, they can be sensibly lighter than the NP scale ($m_a \ll M_{\text{NP}}$) and their couplings to the SM are controlled by the inverse of

the decay constant $1/f$. Generically, one has $M_{\text{NP}} = g_* f$ with g_* being the typical size of the couplings in the NP sector, so that probing weak enough couplings of the pNGB gives an indirect probe of the scale of new physics.

The focus of this paper will be on pNGBs with m_a between 2 and 20 GeV, a mass window within the reach of flavor experiments. The driving question is *whether flavor experiments can be sensitive to couplings of pNGBs small enough to probe new physics beyond the LHC reach*. This question has been partially addressed for ALPs which couple to the SM by mixing with the Higgs sector [2, 3] but it is surprisingly unexplored for ALPs with only gluon and photon couplings.

In the large theory space of all the possible couplings of the ALP to the SM, having a non-zero coupling to gluons is particularly well motivated from the theory perspective. In this paper we will discuss in detail two particularly compelling examples: “heavy” QCD axions [4–16] and the R -axion [17–19] in low energy SUSY-breaking. As we will show, in these two classes of models the gluon coupling is unavoidable, the photon coupling generic, the mass range of interest for this paper can be easily achieved. A TeV decay constant is theoretically favoured by ensuring the quality of the axion potential [20–23] or by explaining the DM relic abundance via thermal freeze out. Besides these two examples, ALPs with both gluon and photons couplings arise for instance as new pions in Composite Higgs models [24–26], in theories with vector-like confinement [27] or in models of EW baryogenesis [28].

The first observation of this paper is that many existing search strategies for light resonances in the 2–20 GeV range [29–35] lose sensitivity as soon as the gluon coupling is switched on. The main reason is that the decay width into gluons dominates over the one into photons unless a non-generic hierarchy of couplings is assumed, therefore strongly suppressing the signals expected in the existing strategies.

The dominant di-jet final states are much more difficult to distinguish from the SM background than diphotons.¹ As a way to overcome this issue, we show that the large production rate in pp collisions induced by the non-zero gluon coupling can be exploited at LHCb, which already has a low mass diphoton trigger designed to look for the rare decay $B_s \rightarrow \gamma\gamma$. To substantiate this point, we use 80 pb^{-1} of public LHCb diphoton data [38] around the B_s mass to derive a limit of $\mathcal{O}(100) \text{ pb}$ on the signal strength of new diphoton resonances. This limit already constitutes the strongest existing probe for ALPs in the mass range between 4.9 and 6.3 GeV and motivates a dedicated LHCb search for diphoton resonances in a broader mass range. We estimate the sensitivity of such a search and show that decay constants at around the TeV scale are within reach of the high-luminosity phase of LHCb. This extends the coverage of low-mass resonance searches down to masses as low as 2 GeV and constitutes a new probe of multi-TeV scale NP which could be difficult to produce directly at the LHC. A similar point was made in ref. [1] with ATLAS, CMS, and Tevatron diphoton searches, that are however limited by trigger issues to masses roughly above 10 GeV.

¹As an example the LEP limit on $\text{BR}(Z \rightarrow \gamma a)$ is $1.7 \cdot 10^{-5}$ from 36.9 pb^{-1} of data if a is a diphoton resonance [36] and $4.7 \cdot 10^{-4}$ from 5.5 pb^{-1} of data if a is a dijet resonance [37].

We finally discuss bounds on light resonances produced from SM meson decays. We estimate the BABAR constraint on $\Upsilon(1, 2, 3S) \rightarrow \gamma a(jj)$ and assess the future Belle-II sensitivity. This production channel currently constitutes the best probe of ALPs below ~ 3 GeV.

2 Results

We consider a spontaneously broken approximate U(1) symmetry in the UV. Integrating out the new physics sector at the scale M_{NP} , we write down the effective interactions between the pNGBs and the SM

$$\mathcal{L}_{\text{eff}} = \frac{1}{2}(\partial_\mu a)^2 - \frac{1}{2}m_a^2 a^2 + \frac{a}{f} \sum_{i=1}^3 c_i \frac{\alpha_i}{4\pi} F_{i,\mu\nu} \tilde{F}_i^{\mu\nu}, \quad (2.1)$$

where i runs over the hypercharge, weak and strong gauge groups, $\tilde{F}_i^{\mu\nu} = \epsilon^{\mu\nu\rho\sigma} F_{i,\rho\sigma}/2$, $\alpha_i = g_i^2/4\pi$ and α_1 is GUT-normalised ($\alpha_1 = 5\alpha_y/3$). The constants c_i are anomaly coefficients which depend on the number of degrees of freedom chiral under the U(1) symmetry and carrying a non-zero charge under the SM gauge group.²

In the NP sector, the strength of the interaction g_* generically limits the maximal number of degrees of freedom to be below $\approx (4\pi)^2/g_*^2$. Therefore, a lower g_* allows for large couplings of the ALP to the SM but at the same time it lowers the scale of new physics $M_{\text{NP}} \simeq g_* f$.

For $m_a \lesssim M_Z$, we can write the ALP couplings to photons and gluons below EWSB using the same notation of the QCD axion

$$\mathcal{L}_{\text{eff}} \supset \frac{N\alpha_3}{4\pi} \frac{a}{f} G_{\mu\nu} \tilde{G}^{\mu\nu} + \frac{E\alpha_{\text{em}}}{4\pi} \frac{a}{f} F_{\mu\nu} \tilde{F}^{\mu\nu}, \quad (2.2)$$

where we have

$$N = c_3 \quad , \quad E = c_2 + 5c_1/3 \quad , \quad g_{a\gamma\gamma} = \frac{\alpha_{\text{em}}}{\pi f} E, \quad (2.3)$$

where $g_{a\gamma\gamma}$ agrees with the standard formula for the QCD axion after normalizing the decay constant with respect to the QCD coupling $f = 2N f_{\text{PQ}}$. The relevant decay widths of the pNGB are

$$\Gamma_{\gamma\gamma} = \frac{\alpha_{\text{em}}^2 E^2}{64\pi^3} \frac{m_a^3}{f^2}, \quad \Gamma_{gg} = K_{gg} \frac{\alpha_s^2 N^2}{8\pi^3} \frac{m_a^3}{f^2}, \quad (2.4)$$

where we include NNLO corrections to the gluon width [42] in K_{gg} (see appendix A for more details). Note that $(0.1 \text{ mm})^{-1} \ll \Gamma_{\text{tot}} = \Gamma_{gg} + \Gamma_{\gamma\gamma} \ll m_{\gamma\gamma}^{\text{bin}}$ over the mass range of our interest. The new resonance decays promptly and has a very narrow width compared to its mass.

The LHCb constraint and sensitivities derived in section 4 are displayed on the ALP parameter space in figure 1, for the benchmark $c_1 = c_2 = c_3 = 10$. We compute $\sigma(pp \rightarrow a)$ with ggHiggs v4 [43–46] using the mstw2008nn1o pdf set. We compare it with that obtained

²If the SM fermions and the Higgs doublet are uncharged under the U(1) symmetry, the couplings of the pNGB to them arise only from loops of SM gauge bosons and can safely be neglected.

Figure 1. Limits (shaded regions) and sensitivities (colored lines) on the ALP parameter space described in eq. (2.1). The bounds from Babar and LHCb are first derived here from data in [31, 38], projections are given for Belle II and future LHC stages. Details are given in section 4. The other bounds are derived from Z width measurements [29, 39], heavy ion collisions [40, 41], $Z \rightarrow \gamma a(jj)$ decays at LEP I [30] and diphoton cross section measurements at CDF (relevant only for $m_a \simeq 10$ GeV), CMS and ATLAS [1]. For the latter we also give sensitivities up to the HL stage as derived in ref. [1]. The thin dashed lines indicate theory benchmarks motivated by heavy QCD axion models and by ALP-portal Dark Matter described in section 3. New coloured and EW states are expected to have masses of order $g_* f$, where $g_* = 4\pi/\sqrt{N_{\text{mess}}} = 4\pi/\sqrt{2}c_i$.

by the use of different pdf sets and of MadgraphLO_v2.6 [47, 48] upon implementing the ALP model in FeynRules [49], finding differences from 20% at $m_a = 20$ GeV to a factor of 2 or larger for $m_a < 5$ GeV. As detailed in appendix A, a more precise determination of the signal would be needed, especially for $m_a \lesssim 5$ GeV.

In figure 1 we also show

- i) the 2σ constraint $\Gamma_Z - \Gamma_Z^{\text{SM}} < 5.8$ MeV [29, 39];
- ii) the LEP limit $\text{BR}(Z \rightarrow \gamma a(jj)) < 1\text{--}5 \times 10^{-4}$ [30];
- iii) the constraint derived in [1] from the ATLAS [50, 51], CMS [52], and CDF [53] inclusive diphoton cross section measurements, corresponding to $\sigma(pp/p\bar{p} \rightarrow X a(\gamma\gamma)) < 10\text{--}100$ pb;
- iv) the sensitivities derived in [1] from inclusive diphoton cross section measurements at ATLAS and CMS. The HL-LHC reach assumes minimal photon p_T cuts of 25 and 22 GeV and minimal photon separation of $\Delta R = 0.4$. These numbers correspond to the 7 TeV measurement in ref. [50]. Higher p_T cuts would increase the minimal value of the invariant mass within the reach of HL-LHC.

v) the BABAR constraint $\text{BR}(\Upsilon_{2S,3S} \rightarrow \gamma a(jj)) < 10^{-4} - 10^{-6}$ [31], where we compute

$$\frac{\text{BR}(\Upsilon \rightarrow \gamma a)}{\text{BR}(\Upsilon \rightarrow \mu\bar{\mu})} \simeq 8 E^2 \frac{\alpha_{\text{em}}}{4\pi} \left(\frac{m_\Upsilon}{4\pi f}\right)^2 \left(1 - \frac{m_a^2}{m_\Upsilon^2}\right)^3, \quad (2.5)$$

where $\text{BR}(\Upsilon_{2S,3S} \rightarrow \mu\bar{\mu}) = 1.92\%, 2.18\%$. The above expression corrects a factor of 4 in the result of ref. [54].

- vi) the Belle-II sensitivity in the same channel, that we determine simply by rescaling the expected sensitivities in [31] by a factor of 10. This assumes that the Belle-II reach will be statistics-dominated, and that it will be based on a factor of 100 more $\Upsilon(3S)$ than the BABAR one (i.e. on $\simeq 1.2 \times 10^{10}$ $\Upsilon(3S)$ in total). The current Belle-II run plan for the first years assumes only a factor of 10 for the above ratio [55, 56], corresponding to a few weeks of dedicated run at the $\Upsilon(3S)$ threshold. An extra factor of 10 could be obtained in a comparable time with dedicated later runs, because a higher instantaneous luminosity is foreseen [56]. An analogous search could be effectively performed, at Belle-II, also analysing the decays of $\Upsilon(1S, 2S)$.
- vii) limits from the diphoton final state from heavy ion collisions are extracted from the recent CMS analysis in ref. [41] and the reinterpretation of the ATLAS light by light scattering data [40] of ref. [57]. The lower reach of these measurements is set to $m_a \gtrsim 5$ GeV as a consequence of the minimal cuts on the two photons transverse momenta.

ATLAS limits from $Z \rightarrow \gamma a(\gamma\gamma)$ [58] are not displayed in figure 1. They imply $\text{BR}(Z \rightarrow \gamma a(\gamma\gamma)) < 2.2 \cdot 10^{-6}$ and turn out to be comparable to the heavy ions bound for our benchmark in figure 1. Similar constraints can be derived from the ATLAS inclusive search in $pp \rightarrow \gamma a(\gamma\gamma)$ [58]. The lower invariant mass reach of these ATLAS searches is set by the diphoton isolation requirement of [58], $\Delta R_{\gamma\gamma} = 0.15$. This corresponds to an ALP mass of 4 GeV as discussed in ref. [59]. Notice that LEP searches for $Z \rightarrow \gamma a(\gamma\gamma)$ [32] are weaker than the ATLAS bound. Future sensitivities from $e^+e^- \rightarrow \gamma a(\gamma\gamma)$ [34, 35] do not reach values of f larger than $\simeq 50$ GeV and are not shown. Finally, the proposed search in $B \rightarrow K^{(*)} a(\gamma\gamma)$ [34] at Belle-II has some sensitivity in a very limited portion of our mass range and it is not shown to avoid clutter.

In figure 2 we fix the ALP masses to two representative values $m_a = 5, 15$ GeV and show the impact of the various searches in the plane $(N/f, E/f)$ which control the ALP's gluon and photon coupling respectively. As one can see from figure 2, diphoton searches for a ALP produced in gluon fusion both at ATLAS/CMS (see ref. [1]) and at LHCb (see section 4) can be sensitive to N/f as small as 10^{-4} GeV $^{-1}$ as long as the coupling to the photons is large enough. Moreover they can cover significant portion of the parameter space where the couplings are of their natural size.

Searches taking advantage of uniquely the photon coupling such as the ones in refs. [33, 35, 58] become relevant only in the upper left corner of the plane where $E/N \gtrsim 50$. Such a hierarchy can be realized in clockwork constructions where the photon coupling is enhanced with respect to the gluon one (see for example ref. [60]).

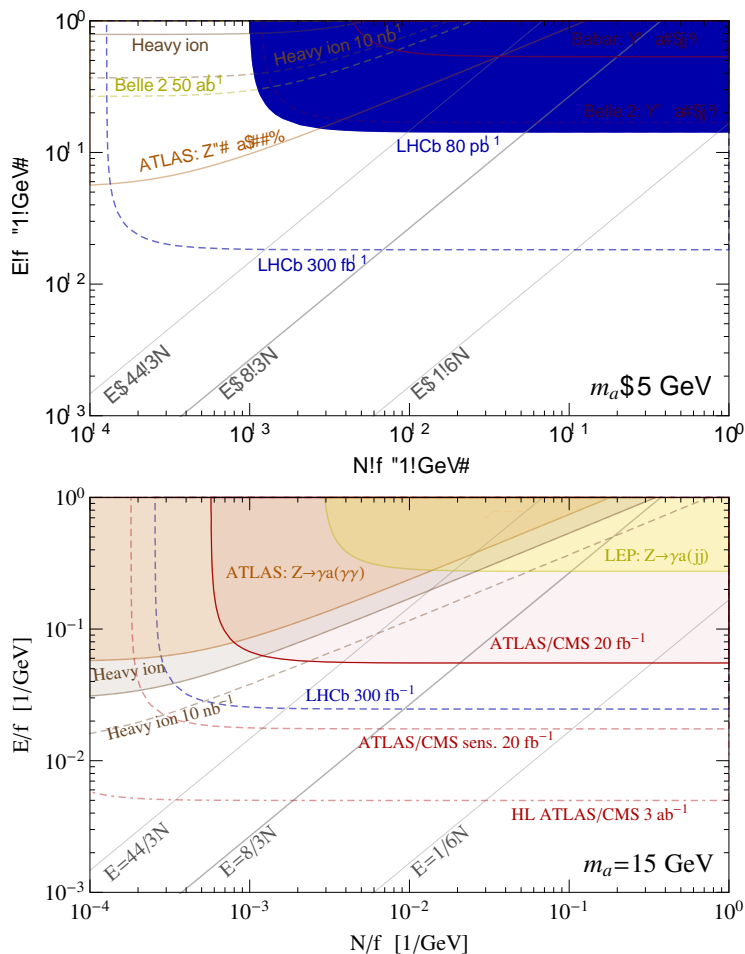

Figure 2. Constraints on the ALP parameter space for fixed masses $m_a = 5, 15$ GeV in the up, down panel respectively. We fix $c_1 = c_2$ so that E in eq. (2.3) controls both the $Z\gamma$ and the $\gamma\gamma$ coupling. The bounds are shown as shaded regions while the projections as dashed lines. The three grey lines show the “axion window” obtained by integrating out fermions in different representations of the SM gauge group, the central one $E = 8N/3$ corresponds to the choice of figure 1.

The ATLAS, CMS and LHCb limits and sensitivities shown in figure 2 are derived assuming gluon fusion as the ALP production process, so they sharply stop at a given small gluon coupling. If other production processes like vector-boson-fusion are taken into account, the limits and sensitivities would be slightly improved in the upper left corner of figure 2. Practically, the Heavy Ion results that we are including will always lead to stronger constraint because of the enhanced photon-fusion production and the loop suppressed background from light-by-light scattering.

The bottom right corner where the new resonance mostly couples to gluons is challenging to constrain in this mass range, even though boosted dijet searches at the LHC were recently able to go down to invariant masses of 50 GeV (see refs. [1, 61, 62]). Of course for $N/f \gtrsim (100\text{GeV})^{-1}$ one expects color states generating the ALP coupling to be within the reach of the LHC.

3 Physics cases

In this section we expand on the two theory lines displayed in figure 1. We would like to motivate: 1) the coupling of the axion to gluons and photons, 2) the TeV decay constant, 3) the mass range considered here.

3.1 Heavy axions

As a first example, we consider a particular class of axion solutions to the strong CP problem in the SM. First of all, introducing a spontaneously broken Peccei-Quinn symmetry $U(1)_{\text{PQ}}$ which is anomalous under QCD [63, 64] leads unavoidably to a light axion with non-zero couplings to gluons [65, 66]. In this sense, the axion coupling to gluons is deeply connected to its role in solving the strong CP problem. Taking the SM fields to be uncharged under the $U(1)_{\text{PQ}}$, the QCD anomaly is generated by heavy vector-like fermions like in KSVZ type of models [67, 68]

$$\mathcal{L}_{\text{PQ}} \supset g_* \Phi \psi \tilde{\psi} + \text{h.c.}, \quad \Phi = \frac{f}{\sqrt{2}} e^{ia/f}, \quad (3.1)$$

where the fermion charges should satisfy $|q_\psi^{\text{PQ}} - q_{\tilde{\psi}}^{\text{PQ}}| = q_\Phi^{\text{PQ}}$ and by writing eq. (3.1) we take $q_\Phi^{\text{PQ}} = 1$. After $U(1)_{\text{PQ}}$ gets spontaneously broken by the VEV of Φ , the fermion mass is at $M_{\text{NP}} = g_* f / \sqrt{2}$. Below the PQ breaking scale we can integrate out the heavy fermions and match to the effective Lagrangian in eq. (2.2):

$$N = q_\Phi^{\text{PQ}} \sum_\psi C_3(R_\psi) \quad E = q_\Phi^{\text{PQ}} \sum_\psi Q_{\text{em}}^2(R_\psi). \quad (3.2)$$

The vector-like fermions are often assumed to carry a non-zero hypercharge in order to allow a non-zero mixing with the SM quarks, to make them decay avoiding cosmological problems. This induces an anomaly of $U(1)_{\text{PQ}}$ with respect to the hypercharge, which leads to a non-zero coupling of the axion to photons: $E \neq 0$. To fix a benchmark, we add N_{mess} complete $SU(5)$ fundamental representations, that lead to $N = N_{\text{mess}}/2$ and $E = 4/3 N_{\text{mess}}$. This is the scaling assumed in figure 1, where we also take $N_{\text{mess}} = (4\pi/g_*)^2$ to ensure calculability below M_{NP} . In figure 2 we go beyond this benchmark and show how E/N can be modified changing the SM representation of the fermions in eq. (3.1) (see ref. [69] for a discussion).

Operators breaking $U(1)_{\text{PQ}}$ other than the QCD anomaly would in general spoil the axion solution of the strong CP problem [20–23]. We can parametrize these contributions as new terms in the potential for the scalar Φ :

$$\Delta V_{\text{PQ}} = \lambda_\Delta \frac{\Phi^\Delta}{\Lambda_{\text{UV}}^{\Delta-4}} + \text{h.c.}, \quad \lambda_\Delta = |\lambda_\Delta| e^{i\alpha_\Delta}. \quad (3.3)$$

In the presence of these new contributions the axion potential below the QCD phase transition is

$$V_a \simeq -\Lambda_{\text{QCD}}^4 \cos \frac{Na}{f} + \frac{1}{2^{\frac{\Delta}{2}-1}} \frac{|\lambda_\Delta| f^\Delta}{\Lambda_{\text{UV}}^{\Delta-4}} \cos \left(\alpha_\Delta + \Delta \frac{a}{f} \right). \quad (3.4)$$

Since the new phase α_Δ is in general not aligned with the contribution given by the QCD anomaly, the presence of the UV operator shifts the axion VEV away from the origin, jeopardizing the solution to the strong CP problem. Note that this holds even if the NP sector inducing eq. (3.3) preserves CP, because a new phase $\alpha_\Delta \sim O(1)$ is induced by rotating away the phase in the quark mass matrices. Requiring $2\langle Na/f \rangle \lesssim 10^{-10}$ to satisfy the present bound on the neutron dipole moment [70, 71] gives an upper bound on the axion decay constant

$$f \lesssim \Lambda_{UV} \left[10^{-10} \cdot \frac{N}{\Delta} \cdot \left(\frac{\Lambda_{QCD}}{\Lambda_{UV}} \right)^4 \right]^{1/\Delta}, \quad (3.5)$$

where we have assumed $|\lambda_\Delta| \sim \alpha_\Delta \sim O(1)$ and neglected other $O(1)$ factors for simplicity. The upper bound on f depends on the scale of the UV completion $\Lambda_{UV} \gtrsim g_* f$ and on the “quality” of the $U(1)_{PQ}$, i.e. the dimension Δ of the lowest dimension operator breaking the symmetry.

In the best case scenario, first discussed in refs. [20–23], the $U(1)_{PQ}$ is only broken by Planck suppressed operators³ but, more generally, one might argue that all the global symmetries should be an accidental consequence of the gauge and matter content of the theory, exactly like in the SM. In the latter case the Λ_{UV} in eq. (3.5) will be below M_{Pl} . Taking eq. (3.5) at face value, the most dangerous contribution comes from $\Delta = 5$ operators, that would require $f \lesssim O(10)$ GeV even for $\Lambda_{UV} = M_{Pl}$. However, if operators of dimension five are forbidden (for example by a discrete Z_2 -symmetry) then $\Delta = 6$ contributions give $f \lesssim O(10)$ TeV for $\Lambda_{UV} = M_{Pl}$ and $f \lesssim O(1)$ TeV for $\Lambda_{UV} = M_{GUT}$, motivating the ranges of decay constant of interest for this paper. Having f around the TeV scale would lead to axion solutions relying on $U(1)_{PQ}$ with the same quality of the baryon number in the SM.

In the usual QCD axion where $m_a \simeq 6 \text{ keV} \cdot \text{TeV}/f$ (see e.g. [74]), values of the decay constant motivated by the axion quality problem are abundantly excluded by star cooling bounds [75] and $K \rightarrow \pi a$ transitions [3, 76]. A common solution to this problem is to go to higher values of f and require a $U(1)_{PQ}$ with higher quality. Such a $U(1)_{PQ}$ can be made accidental in extra-dimensions or with more complicated UV completions in 4 dimensions (we refer to refs. [77–80] for an illustration of the challenges involved in constructing gauge theories with a $U(1)_{PQ}$ with arbitrarily high quality).

Alternatively, one can construct QCD axion models where the axion mass is heavier than its QCD value. The idea is to introduce new contributions to the axion potential which are aligned to the QCD one, so that the axion mass gets larger without spoiling the solution to the strong CP problem. A larger m_a then relaxes the experimental constraints on f , potentially allowing to satisfy eq. (3.5). There are several classes of models of this type which differ from the way the alignment is achieved: mirror axion models with one

³Gravity is expected to break global symmetries at the non perturbative level via wormhole solutions swallowing the PQ charge [72]. In this case the Wilson coefficient of the operators in eq. (3.3) can be very suppressed for a large enough wormhole action: $|\lambda_\Delta| \sim e^{-S_{Euc1}}$. The latter has been shown in ref. [73] to be too small in the Einstein theory of gravity but large enough in theories where the Einstein theory is suitably modified at Planckian distances.

axion and two mirror QCD's [4–8], models where the QCD running is modified at high energies [9–14], and a more recent proposals [15] where the QCD group is embedded in $SU(3)^N$ with N axions relaxing each one of the allowed θ -angles.

All the solutions of the strong CP problem mentioned above can easily achieve the 2–20 GeV mass range, and result in an axion which generically couples to both gluons and photons with a decay constant at the TeV scale or lower. These are a perfect benchmark for the collider searches discussed here. For illustrative purposes we show in figure 1 the value of f corresponding to a $U(1)_{PQ}$ broken by $\Delta = 6$ operators generated at $M_{GUT} = 10^{15}$ GeV.

3.2 ALP-mediated dark matter

The second example of ALP with coupling and masses of interest for this study comes from demanding it to be the mediator that couples the SM to fermion DM, singlet under the SM gauge group. This possibility has particular interest for colliders because direct detection constraints are totally irrelevant, see e.g. [81].

We write the ALP coupling to DM as in equation (3.1) and identify the DM as the Dirac fermion $(\psi, \tilde{\psi}^\dagger)$, so that $m_\psi = g_* f / \sqrt{2}$. The DM annihilation cross section into SM particles, mediated by the ALP, is dominated by final state gluon pairs and reads

$$(\sigma v)_{gg} = \frac{2}{\pi} \left(\frac{c_3 \alpha_s}{4\pi} \right)^2 \frac{g_*^2}{f^2}, \tag{3.6}$$

where α_s is evaluated at the scale $\mu = 2 m_\psi$. The cross section for t -channel annihilation into a pair of mediators is p -wave and reads [82]

$$(\sigma v_{\text{rel}})_{aa} = \frac{v_{\text{rel}}^2}{384\pi} \frac{g_*^4}{m_\psi^2}, \tag{3.7}$$

therefore it is negligible with respect to the annihilation into gluons for the parameter values we are interested in, even for relativistic v_{rel} . Requiring eq. (3.6) to match 4.8×10^{-26} cm^3/sec , which is the value needed for heavy Dirac DM to reproduce the correct DM abundance via thermal freeze-out [83], we find

$$m_\psi \simeq 4.6 \text{ TeV} \frac{c_3}{10} \left(\frac{g_*}{3} \right)^2 \Rightarrow f \simeq 1.9 \text{ TeV} \frac{3}{g_*}, \tag{3.8}$$

where in the second equality we have assumed the scaling $c_3 \simeq 8\pi^2/g_*^2$. This is the benchmark value we display in figure 1. It is interesting to note that indirect detection is still far from probing thermal values of the annihilation cross section for DM in this mass range (see e.g. [84–86]), thus adding further motivation to test this scenario with colliders.

Note that we have neglected the possible Sommerfeld enhancement from exchange of the ALP in the initial state. The precise computation of this effect is still the object of some debate, see e.g. [87] for a recent study with references, so that for simplicity we do not include it here. Its inclusion would result in an $O(1)$ change in the favoured value of f , but would not affect our physics point that pseudoscalar mediated DM motivates ALP searches at flavor factories.

3.3 R-axion in supersymmetry

We finally notice that the simplified DM model presented above arises naturally in theories of low-scale SUSY breaking. These predict that the lightest supersymmetric particle (LSP) is the Gravitino, whose mass $m_{3/2}$ is generically too small to account for the observed DM abundance. Indeed, using the power counting described in [19], one gets $m_{3/2} = F/(\sqrt{3}M_{\text{Pl}}) \simeq 11 \text{ meV} \cdot (g_*/3) \cdot (f/4 \text{ TeV})^2$. While not reproducing the observed value of DM, Gravitino masses in this ballpark are safe both from collider [88–90] and cosmological [91] constraints.

In the absence of stable superpartners, the natural DM candidate in these SUSY theories are particles belonging to the messenger or SUSY breaking sectors, see [92] for a first study of this possibility. In this case, as first noted in [93] (see [94] for further model building), the DM phenomenology may be dominated by its interactions with a pseudoscalar that is naturally present in the theory, the R -axion.

This arises as the pNGB of the $U(1)_R$ symmetry, defined as the only abelian global symmetry which does not commute with the SUSY generators. The spontaneous breaking of the $U(1)_R$ is intimately related to SUSY-breaking according to the general results of [17, 95]. The R -axion couplings to gluons and photons are unavoidably generated by loops of gauginos, whose Majorana masses are chiral under the $U(1)_R$, and possibly by UV messengers. Couplings to fermions and to the Higgs are less generic and can be suppressed by suitable charge assignment (see [19] for more details). Under these circumstances, the R -axion matches perfectly the Lagrangian in eq. (2.1).

For $f = O(\text{TeV})$, motivated here not only by DM but also by the naturalness of the Fermi scale, i) its mass is expected to lie in the MeV range [96] or above [19, 95], thus motivating searches at flavor factories, ii) superpartners can be taken outside the LHC reach, thus making it potentially the first sign of SUSY at colliders [19].

4 Diphoton searches at LHCb

LHCb detects photons either as “unconverted”, i.e. they reach the electromagnetic calorimeter (ECAL), or as “converted”, i.e. they convert to an e^+e^- pair upon interacting with the detector material before reaching the ECAL. The public LHCb note [38] presents the trigger and cut strategy that will be used to look for $B_s \rightarrow \gamma\gamma$, and classifies diphoton events into two unconverted (0CV), one unconverted and one converted (1CV LL and DD, corresponding to conversions occurring in the Vertex Locator region or after it) and two converted (2CV) samples.

Searches for $B_s \rightarrow \gamma\gamma$ benefit from requiring the $\gamma\gamma$ vertex to be displaced from the pp interaction point, while the resonances we are interested in typically have a lifetime much shorter than the B_s one. A displaced $\gamma\gamma$ vertex is however not imposed on the 0CV sample, because the resolution on the directions of the photons does not allow for a precise enough vertex reconstruction. Therefore this sample can be used to derive a bound on prompt diphoton resonances.

Measured diphoton events that pass the cuts are reported in [38] for $L = 80 \text{ pb}^{-1}$ of data, for each conversion category, in a diphoton invariant mass interval $4.9 \text{ GeV} <$

$m_{\gamma\gamma} < 6.3$ GeV and in bins of 14.5 MeV. No known QCD or SM resonance is expected to give a signal within the LHCb reach, explaining why the event distributions in $m_{\gamma\gamma}$ are very smooth in all categories, so that they constitute an ideal avenue to look for BSM resonances. Therefore, we place an upper limit on the signal cross section of a resonance a decaying to diphotons as

$$N_{\text{sig}}(m_a) < 2\sqrt{N_{\text{bkg}} \frac{m_{\gamma\gamma}^{\text{bin}}}{14.5 \text{ MeV}}}, \quad (4.1)$$

where

$$N_{\text{sig}} = \epsilon \times \sigma_{\text{fid}} \times L, \quad \sigma_{\text{fid}} = A \times \sigma(pp \rightarrow Xa(\gamma\gamma)), \quad (4.2)$$

with A the geometrical acceptance of the signal in the LHCb detector and ϵ the total efficiency of the cuts plus detector effects in a given diphoton category. We use

$$A = 0.15, \quad \epsilon_{0\text{CV}} = 0.142, \quad (4.3)$$

where the latter is given in [38] for the SM “signal” $B_s \rightarrow \gamma\gamma$, and we determine the former by simulating the signal (see appendix D for details) and imposing $2 < \eta < 5$ at truth level.

Coming to the right-hand side of eq. (4.1), N_{bkg} is the number of background events in the 14.5 MeV bin reported in [38], which we take constant as the distribution in $m_{\gamma\gamma}$ is actually flat well within its statistical uncertainties.⁴ $m_{\gamma\gamma}^{\text{bin}}$ is the size of the bin centered on $m_{\gamma\gamma} = m_a$ that we expect to contain most of the signal from the resonance, which we assume to be narrow. In practice we use

$$N_{\text{bkg}} = 8000 \times \frac{L}{80 \text{ pb}^{-1}}, \quad m_{\gamma\gamma}^{\text{bin}} = 4\delta m_{\gamma\gamma}, \quad (4.4)$$

where $\delta m_{\gamma\gamma}$ is the invariant mass resolution for the 0CV category which can be derived from the energy resolution and the granularity of the LHCb ECAL (see appendix C). Fixing for definiteness $m_{\gamma\gamma}^{\text{bin}}/m_{\gamma\gamma} = 13\%$, we obtain

$$\sigma_{\text{fid}}^{0\text{CV}} \lesssim 106 \text{ pb} \cdot \sqrt{\frac{m_a}{5 \text{ GeV}}} \cdot \sqrt{\frac{80 \text{ pb}^{-1}}{L}}. \quad (4.5)$$

The sensitivities that could be achieved by the current full dataset of $\simeq 8 \text{ fb}^{-1}$ and by the High Luminosity phase of LHCb with $\simeq 300 \text{ fb}^{-1}$ of data can be easily obtained from the above equation.⁵

We also extend the mass range of the search to $3 < m_{\gamma\gamma}/\text{GeV} < 20$, where the lower bound is chosen to make the computation of the signal strength reliable (see also

⁴While this holds for the 1CV and 2CV categories, the distribution in the 0CV category is flat up to $m_{\gamma\gamma} \simeq 5.7 \text{ GeV}$, and then drops smoothly. A possible origin of this drop is the use of 2×2 ECAL cells to measure the photon energy deposition at the first level of the software trigger (HLT1) [38]. In appendix B we verified that imposing invariant mass cuts at HLT1 can cause a flat background at HLT1 to develop a dropping shape at higher level, where the invariant mass is defined using 3×3 cells.

⁵Actually only $\simeq 2 \text{ fb}^{-1}$ have been recorded outside the B_s mass window, we neglect this drop in luminosity for simplicity.

appendix A) and the upper bound is chosen somehow arbitrarily at 20 GeV, where the reach of the current ATLAS/CMS inclusive diphoton dataset [1] is already stronger than the projections of LHCb. For simplicity we take the signal acceptance and the efficiency to be constant and equal to the ones in eq. (4.3). We discuss in appendix D the motivations for this simplified assumption. Moreover we assume that the background is also constant in the extended mass range and equal to the one in eq. (4.4). This simple procedure sets a useful benchmark for the actual search, which is good enough for the purpose of this paper. The resulting reach in the ALP parameter space is shown in figure 1.

We finally speculate about the limit and reach obtainable if the 1CV photon categories could be used. To set an optimistic reach, we do not take into account the signal loss because of the requirement of vertex displacement in present LHCb search. With this assumption, we repeat the procedure described above, with constant background $N_{\text{bkg}}^{1\text{CV},\text{DD}} = 1600$ and $N_{\text{bkg}}^{1\text{CV},\text{LL}} = 1300$ and constant efficiencies $\epsilon_{1\text{CV},\text{DD}} = 1.35\%$ and $\epsilon_{1\text{CV},\text{LL}} = 1.32\%$ as reported in ref. [38]. Concerning the mass resolution, we take the one of the 0CV category divided by $\sqrt{2}$ to roughly account for the much better energy resolution of the converted photon. With all these assumptions we combine in quadrature the exclusions from the LL and DD single-converted categories and get

$$\sigma_{\text{fid}}^{1\text{CV}} \lesssim 283 \text{ pb} \cdot \sqrt{\frac{m_a}{5 \text{ GeV}}} \cdot \sqrt{\frac{80 \text{ pb}^{-1}}{L}}, \quad (4.6)$$

which is almost a factor of 3 weaker than the 0CV bound. In more realistic conditions we expect a sensible loss of signal from the requirement of displacement, although better background discrimination might be also achieved thanks to the converted photon. We do not even study the 2CV photon category because it is plagued by a very small signal efficiency.

As a useful input for future more detailed studies, we collect here some considerations about the LHCb reach outside the interval $4.9 \text{ GeV} < m_{\gamma\gamma} < 6.3 \text{ GeV}$:

- ◊ As far as the signal is concerned, we do not expect a significant drop in the efficiency going at higher invariant masses. As detailed in appendix D at higher invariant masses the diphoton final state will be less forward, reducing the geometric acceptance. However, the decreasing boost of the produced particle is more than compensated by the higher efficiency of the photon p_T cuts. Practically, the ultimate high mass reach of LHCb is not very relevant for the purposes of discovering new physics, since above 10–20 GeV it is likely to be superseded by the ATLAS/CMS diphoton searches (see [1] for details).
- ◊ The most stringent limitation for scanning masses above $\sim 12 \text{ GeV}$ at LHCb is the current dynamic range of the ECAL. This range, which depends on the electronics and not on the actual configuration of the detector, limits at the moment reconstructing photons with E_T above $\sim 10 \text{ GeV}$ ($\sim 6 \text{ GeV}$ at the level of the first level of the software trigger HLT1). Therefore, a potential increase in the dynamic range of the ECAL after the LHCb Upgrade would be very beneficial to increase LHCb's sensitivity to higher masses. For instance, modifying the electronics to increase the

range to 15–20 GeV would be enough to cover all the mass range for which ATLAS and CMS have a poor sensitivity.

- ◊ As already mentioned, the invariant mass distribution in the 0CV category from the data in ref. [38] displays a drop for masses larger than approximately $m_{\gamma\gamma} \simeq 5.7$ GeV. In appendix B, we argue that such drop is a consequence of the use of 2×2 ECAL cells to measure the photon energy deposition at HLT1. If our guess is correct there should be another drop of the background at low invariant masses in a region not showed by the plot of ref. [38].
- ◊ Understanding the composition of the diphoton background given in ref. [38] would require a detailed MC simulation, including detector effects, which is beyond the scope of this paper. In appendix C we provide a simple kinematical argument which shows that the background from boosted π^0 faking photons is likely to dominate over the one from real photons. A categorization of the data in different η regions would help suppressing this background at small η . This could be used to maximize the reach. A quantitative assessment of this is left for future studies.
- ◊ The precise assessment of the 1CV limit and sensitivities would require a dedicated search for promptly decaying resonances *without* the requirement of a displaced vertex. In this case one could get an even better reach than the one presented here by combining the 0CV and the 1CV category.

We hope that this work could provide enough motivation to explore further the open issues described above and in general the possibility of performing bump hunts on the top of the diphoton background at such low invariant masses.

5 Conclusions

The LHC has pushed the energy scale of many motivated SM extensions beyond the TeV range. How to experimentally test NP models at and beyond those scales? A possibility is to look for low energy remnants of such theories, like pseudo-Goldstone bosons (aka ALPs) from an approximate global symmetry.

In section 3 we showed that ALPs with masses and decay constants of interest for flavor factories arise as a solution to the strong CP problem (“heavy QCD axions”) and in frameworks motivated by Dark Matter freeze-out and the Higgs hierarchy problem (e.g. the SUSY R -axion as mediator of DM interactions). These scenarios share the prediction of ALP couplings to gluons and photons, that are currently tested in a particularly poor way for masses below $O(10)$ GeV.

In section 4, we have used 80 pb^{-1} of public LHCb data to set a bound on diphoton resonances of $\sigma(pp \rightarrow Xa(\gamma\gamma)) \lesssim 100 \text{ pb}$, and we have performed a first study to assess future LHCb sensitivities. This bound is already the strongest existing one on the ALPs discussed above, and shows that LHCb has a very promising potential to test unexplored territory of well-motivated BSM extensions. Technical results that might be useful for future LHCb studies are provided in appendices C and D. We have also recasted BABAR

limits on $\Upsilon \rightarrow \gamma a(jj)$ on this model, and estimated the associated future capabilities of Belle-II, finding they would be particularly relevant for masses below ≈ 3 GeV. These results are summarised in figure 1.

Our findings provide a strong motivation to pursue the phenomenological and experimental program of testing this class of ALPs at LHCb and Belle-II, thus enriching the physics case of both machines.

Acknowledgments

We thank Sean Benson and Albert Puig Navarro for many useful discussions, in particular about the LHCb note [38], and Marco Bonvini for clarifications about ggHiggs. D.R. thanks Simon Knapen for discussion and clarifications on ref. [57]. A More on the signal

We compute the gluon fusion production cross section at N3LO using ggHiggs v4 [43–46] and at LO using MadGraphLO. We compare the two predictions in figure 3 left, for different choices of the pdf sets, and rescaling the ggHiggs cross section using that $c_3/f = 1/(\sqrt{2}v)$ with $v \simeq 246$ GeV (anomaly coefficient coming from a top loop). The agreement between these determinations goes from the 20% level at $m_a = 20$ GeV, down to a factor of 2 and worse for $m_a \leq 4$ GeV. We mention that at such low values the ggHiggs output should be taken with extra care, as it also yields some negative LO and NLO cross sections. This comparison underlines the need for a more precise determination of the production cross section, especially for ALP masses below 5 GeV or so. This task goes however beyond the purpose of this paper. We use the ggHiggs prediction with the `mstw2008nnlo` pdf set for all the LHC phenomenology in section 2.

Figure 3. Left: production cross section of an ALP coupled to $G\tilde{G}$, as determined with MadGraphLO and with ggHiggs at N3LO, for various choices of the pdf sets, fixing $f = 1$ TeV and $c_3 = 1$. For ggHiggs we display the band enclosed by $\mu_f = \mu_r = m_a/2$ and $\mu_f = \mu_r = 2m_a$. Right: ALP branching ratio into diphoton at LO, NLO and NNLO, and from MadGraphLO.

Coming now to the ALP branching ratios, we use the NNLO QCD correction to the width of a pseudoscalar into gluons from [42]. In the notation of eq. (2.4), it reads $K_{gg} = 1 + \frac{\alpha_s^{(5)}}{\pi} E_A + \left(\frac{\alpha_s^{(5)}}{\pi}\right)^2 E_A \left(\frac{3}{4} E_A + \frac{\beta_1}{\beta_0}\right)$, where $E_A = \frac{97}{4} - \frac{7}{6} N_f$, $\beta_0 = \frac{11}{4} - \frac{N_f}{6}$, $\beta_1 = \frac{51}{8} - \frac{19}{24} N_f$. In figure 3 right we plot the resulting diphoton branching ratio together with its NLO and LO value and with the one given by Madgraph. NNLO corrections to the diphoton branching ratio reduce its LO value by a factor of $\simeq 2$, over the whole mass range we consider. We use the NNLO expression for all the limits and sensitivities described in section 2.

B $m_{\gamma\gamma}$ distribution of the 0CV category

In our analysis, we assume the background yield to be roughly constant with respect to the diphoton invariant mass even outside the mass range reported in ref. [38]. This is to provide an order-of-magnitude estimate of the background for the LHCb sensitivities to ALPs. The flatness of the data is actually seen in the 1CV and 2CV categories of figure 4(b–c) of ref. [38]. However, in the 0CV category (figure 4(a)), a kink is observed at large invariant masses. In what follows, we argue that this is an artifact due to the trigger level invariant mass cut.

In the invariant mass calculation at the trigger level of the 0CV category, two approximations are employed to speed up the calculation: 1) the photon energy is calculated from the energy deposition in 2×2 ECAL cells, 2) the mass formula takes into account only the leading order of the diphoton opening angle, $m_{\gamma\gamma}^{\text{trigger}} = \sqrt{E_{\gamma_1}^{(2 \times 2)} E_{\gamma_2}^{(2 \times 2)}} \Delta\theta_{\gamma_1\gamma_2}$. We examined these two approximation and concluded that 1) could be the reason for the kink.

It is easy to show that the approximate mass formula is equivalent to the full mass formula with $\mathcal{O}(0.01)$ accuracy. This comes from the fact that the diphoton events within the LHCb fiducial volume have a small opening angle $\Delta\theta_{\gamma_1\gamma_2} = \mathcal{O}(0.1)$, after the E_T trigger cuts are imposed. On the other hand one needs to use 3×3 cells to capture full energy deposit of a photon, so the information based on 2×2 cells underestimates the photon energy, which leads to the lower invariant mass, $m_{\gamma\gamma}^{\text{trigger}} < m_{\gamma\gamma}^{\text{full}}$. Because the first

Figure 4. Left: ALP signal event with $m_a = m_{B_s}$ in diphoton invariant mass $m_{\gamma\gamma}^{\text{full}}$ (yellow) and trigger level diphoton invariant mass $m_{\gamma\gamma}^{\text{trigger}}$ (blue). Fraction of energy, $E_{\gamma}^{(2 \times 2)} = E_{\gamma}^{\text{full}} \min[1, \mathcal{P}_{\text{normal}}(\mu = 0.95, \sigma = 0.1)]$, is used for the calculation of trigger level invariant mass. Right: SM diphoton event with a cut, $3.5 \text{ GeV} < m_{\gamma\gamma}^{\text{trigger}} < 6 \text{ GeV}$, in $m_{\gamma\gamma}^{\text{full}}$ (yellow) and in $m_{\gamma\gamma}^{\text{trigger}}$ (blue). To demonstrate bin migration effect, the distribution in $m_{\gamma\gamma}^{\text{trigger}}$ is flat normalized.

invariant mass cut is made at the trigger level, $3.5 \text{ GeV} < m_{\gamma\gamma}^{\text{trigger}} < 6 \text{ GeV}$, bins with a given $m_{\gamma\gamma}^{\text{trigger}}$ migrate to bins with $m_{\gamma\gamma}^{\text{full}} > m_{\gamma\gamma}^{\text{trigger}}$. This could explain why the reduction of the yield appears above $m_{\gamma\gamma}^{\text{full}} \sim 6 \text{ GeV}$. This argument is confirmed by figure 1 bottom of [38], that shows how the trigger level mass distribution of the B_s signal shifts to higher values of off-line invariant mass.

We further validate the argument modelling the energy smearing of the LHCb ECAL. For simplicity, we focus on the inner ECAL and approximate 2×2 cells as a circle of radius 4 cm. Because the Molière radius of a photon in the LHCb ECAL is 3.5cm,⁶ the energy deposit inside the 2×2 cells is expected to be 95% of the total energy deposit on average. In order to model a realistic environment we include a stochastic gaussian smearing from the average value. We choose a standard deviation of 10%⁷ such that the shift of the signal at $m_a = m_{B_s}$ reproduces figure 1 bottom of [38]. This result is shown in figure 4 left. Then, we use the same prescription for the background-like events. The result is shown in figure 4 right. The invariant mass distribution in terms of $m_{\gamma\gamma}^{\text{trigger}}$ is normalized to be rectangular after the invariant mass cut. When the same dataset is plotted in terms of $m_{\gamma\gamma}^{\text{full}}$ we can see that a kink is induced.

C Details on the LHCb calorimeter

The Electromagnetic Calorimeter (ECAL) of LHCb has three layers with different granularities and is placed vertically with respect to the beam axis at $z_{\text{Ecal}} = 12.52 \text{ m}$ away from the collision point. The ECAL square cells have side lengths of $\Delta x_{\text{cell}} = 4.04, 6.06 \text{ cm}$, 12.12cm for inner, middle, and outer layer, respectively [97]. The photon reconstruction

⁶Inside the Molière radius, the energy deposit into the corresponding area is 90% of the total energy on average.

⁷ $E_{\gamma}^{(2 \times 2)} = E_{\gamma}^{\text{full}} \min[1, \mathcal{P}_{\text{normal}}(\mu = 0.95, \sigma = 0.1)]$.

algorithm uses patterns of 3×3 cells in each layer. Therefore, the inner layer, where most of the energy is expected to be deposited, has the best angular resolution.

Invariant mass resolution. The invariant mass can be written as

$$m_{\gamma\gamma}^2 = 2E_{\gamma_1}E_{\gamma_2}(1 - \cos \theta_{\gamma\gamma}), \quad (\text{C.1})$$

where $E_{\gamma_{1,2}}$ are the energies of the two photons and $\theta_{\gamma\gamma}$ is the angular separation between them. Using the above formula, we can relate the invariant mass smearing to the photon energy smearing and the ECAL granularity

$$\begin{aligned} \frac{\delta m_{\gamma\gamma}}{m_{\gamma\gamma}} &\simeq \frac{1}{2} \frac{\delta m_{\gamma\gamma}^2}{m_{\gamma\gamma}^2} = \frac{1}{2} \left(\frac{\delta E_{\gamma_1}}{E_{\gamma_1}} \oplus \frac{\delta E_{\gamma_2}}{E_{\gamma_2}} \oplus \frac{\sin \theta_{\gamma\gamma} \delta \theta}{1 - \cos \theta_{\gamma\gamma}} \right) \\ &\simeq \frac{1}{\sqrt{2}} \frac{\delta E_{\gamma}}{E_{\gamma}} \oplus \frac{\delta \theta}{\theta_{\gamma\gamma}} = 6.4\% \sqrt{\frac{\text{GeV}}{E_{\gamma}}} \oplus 0.6\% \oplus 0.3\% \frac{E_{\gamma}}{m_{\gamma\gamma}}. \end{aligned} \quad (\text{C.2})$$

In the second line we assumed for simplicity $E_{\gamma_1} \simeq E_{\gamma_2} \simeq E_{\gamma}$ and approximated our result at the first order in $\theta \ll 1$. To obtain the second expression in the second line, we used the LHCb ECAL energy resolution $\delta E/E \simeq 9\% \sqrt{\text{GeV}/E} \oplus 0.8\%$ reported in ref. [98] and the granularity of the inner layer of the ECAL $\delta \theta = \Delta x_{\text{cell}}/z_{\text{Ecal}} \simeq 0.003$. Moreover, we have approximated $\theta_{\gamma\gamma} \simeq m_{\gamma\gamma}/E_{\gamma}$ to get an expression of the typical energy smearing as a function of the typical photon energy. In computing the invariant mass resolution in the text, we take $E_{\gamma} = 50\text{GeV}$. We believe this is a realistic benchmark value for this analysis because $E_{\gamma} = E_{T\gamma} \cosh \eta$ and the LHCb analysis in ref. [38] imposes $E_{T\gamma} > 3.5\text{GeV}$ and $E_{T\gamma_1} + E_{T\gamma_2} > 8\text{GeV}$ on 2×2 cell clusters.

Background from π^0 faking single photon. One of the advantages to study low mass diphoton resonances at LHCb is that low energy fake photons from QCD can be distinguished from real photon candidates. Here we focus on fake photons from π^0 decays whose collimated diphoton decay can mimic a single photon candidate.

Photon pairs from π^0 decay have angular separation $\theta_{\gamma\gamma}^{\pi^0} \simeq m_{\pi^0}/E_{\gamma} \simeq 2m_{\pi^0}/E_{\pi^0}$. The corresponding separation on a given ECAL layer is then

$$\Delta r_{\gamma\gamma}^{\pi^0} \simeq z_{\text{Ecal}} \theta_{\gamma\gamma}^{\pi^0} \simeq \frac{2z_{\text{Ecal}} m_{\pi^0}}{E_{\pi^0}}. \quad (\text{C.3})$$

If the π^0 is very energetic, the diphoton separation $\Delta r_{\gamma\gamma}^{\pi^0}$ is smaller than a single cell size and the object is mostly misidentified as a single photon candidate of energy E_{π^0} . Viceversa, when a pion is less energetic and the diphoton separation is large, $\Delta r_{\gamma\gamma}^{\pi^0} > \mathcal{O}(2)\Delta x_{\text{cell}}$, two photon clusters are separately formed and a pion is *resolved*. In a regime where $1.8\Delta x_{\text{cell}} > \Delta r_{\gamma\gamma}^{\pi^0} \gtrsim 0.5x_{\text{cell}}$, the shower shape information makes a single energy cluster identified as a π^0 , which is called *merged* π^0 [99]. The identification efficiency using both *resolved* and *merged* π^0 is $\mathcal{O}(50\%)$ for $p_{T\pi^0} \lesssim 10\text{GeV}$ (figure 21 left of ref. [99]). As shown in figure 5, the final energy thresholds vary depending on the ECAL layer. For example, in the inner ECAL diphotons with $E_{\pi^0} < 28\text{GeV}$ corresponding to a large separation of $\Delta r_{\gamma\gamma}^{\pi^0} > 3\Delta x_{\text{cell}}$

Figure 5. Separation of photon pairs from π^0 decay as a function of the pion total energy E_{π^0} . If this photon pair is misidentified as a single (fake) photon, E_{π^0} is the energy of the fake photon. Cases of inner, middle, and outer layers are plotted in blue, red and magenta respectively.

can be reconstructed as resolved π^0 s, while the ones with $46 \text{ GeV} < E_{\pi^0} \lesssim 160 \text{ GeV}$ could be seen as merged π^0 s.

The planned LHCb $B_s \rightarrow \gamma\gamma$ analysis uses a photon energy threshold of $E_{T\gamma} > 3.5 \text{ GeV}$ which corresponds to $E_\gamma = 13(260) \text{ GeV}$ at $\eta = 2(5)$. Comparing with the threshold determined above for the pions to be detected as fake photons, one learns that i) the background to the current search contains a non-negligible amount of fake photons; ii) a categorization in η of the data could help in reducing photon fakes.

D Signal acceptance and efficiency

In this appendix we discuss the strategy that we adopted to estimate the acceptance and efficiency of the signal. As mentioned in the main text, we eventually consider a constant value for the product of acceptance times efficiency on the mass range of interest for this paper. As reference value, we have chosen the one at the invariant mass of 5 GeV , corresponding to the B_s signal considered in the LHCb note [38].

In order to estimate the acceptance and efficiency of the signal at LHCb, we implement the axion model in FeynRules [49], we generate events with MadgraphLO_v2.6 [47, 48] and shower them with Pythia 8.1 [100, 101], matching up to 1 extra jets [102]. We then perform a simple analysis of the resulting samples using MadAnalysis5 [103]. Note that the signal events which are inside the acceptance of LHCb contain topologies where the axion has acquired a significant longitudinal boost, without the need of extra hard radiation. As a consequence the signal efficiency is essentially not changed by including extra jets (the minimal E_T cuts of the LHCb selection can be satisfied with just a small transverse boost). This has to be contrasted with the low invariant mass searches at ATLAS/CMS where the recoil of the resonance against the extra jet increases the signal efficiency of the p_T cuts significantly, as it was shown in ref. [1].

$m_a[\text{GeV}]$	5	7	9	11	13	15
\mathcal{A}	0.15	0.15	0.14	0.13	0.12	0.12
ϵ	0.26	0.36	0.46	0.64	0.72	0.81

Table 1. Acceptance (D.1) and efficiency (D.2) for the axion signal in the LHCb analysis, for different mass values.

In table 1 we report the acceptance and the efficiency that we find in the mass range 5–15 GeV by following the selection cuts of ref. [38], that is

$$\mathcal{A} : 2 < \eta(\gamma) < 5 \tag{D.1}$$

$$\epsilon : \begin{cases} E_T(\gamma) > 3.5 \text{ GeV}, \\ E_T^{\gamma_1} + E_T^{\gamma_2} > 8 \text{ GeV} \\ p_T(\gamma_1\gamma_2) > 2 \text{ GeV} \end{cases} \tag{D.2}$$

We first observe that the value we find for the product $\mathcal{A} \times \epsilon$, though in the same ballpark than the number reported by the LHCb note (see eq. (4.3)), differs by around a factor of 2 on the case of $m_a = 5 \text{ GeV}$. In order to check wheter the discrepancy could be caused by detector effects, we also processed the same samples using Delphes as fast LHCb detector simulator, but we did not find a substantial improvement in the agreement.

However, besides the discrepancy on the benchmark of 5 GeV, our simple analysis provides indications on what could be the expected product of $\mathcal{A} \times \epsilon$ for the selection cuts (D.2) for different mass values. As one can observe from table 1, increasing the mass of the axion the acceptance generically decreases. This is due to the fact that a heavier resonance will more likely be produced with less boost on the longitudinal axis, and hence the resulting photons will be less into the forward region which is covered by the LHCb detector. On the other hand, for larger values of the axion mass the outgoing photons will be more energetic and will more likely pass the energy and p_T cuts, hence resulting in an increase in the signal efficiency. The combination of these two effects result in a product of acceptance times efficiency which actually slightly grows along the mass interval 5–15 GeV, but does not changes significantly. This justifies the simplified choice that we have adopted in the main part of the paper.

ABSTRACT

We derive a new bound on diphoton resonances using inclusive diphoton cross section measurements at the LHC, in the so-far poorly constrained mass range between the Υ and the SM Higgs. This bound sets the current best limit on axion-like particles that couple to gluons and photons, for masses between 10 and 65 GeV. We also estimate indicative sensitivities of a dedicated diphoton LHC search in the same mass region, at 7, 8 and 14 TeV. As a byproduct of our analysis, we comment on the axion-like particle interpretation of the CMS excesses in low-mass dijet and diphoton searches.

1. Introduction

Searches for two body decays of heavy resonances led to fundamental discoveries in the history of particle physics such as the J/ψ [1,2], the Υ [3] and the Z boson [4]. An extensive program is currently looking for higher mass resonances at the LHC in various final states (see [5] for a complete list).

Despite the high background rates, advances in data-driven background estimates guarantee good sensitivities to discover/exclude such peak signals. A marvelous proof of the high performance of resonance searches at the LHC is the recent discovery of the Standard Model (SM) Higgs boson in the diphoton channel [6,7].

As a matter of fact, the current LHC search program is mostly tailored to probe new resonances of mass higher than roughly 100 GeV. This is the result of a general theoretical bias towards heavy new physics (NP) and of the common belief that either previous collider experiments (UA1, UA2, LEP and Tevatron) and/or Higgs coupling fits (through the decay of the Higgs into two new particles) put constraints on lighter resonances that are stronger than the LHC capabilities. On the experimental side, going to low masses poses the challenge of looking for resonances with a mass below the sum of the cuts on the transverse momentum (p_T) of the decay products.

The aim of this letter is to go beyond these common beliefs and to motivate the LHC collaborations to look for resonances down to the smallest possible mass. We first derive a new bound (of 10–100 pb) on the diphoton signal strength of a new resonance in the mass range between the Υ and the SM Higgs. This new bound comes from inclusive diphoton cross section measurements at ATLAS [8,9] and CMS [10]. Assuming zero knowledge about the background, we simply impose that the NP events are less than the total measured events plus twice their uncertainty.

We show how this conservative procedure sets already the strongest existing constraint on axion-like particles (ALPs) with mass between 10 and 65 GeV. We finally estimate the indicative reaches on the diphoton signal strengths that could be attainable by proper searches at the LHC, up to its high luminosity (HL) phase, and interpret their impact on the ALP parameter space.

2. Axion-like particles in diphotons

When a $U(1)$ global symmetry (which can be the subgroup of some larger global symmetry \mathcal{G}) is spontaneously broken in the vacuum, then a massless Nambu–Goldstone boson (NGB) arises in the low energy spectrum. If the $U(1)$ symmetry is only approximate, the NGB gets a mass m_a and it becomes a pseudo-Nambu–Goldstone boson (pNGB), often called axion-like particle (ALP). The mass m_a of the pNGB is a technically natural parameter which depends on the explicit breaking of the $U(1)$ global symmetry, and is smaller than the associated NP scale $M_{\text{NP}} \sim 4\pi f_a$, where f_a is

* Corresponding author.

E-mail address: filippo.sala@desy.de (F. Sala).

the scale of spontaneous breaking. In particular m_a can be smaller than the SM Higgs mass without any fine-tuning price.

The axial couplings of the pNGB to SM gauge bosons can be written as

$$\mathcal{L}_{\text{int}} = \frac{a}{4\pi f_a} \left[\alpha_s c_3 G\tilde{G} + \alpha_2 c_2 W\tilde{W} + \alpha_1 c_1 B\tilde{B} \right], \quad (1)$$

where $\alpha_1 = 5/3\alpha'$ is the GUT normalized $U(1)_Y$ coupling constant, a is the canonically normalized pNGB field, and the coefficients c_i encode the Adler–Bell–Jackiw (ABJ) anomalies of the global $U(1)$ with $SU(3)$ and $SU(2) \times U(1)_Y$. Further couplings of the pNGB with the SM Higgs and/or with the SM fermions can be set to zero if these fields are not charged (or very weakly charged) under the global $U(1)$.

As one can see from Eq. (1), the strength of the couplings of the pNGB is controlled by its decay constant f_a . As we will show, the phenomenology of the pNGB becomes of interest for this study, and more in general for present colliders, for $f_a \sim 0.1$ –10 TeV. Decay constants in this range are ubiquitous in popular theoretical frameworks addressing the naturalness of the EW scale, like low-scale Supersymmetry (SUSY) and Compositeness.¹ Note that generically we expect that other fields associated to the $U(1)$ spontaneous breaking (e.g. the radial mode) should have a mass $\lesssim 4\pi f_a$. Hence in the lower extreme of the range for f_a other signatures associated to the BSM theory could be accessible at the LHC.

Supersymmetry (SUSY) and its breaking predict on general grounds the existence of an R -axion [20], pNGB of the $U(1)_R$ symmetry, potentially accessible at the LHC if the SUSY scale is sufficiently low [21]. In this context the couplings to gauge bosons of Eq. (1) are realized naturally from ABJ anomalies between $U(1)_R$ and the SM gauge group, while the couplings to SM fermions and Higgses can be set to zero with a well-defined R -charge assignment ($R_H = 0$ in the notation of [21]). In composite Higgs models, attempts of fermionic UV completions point to the need of non-minimal cosets (see e.g. [22–24]), which in turn imply the existence of pNGBs lighter than the new confinement scale. See [25] for recent work about these pNGBs, and [26] for a systematic classification of the cosets structures that give rise to pNGBs that couple to both gluons and EW gauge bosons.

A common feature of both SUSY and Composite Higgs models is that the QCD anomaly receives an irreducible contribution from loops of colored states, like gluinos and/or tops, which are generically chiral under the spontaneously broken $U(1)$. As a consequence one typically expects $c_3 \neq 0$, unless model dependent cancellations occur. In conclusion, $f_a \sim 0.1$ –10 TeV and $c_3 \neq 0$ in a broad class of SUSY and Composite Higgs models, so that a is copiously produced in pp collisions at the LHC. For this reason we believe that our study applies to a wide range of theoretically motivated ALP models.

From a phenomenological point of view, ALPs of interest for this study have received much attention as mediators of simplified Dark Matter models (see for example the recent [27]). Finally, ALPs can exist if Strong Dynamics is present at some scale [28]. In such a case, having $f_a \sim 0.1$ –10 TeV would be a phenomenological assumption not motivated by any naturalness consideration.

For $m_a \lesssim m_h$, the relevant two body decays of a are in diphotons and dijets, with widths

$$\Gamma_{gg} = K_g \frac{\alpha_s^2 c_3^2 m_a^3}{8\pi^3 f_a^2}, \quad \Gamma_{\gamma\gamma} = \frac{\alpha_{\text{em}}^2 c_\gamma^2 m_a^3}{64\pi^3 f_a^2}, \quad (2)$$

where $c_\gamma = c_2 + 5c_1/3$, and where both α_s and α_{em} are computed at the mass of m_a . We encode the higher-order QCD corrections in $K_g = 2.1$ [29]. Unless $c_{1,2} \gtrsim 10^2 c_3$, the width into gluons is the dominant one. The total width Γ_{tot} is typically very narrow, for example for $f_a \gtrsim 100$ GeV and $c_i \sim O(1)$ one obtains $\Gamma_{\text{tot}}/m_a \lesssim 10^{-3}$.

For simplicity, we do not study the phenomenology associated to the $Z\gamma$ decay channel, which is anyhow open only for $m_a > m_Z$, and phenomenologically more relevant than $\gamma\gamma$ only for specific values of c_1 and c_2 .

3. Current searches

A new resonance decaying in two jets or two photons is probed at colliders by looking at the related invariant mass distributions, possibly in addition with extra objects, either SM or BSM (see e.g. [30,31]) depending on the production mechanism. We summarize and discuss here the most relevant searches for light resonances at the LHC, and refer to the supplementary material for a more complete list and a discussion of the existing searches and of diphoton cross section measurements, at the LHC, Tevatron, LEP and Sp \bar{p} S.

- ◇ Dijet resonances down to 50 GeV have been recently looked for by CMS [32]. In order to overcome the trigger on the jet p_T 's, CMS has a strong cut on the total hadronic activity H_T . Recoiling against the hard jet, the resonance is boosted and its decay products collimated. For this reason advanced jet substructure techniques were essential to reconstruct the dijet resonance inside a single “fat” jet [33,34]. The CMS low-mass dijet limits are given on the inclusive dijet signal strength of a $q\bar{q}$ -initiated resonance $\sigma_{q\bar{q}}^{\text{CMS}}$. We recast them for a gluon initiated resonance as

$$\sigma_{gg}^{\text{our}} = \sigma_{q\bar{q}}^{\text{CMS}} \cdot \frac{\epsilon_{H_T}^{q\bar{q}}}{\epsilon_{H_T}^{gg}}, \quad (3)$$

where $\epsilon_{H_T}^{q\bar{q}}$ and $\epsilon_{H_T}^{gg}$ are the efficiencies of the cut in hadronic activity $H_T > 650$ GeV.² These are estimated from simulations³ of a gg and a $q\bar{q}$ initiated scalar signals (including matching up to 2 jets and detector simulation). We take the efficiency ratio in Eq. (3) to be constant and equal to 0.08, which is the value that we find at $m_a = 80$ GeV. Accounting for the m_a dependence introduces variations up to 20% within the mass range 50–125 GeV. The fact that the efficiency ratio is roughly constant in m_a can be understood observing that \sqrt{s} is always dominated by the cut of $H_T > 650$ GeV, which is much larger than any of the values of m_a of our interest.

- ◇ Existing diphoton searches are inclusive and extend to a lower invariant mass of 65 GeV [43–46], where the two photons satisfy standard isolation and identification requirements. The ATLAS diphoton search at 8 TeV [43] is the one extending down to 65 GeV. The bound is given in term of the diphoton “fiducial” cross-section $\sigma^{\text{fid}} = \sigma^{\text{th}} \cdot \epsilon_5 / C_X$. C_X is a model independent number that we take from [43] and encodes the

¹ String theory constructions could provide an extra motivation for ALPs. However, the expected values of f_a in string models like [11–13] are order of magnitudes too high for being phenomenologically interesting at colliders. Similarly, solutions of the strong CP problem based on a QCD axion [14–17] with a decay constant f_a at the TeV scale are hard to conceive (see however [18,19]).

² We thank Phil Harris for private communications on [32].

³ Throughout this paper we use FeynRules 2.0 [35], MadGraph 5 v2 LO [36,37] with the default pdf set, Pythia 8.1 [38,39], DELPHES 3 [40] and MadAnalysis 5 [41]. The MLM matching [42] is performed to include matrix element correction to ISR's.

detector acceptance once the kinematical cuts are already imposed ($C_X \simeq 0.6$ in the mass range of our interest).⁴ To extract the efficiency ϵ_S we simulated the signal for the ALP model in Eq. (1) accounting for all the cuts of [43].

The CMS searches at 8 and 13 TeV [44,46] provide the bound on the theoretical signal strength for a resonance with the same couplings of the SM Higgs but lighter mass. Since gluon fusion is the dominant production mechanism for a SM Higgs in the low mass range [47], we take the CMS result as a bound on the theoretical diphoton signal strength of our ALP.

4. New bound and LHC sensitivities from $\gamma\gamma$ cross-section measurements

Here we extract a new bound on diphoton resonances from inclusive diphoton measurements at the LHC and at Tevatron, and we present the projected LHC sensitivities.

New bound from measurements The papers [8–10,49] provide tables of the measured differential diphoton cross sections per invariant mass bin, $d\sigma_{\gamma\gamma}/dm_{\gamma\gamma}$, together with their relative statistical (Δ_{stat}) and systematical (Δ_{sys}) uncertainties. We derive a conservative bound on the theoretical signal strength $\sigma_{\gamma\gamma}^{\text{th}}$ of a diphoton resonance by imposing

$$\sigma_{\gamma\gamma}^{\text{th}}(m_a) \lesssim \left[m_{\gamma\gamma}^{\text{Bin}} \cdot \frac{d\sigma_{\gamma\gamma}}{dm_{\gamma\gamma}} (1 + 2\Delta_{\text{tot}}) \right] \cdot \frac{1}{\epsilon_S(m_a)}, \quad (4)$$

where $\Delta_{\text{tot}} = \sqrt{\Delta_{\text{sys}}^2 + \Delta_{\text{stat}}^2}$, $m_{\gamma\gamma}^{\text{Bin}}$ is the size of the bin containing m_a , and ϵ_S is the signal efficiency accounting for the kinematical and the isolation cuts of the photons.

At a given center of mass energy s , we derive ϵ_S as

$$\epsilon_S(m_a) = \frac{\sigma_{\gamma\gamma}^{\text{MCcuts}}(m_a, s)}{C_s \sigma_{\gamma\gamma}^{\text{LO}}(m_a, s)}. \quad (5)$$

$\sigma_{\gamma\gamma}^{\text{LO}}(m_a, s)$ is the LO gluon fusion cross section, derived using the gluon pdf from [51], multiplied by the LO branching ratio into $\gamma\gamma$ computed from Eq. (1). We also compute a total “simulated” diphoton signal strength $\sigma_{\gamma\gamma}^{\text{MCTot}}$, which includes matching up to 2 jets, by a Monte Carlo (MC) simulation of the signal for the ALP model in Eq. (1). We find that $\sigma_{\gamma\gamma}^{\text{LO}}$ reproduces up to a constant factor C_s the shape of $\sigma_{\gamma\gamma}^{\text{MCTot}}$ for $m_{\gamma\gamma} \gtrsim 60$ GeV (i.e. sufficiently far from the sum of the minimal detector p_T cuts on the photons). A constant factor $C_s \equiv \sigma_{\gamma\gamma}^{\text{MCTot}}(s)/\sigma_{\gamma\gamma}^{\text{LO}}(s)$ is hence included in Eq. (5) and we obtain $C_{7\text{ TeV}} \simeq C_{8\text{ TeV}} \simeq 0.85$ while $C_{2\text{ TeV}} \simeq 1$ at the Tevatron center of mass energy. The signal strength after cuts $\sigma_{\gamma\gamma}^{\text{MCcuts}}$ is obtained by the MC simulations imposing on the events samples the relevant cuts for each of the experimental search.

To validate our procedure with a measured quantity, we simulate the SM diphoton background and verify that it reproduces well the experimental diphoton cross section measurements of [8,9].

Fig. 1. Bounds (shaded) and expected sensitivities (lines) on the diphoton signal strength of a resonance produced in gluon fusion, at 8 TeV. More details in the text.

We refer the reader to the supplementary material for more details on our derivation of $\epsilon_S(m_a)$, including validations. We list in Table 1 the efficiencies as a function of m_a for the various cross section measurements.

We stress that, for very light mass values, a NP resonance can pass the cuts on the photon p_T 's by recoiling against a jet, which is not vetoed since the cross section measurements are inclusive. This is reflected in the efficiencies of the signal which are non vanishing (though small) also in the region of very low resonance mass.

Our final results are shown in Fig. 1, where the conservative bound extracted from 8 TeV ATLAS data [9] using Eq. (4) is compared against the existing 8 TeV searches at ATLAS [43] and CMS [44].

Sensitivities from measurements An expected sensitivity $\sigma_{\gamma\gamma}^{\text{sens}}$ can be derived by assuming the measured cross section to be dominated by the SM diphoton background, and requiring the signal to be within the $2\Delta_{\text{tot}}$ variation of the background:

$$\sigma_{\gamma\gamma}^{\text{sens}}(m_a) = \left[m_{\gamma\gamma}^{\text{Bin}} \cdot \frac{d\sigma_{\gamma\gamma}}{dm_{\gamma\gamma}} \cdot 2\Delta_{\text{tot}} \right] \cdot \frac{1}{\epsilon_S(m_a)}. \quad (6)$$

The sensitivities we present in Fig. 1 as thick continuous and dashed lines correspond to two different choices of $m_{\gamma\gamma}^{\text{Bin}}$, and both correspond to 8 TeV data with integrated luminosity 20.2 fb^{-1} [9].

The most conservative sensitivity between the two corresponds to the binning given directly in the ATLAS 8 TeV cross section measurement [9], where the mass bins have a size of 30 to 10 GeV in the region of our interest. A better sensitivity is obtained by reducing the bin size $m_{\gamma\gamma}^{\text{Bin}}$ down to the invariant mass resolution obtained from the ATLAS and CMS ECAL energy resolution on a single photon, that we extract from [52] and [40], and which leads

⁴ We thank Liron Barak for private communications on [43].

to mass bins of size $\simeq 3$ GeV for values of m_a below the sum of the minimal p_T cuts of the photons (see the supplementary material for more details). Since the signal is narrow, the number of signal events in the bin is not affected. The number of background N_{bkg} events is instead reduced and the sensitivity increased assuming that the errors scale as $\sqrt{N_{\text{bkg}}}$.⁵ This scaling holds for statistical errors and we assume the same scaling for systematic ones. The assumption is motivated by the scaling of some of the systematics (e.g. those associated to poor statistics in control regions) and by the fact that the CMS cross section measurements [10] do not separate statistical from systematical uncertainties.

Sensitivities adding MC input, up to 14 TeV Now we discuss how to rescale the sensitivities from lower energies \sqrt{s}_{low} to higher energies \sqrt{s}_{high} . To rescale the diphoton background we first obtain, from MC simulations, $\sigma_{\text{low}}^{\text{MC}}$ and $\sigma_{\text{high}}^{\text{MC}}$. These are the SM diphoton cross sections at \sqrt{s}_{low} and \sqrt{s}_{high} after the cuts of the cross section measurements at \sqrt{s}_{low} are imposed. We then take $\sigma_{\gamma\gamma,\text{high}}^{\text{bkg}} = \sigma_{\gamma\gamma,\text{low}}^{\text{bkg}} \sigma_{\text{high}}^{\text{MC}} / \sigma_{\text{low}}^{\text{MC}}$, where $\sigma_{\gamma\gamma,\text{low}}^{\text{bkg}}$ is extracted from the experimental measurements. The total relative uncertainties for the background are rescaled as the squared root of the total number of events so that $\Delta_{\text{high}} = \sqrt{L_{\text{low}}/L_{\text{high}}} \sqrt{\sigma_{\text{low}}^{\text{MC}}/\sigma_{\text{high}}^{\text{MC}}} \Delta_{\text{low}}$. Finally we also account for the different efficiencies for the signal going from \sqrt{s}_{low} to \sqrt{s}_{high} . All in all, starting from Eq. (6) we get

$$\sigma_{\gamma\gamma,\text{high}}^{\text{sens}}(m_a) = \sqrt{\frac{L_{\text{low}}}{L_{\text{high}}} \cdot \frac{\sigma_{\text{high}}^{\text{MC}}}{\sigma_{\text{low}}^{\text{MC}}} \cdot \frac{\epsilon_S^{\text{low}}}{\epsilon_S^{\text{high}}}} \cdot \sigma_{\gamma\gamma,\text{low}}^{\text{sens}}(m_a). \quad (7)$$

We show it in Fig. 1 for the extrapolation of the ATLAS reach from $\sqrt{s}_{\text{low}} = 7$ TeV and 4.9 fb^{-1} of data to $\sqrt{s}_{\text{high}} = 8$ TeV and 20.2 fb^{-1} of data (thus with the cuts of the ATLAS7 measurement [8]). The overlap (in the region where the difference in the cuts matters less) between the 8 TeV sensitivities and the rescaled ones from 7 TeV is a nice consistency check of our procedure. We find an analogous agreement between the two 14 TeV sensitivities derived from 7 and 8 TeV data, as shown in the supplementary material.

5. Discussion

Our sensitivities assume the uncertainties from MC modeling to be subdominant with respect to the ones associated to the measurement. However, this might not be the case in the entire mass range (see e.g. [8–10]) and a better control on the MC modeling might be necessary. The current MC uncertainty can be read off e.g. [9], and can be as large as 40% for $m_{\gamma\gamma}$ below the minimal p_T cuts of the photons (see also [53] for a discussion of the challenges of background modeling in the context of high mass diphoton resonances). While the relatively good agreement of the MC modeling with the observed data would in principle make a discovery possible for large enough signal cross sections, the large MC uncertainties are a limiting factor to the discovery potential of a resonance search below the minimal p_T cuts for the photons.

On the theory side this motivates an improvement in the diphoton MC's, while on the analysis side it pushes to extend the data-driven estimates of the background to lower $m_{\gamma\gamma}$, reducing further

the associated uncertainties and thus improving the limits. Data-driven estimates of the SM background were indeed used in the ATLAS 8 TeV analysis [43], and we believe their effectiveness is at the origin of the discrepancy between our 8 TeV sensitivities and the actual ATLAS limits. As shown in Fig. (1) the discrepancy amounts to a factor of ~ 5 .⁶

The experimental challenge of going to lower invariant masses is ultimately related to lowering the minimal cuts $p_{T1,2}^{\text{min}}$ on the two photon p_T 's and/or relax the photon isolation requirement $\Delta R \gtrsim 0.4$, where $\Delta R \equiv \sqrt{\Delta\phi^2 + \Delta\eta^2}$ is the photon separation. Indeed by simple kinematics we get the strict lower bound on $m_{\gamma\gamma}$

$$m_{\gamma\gamma} > \Delta R \cdot \sqrt{p_{T1}^{\text{min}} p_{T2}^{\text{min}}}, \quad (8)$$

where we used $m_{\gamma\gamma}^2 = 2p_{T1}p_{T2}(\cosh\Delta\eta - \cos\Delta\phi)$ that for small $\Delta\phi$ and $\Delta\eta$ is $m_{\gamma\gamma}^2 \simeq \Delta R^2 \cdot p_{T1}p_{T2}$. This absolute lower bound on $m_{\gamma\gamma}$ explains why in Fig. 1 the 8 TeV reach derived from ATLAS7, which has the lowest $p_{T1,2}^{\text{min}}$, can reach lower $m_{\gamma\gamma}$ than the ones derived from ATLAS8 measurements.

From Eq. (8) we conclude that in order to extend the diphoton resonant searches to lower invariant masses one would have to lower either $p_{T1,2}^{\text{min}}$ or ΔR . Both these possibilities deserve further experimental study.

A first possible strategy would be to require a hard ISR jet in the diphoton analysis, along the way of what was done in the recent CMS search for low-mass dijet resonances [32]. The hard jet requirement would raise the p_T of the resonance recoiling against it, collimating the two photons and hence posing the challenge of going to smaller ΔR . In this kinematical regime, the two photons would look like a single photon-jet [54,55] and it would be interesting to study if substructure techniques similar to those used in [32] for dijet resonances can be applied to such an object.

A second strategy would be to lower the photon $p_{T1,2}^{\text{min}}$. This, however, poses well-known problems with the SM background, like the larger backgrounds from QCD processes (see e.g. [56]) and the challenge of recording, storing, and processing so many events.⁷ One might handle the high data-rate and long-term storage challenge with the data scouting/Trigger-object Level Analysis methods [57–61] where, rather than storing the full detector data for a given event, one stores only a necessary subset. Alternatively, one could accommodate lower trigger thresholds by recording full events for only a fixed fraction of the data [61,62], with *prescaled* triggers, and/or setting aside these data for processing and analysis later [57,63] (data parking/delayed stream). Such techniques have already been used in searches for dijet signals [58–60,63], where one is similarly interested in localized deviations from smooth, data-driven background estimates.

The quantitative comparison of the reach of these different possibilities for low-mass diphoton resonances goes beyond the scope of this paper, but we do encourage the ATLAS and CMS collaborations to take steps in these directions.

6. Impact on ALP parameter space

To determine the diphoton signal strength $\sigma_{\gamma\gamma}^{\text{th}}$ that enters the bound in Eq. (4) and that should be compared with the sensitivities in Eqs. (6) and (7), we multiply the tree level pp cross section by a constant K -factor $K_\sigma = 3.7$ (see the supplementary material for more details) and we use the widths of Eq. (2).

⁵ The CMS sensitivities using different binning in Fig. 1 are very close in the 75–100 GeV range. This is because in this mass range CMS reports its measurement in 5 GeV bins, comparable to the ECAL mass resolution of ~ 2.5 GeV, while in other mass ranges (and in the ATLAS measurements) the bin sizes vary between 10 and 40 GeV.

⁶ We checked further differences between Ref. [43] and the procedure used here, such as a finer categorisation of the diphoton final states as in [6], and a fully unbinned analysis. We find that they can affect the sensitivity at most by 20–40%.

⁷ We thank Antonio Boveia and Caterina Doglioni for many clarifications on these matters.

Fig. 2. Shaded: constraints on the ALP parameter space from existing collider searches at LEP [64] and the LHC [32,43,44,46] (see text for our rescaling of the CMS dijet bound [32]), and from the bound derived in this work using the data in [8–10]. Lines: our LHC sensitivities at 8 and 14 TeV.

In Fig. 2 we show how the different searches at the LHC, at Tevatron and at LEP constrain the ALP decay constant f_a for a given value of the ALP mass m_a . We fix for reference the anomalies to their GUT inspired value $c_1 = c_2 = c_3 = 10$. On the right y-axes, we write the pNGB coupling to photons in a notation inspired by the QCD axion, as $g_{a\gamma\gamma} = \frac{\alpha_{em}}{\pi f_a} \frac{c_\gamma}{c_3}$.

Our conservative bound extracted from Eq. (4) by combining 8 TeV and 7 TeV LHC data together with Tevatron data sets the strongest existing limit on ALPs between 10 and 50 GeV: $f_a \gtrsim 500$ GeV, corresponding to $g_{a\gamma\gamma} \lesssim 10^{-5}$ GeV. This is a major improvement with respect to the strongest existing bound in that range, which comes from measurements of $Z \rightarrow \gamma a(jj)$ at LEP I [64] giving $\text{BR}(Z \rightarrow \gamma + jj) < 1 - 5 \cdot 10^{-4}$. We checked that the other LEP limits in [65–67] are not relevant for our choice of the anomalies. The limit from the boosted dijet search of CMS [32] is the strongest one between 50 and 65 GeV, while above 65 GeV the ATLAS [43] and CMS [46] diphoton searches take over.

The LHC has the potential to probe values of f_a much larger than 1 TeV, as shown by the sensitivities lines in Fig. 2. The solid line is obtained from Eq. (6) combining both 8 TeV and 7 TeV data with the finer possible binning. The dashed and dotted lines are the projected sensitivities respectively at LHC14 and HL-LHC, from 8 TeV and 7 TeV data, based on Eq. (7). Notice that the HL-LHC projection is stronger than the future ILC [68] and FCC-ee [69] reaches. The latter is expected to probe $\text{BR}(Z \rightarrow \gamma + jj) \lesssim 1 - 5 \cdot 10^{-7}$, which correspond to $f_a \sim 1 - 3$ TeV if $\mathcal{O}(10^{12})$ Z's will be produced.

The relative importance of low-mass diphoton bounds and sensitivities with respect to the other existing searches is robust with respect to choosing different values of the anomalies $c_{1,2,3}$, as long as $c_3 \neq 0$. For $c_{1,2} \gtrsim 4c_3$, our conservative low-mass diphoton limit even overcomes the dijet exclusions between 50 and 65 GeV, while still doing largely better than LEP.

Other processes that could be relevant for an ALP with couplings as in Eq. (1) and mass above 10 GeV, like $Z \rightarrow 3\gamma$ at LEP (see e.g. [56,70] for recent studies of this and other signatures), set limits that are too weak to even appear on the parameter space presented in Fig. 2. Analogously, the sensitivity of ALP searches in heavy ion collisions estimated in [71] is sizeably weaker than our conservative bounds. The obvious reason is the generic suppres-

sion of the photon width compared to the gluon one by $(\alpha_{em}/\alpha_s)^2$. If Higgs decays to ALP pairs were allowed by the UV charge assignments, then the related constraints [72–74] would apply. Their relative importance would be model dependent but in any case they would typically not probe f_a values beyond a TeV, see [21] for more details.

As an exercise to conclude this section, we comment on the ALP interpretation of the excesses recently reported (both at 2.9σ local) by CMS in diphoton [46] and dijet [32] searches, at invariant masses of 95 and 115 GeV respectively. The ALP parameters that would fit each of them are

$$\frac{f_a}{c_\gamma} \simeq 470 \text{ GeV} \sqrt{\frac{50 \text{ fb}}{\sigma_{\gamma\gamma}^{\text{sign}}}}, \quad c_3 \lesssim 2 \cdot c_\gamma, \quad (9)$$

for the 95 GeV $\gamma\gamma$ excess, and

$$\frac{f_a}{c_3} \simeq 310 \text{ GeV} \sqrt{\frac{300 \text{ pb}}{\sigma_{gg}^{\text{sign}}}}, \quad c_\gamma \lesssim 0.8 \cdot c_3, \quad (10)$$

for the 115 GeV jj one. $\sigma_{\gamma\gamma,gg}^{\text{sign}}$ are the theoretical signal cross sections of the excesses, whose normalization is chosen as follows. For the 95 GeV $\gamma\gamma$ excess we use the expected sensitivity at that mass as reported in Ref. [46], for the 115 GeV jj we use the analogous sensitivity reported in [32] for a Z' , and rescale it to an ALP produced in gluon fusion using Eq. (3). Dijet bounds [32] on the 95 GeV $\gamma\gamma$ excess [46], and diphoton bounds [43] on the 115 GeV jj excess [32], give the second inequalities in Eqs. (9) and (10) respectively.

Eqs. (9) and (10) allow to conclude that either of the two excesses, if coming from an ALP, could be interpreted in terms of reasonable values of f_a and of the ABJ anomalies. Such an ALP could be the first sign of a NP scale not too far from a TeV, still allowing the rest of the new states to be at $M_{\text{NP}} \sim 4\pi f_a$ and hence out of the current LHC reach.

7. Conclusions

Theoretical frameworks such as Supersymmetry and Compositeness predict, on general grounds, the existence of pNGBs (ALPs) with couplings of relevance for colliders. Similar ALPs have also received much attention as mediators of Dark Matter interactions with the SM. The current experimental searches for these particles, however, still contain holes. In particular huge ($> 10^4$ pb) gluon fusion cross sections at the LHC, for ALP masses below 65 GeV, are allowed by all existing constraints.

In this paper, we used public data from inclusive diphoton cross section measurements at the LHC [8–10] to put a new bound on diphoton resonances between 10 and 65 GeV. We showed how this bound sets the by-far strongest existing constraint on the parameter space of ALPs that couple to both gluon and EW boson field strengths, see Fig. 2. We have also derived indicative sensitivities that would be achievable by a proper LHC analysis, both with already existing 8 TeV data and at higher energies.

We hope that this work will motivate the LHC collaborations to extend the mass range of their diphoton resonant searches to lower values. Similar ideas could in principle be applied to probe light resonances decaying into other final states than diphotons. A great example is the current CMS search of boosted dijet resonances [32]. Going to lower invariant masses in dijet—and perhaps in other—final states would certainly deserve further experimental effort.

(Received 12 April 2017; published 5 October 2017)

We study the effective theory of a generic class of hidden sectors where supersymmetry is broken together with an approximate R -symmetry at low energy. The light spectrum contains the gravitino and the pseudo-Nambu-Goldstone boson of the R -symmetry, the R -axion. We derive new model-independent constraints on the R -axion decay constant for R -axion masses ranging from GeV to TeV, which are of relevance for hadron colliders, lepton colliders, and B factories. The current bounds allow for the exciting possibility that the first sign of supersymmetry will be the R -axion. We point out its most distinctive signals, providing a new experimental handle on the properties of the hidden sector and a solid motivation for searches of axionlike particles.

DOI: 10.1103/PhysRevLett.119.141804

In this Letter we argue that there are generic signs of supersymmetry (SUSY) to be looked for at colliders that have not yet been satisfactorily explored: those associated with the R -axion, the pseudo-Nambu-Goldstone boson (PNGB) of a spontaneously broken R -symmetry.

Although it is well known that supersymmetry must be broken in a “hidden sector,” its dynamics is left unspecified in the vast majority of phenomenological studies, which instead focus on the “visible sector,” e.g., the minimal supersymmetric standard model (MSSM). Here we point out that in an extensive class of models the hidden sector leaves its footprints in observables accessible to the current experimental program. In particular, we perform a thorough phenomenological study of the R -axion at high- and low-energy hadron and lepton colliders.

The $\mathcal{N} = 1$ SUSY algebra contains a single $U(1)_R$ (“ R -symmetry”) under which supercharges transform, $[R, Q_\alpha] = -Q_\alpha$, such that components of a given supermultiplet have R charges r differing by one unit (e.g., gauge fields carry no R charge while gauginos have $r_\lambda = 1$). R -symmetry plays a crucial role in models of low-energy dynamical SUSY breaking. According to the general result of Nelson and Seiberg, an R -symmetry must exist in any generic, calculable model which breaks SUSY with F

terms, and if the R -symmetry is spontaneously broken then SUSY is also broken [1]. Spontaneous R -symmetry breaking often occurs also in incalculable models like in [2,3]. If the SUSY-breaking vacuum is metastable, like in Intriligator-Seiberg-Shih (ISS) constructions [4], then an analogue of the Nelson-Seiberg result holds for an approximate R -symmetry [5]. When $U(1)_R$ is explicitly broken by a suitable deformation of the hidden sector, the R -axion gets a mass in addition to the irreducible contribution from supergravity [6] but can remain naturally lighter than the other hidden-sector resonances.

In light of the above observations, and contrary to what previously explored in the literature, we treat the R -axion mass m_a as a free parameter, together with its decay constant f_a . Our analysis shows that such a particle could well be the first sign of SUSY to show up in experiments. We also derive model-independent bounds on the scale of spontaneous R -symmetry breaking, opening a new observational window on the properties of the SUSY-breaking hidden sector.

Setup.—We parametrize with m_* the SUSY mass gap of the hidden sector and with g_* the coupling strength between hidden-sector states at m_* . The generic size of the SUSY-breaking vacuum expectation value (VEV) is then $F \sim m_*^2/g_*$, an outcome of naive dimensional analysis (NDA) with a single scale and coupling [7,8]. The R -axion decay constant is $f_a \sim m_*/g_*$, while the R -axion mass should satisfy $m_a \ll m_*$ in order for the R -symmetry axion to be a PNGB.

As a generic consequence of spontaneous SUSY breaking, a light gravitino is also present in the low-energy

spectrum. In the rigid limit (i.e., $M_{\text{Pl}} \rightarrow \infty$) the transverse degrees of freedom of the gravitino decouple, leaving a massless Goldstino in the spectrum. The effective action of the Goldstino and the R -axion can be written using the nonlinear superfield formalism of [9] and reads

$$\begin{aligned} \mathcal{L}_{\text{hid}} = & \int d^4\theta \left(X^\dagger X + \frac{f_a^2}{2} \mathcal{R}^\dagger \mathcal{R} \right) \\ & + \int d^2\theta (FX + w_R \mathcal{R}^2) + \text{c.c.} \\ \supset & -F^2 + i\bar{G}\bar{\sigma}^\mu \partial_\mu G + \frac{f_a^2}{2} (\partial_\mu a)^2 \\ & - \frac{w_R}{F^2} (iG^2 e^{-2ia} \square a + \text{c.c.}), \end{aligned} \quad (1)$$

where X and $\mathcal{R} = e^{iA}$ carry R charge 2 and 1, respectively (the R charge of a supermultiplet is identified with that of its bottom component) and satisfy the nonlinear constraints $X^2 = 0$ and $X(\mathcal{R}^\dagger \mathcal{R} - 1) = 0$. The above constraints, in combination with (1), give $X = G^2/2F^2 + \sqrt{2}G\theta - F\theta^2$, $A = a + O(aG)$; see the Supplemental Material for more details [10].

Since the R charge of \mathcal{R} is 1, its effective action differs from the one of a SUSY axion in that a superpotential term is allowed. This is controlled by the dimension-three parameter w_R , which is related to the VEV of the superpotential and satisfies the inequality $w_R < f_a F/2\sqrt{2}$, under the assumption of no extra light degrees of freedom other than the R -axion and the Goldstino [11,12]. The superpotential term induces cubic interactions between the R -axion and two Goldstini, proportional to m_a^2 , that lead to an invisible decay channel for the R -axion. The corresponding decay rate of the R -axion into two Goldstini is

$$\Gamma(a \rightarrow GG) = \frac{1}{4\pi} \left(\frac{m_a^5 w_R^2}{f_a^2 F^4} \right) < \frac{1}{32\pi} \frac{m_a^5}{F^2} \quad (2)$$

and it is bounded from above as a consequence of the upper bound on w_R , saturated only in free theories. Our power counting gives $w_R \sim F f_a$, making the width within an $O(1)$ factor of the upper limit in Eq. (2). For ordinary axions, w_R would instead break explicitly the associated global symmetry, resulting in a suppression of the decay width into Goldstini by extra powers of m_a^2/m_*^2 . Hence, a sizable invisible decay width is a distinctive feature of the R -axion compared to other axionlike particles.

The R -axion mass is generated by sources of explicit R -symmetry breaking and can be parametrized as

$$m_a^2 \sim \frac{\epsilon_{\mathcal{R}} F}{f_a^2} r_\epsilon^2 \ll m_*^2 \quad \text{from } \mathcal{L}_{\mathcal{R}} = \int d^2\theta \frac{1}{2} \epsilon_{\mathcal{R}} X R^{-r_\epsilon}, \quad (3)$$

where r_ϵ is the R charge of the explicit-breaking spurion $\epsilon_{\mathcal{R}}$, with $\epsilon_{\mathcal{R}}/F \ll 1$ technically natural. Explicit examples of this mass hierarchy arise by adding suitable R -symmetry

breaking deformations in calculable models of dynamical SUSY breaking like the 3-2 model [1,13,14] or in SUSY QCD at large N once the hidden gauginos and squarks get soft masses [15,16]. Moreover, in SUSY-breaking models like the one in [5], the explicit breaking of the R -symmetry is generically bounded from above ($\epsilon_{\mathcal{R}}/F \ll 1$) by requiring the SUSY-breaking vacuum to be metastable.

The R -symmetry breaking contribution (3) can well be expected to dominate over the unavoidable supergravity (SUGRA) contribution arising from the tuning of the cosmological constant [6], which gives rise to $m_a^2 \sim (10 \text{ MeV})^2 \times m_*/10 \text{ TeV} \times m_{3/2}/\text{eV}$ (we refer to the Supplemental Material for its derivation [10]).

We now study the couplings of the R -axion with the visible-sector fields, which we take to be the MSSM (with matter or R parity). The superpartners get SUSY-breaking masses m_{soft} from their interactions with the hidden sector, which are controlled by a perturbative coupling g . This coupling is a proxy for the SM gauge coupling constants in gauge mediation models [17,18] or for Yukawa-type interactions in extended gauge mediation; see [19] for a review. The scaling of m_{soft} strongly depends on the type of mediation mechanism. We can estimate it as

$$m_{\text{soft}} \sim \left(\frac{g}{g_*} \right)^n \times g \frac{F}{m_*} = \left(\frac{g}{g_*} \right)^{n+1} \times m_*. \quad (4)$$

In this Letter we assume that gauginos get a mass via their coupling to the hidden-sector global current, so that $m_{\text{soft}} \sim (g/g_*)^2 m_*$. Notice that if $g_* = 4\pi/\sqrt{N_{\text{mess}}}$ we recover the ordinary gauge mediation scaling where N_{mess} is the number of messengers. Other scaling, e.g., the one of [20] for Dirac gauginos ($n=0$), will be discussed elsewhere. Besides, whatever the scaling in Eq. (4), there is always a large portion of parameter space where the R -symmetry axion is lighter than the superpartners, which correspond to $r_\epsilon \sqrt{g_* \epsilon_{\mathcal{R}}}/m_* \lesssim (g/g_*)^{n+1}$. It would also be interesting to depart from the NDA expectation for the scales F and f_a and explore models where a large separation between the two is realized.

We consider in the following a small SUSY-breaking scale \sqrt{F} in the range from 1 to a few 100s of TeV. This regime is welcome for fine-tuning and Higgs mass considerations. The resulting gravitino mass lies in the window $10^{-4} \text{ eV} \lesssim m_{3/2} \lesssim 5 \text{ eV}$, where the upper limit comes from cosmological and astrophysical bounds on gravitino abundance [21–23], while the lower limit comes from LEP [24] and LHC [25,26] bounds.

Since the visible sector feels the SUSY breaking only through g/g_* effects, we can treat the MSSM superfields linearly and “dress” the R -charged operators with appropriate powers of the R -axion. We also neglect subleading effects from explicit R -breaking terms, suppressed by powers of $\sim m_a/m_*$. The interactions of the R -axion with the MSSM gauge sector are then

$$\begin{aligned} \mathcal{L}_{\text{gauge}} &= \int d^2\theta \left(-ig_i^2 \frac{c_i^{\text{hid}}}{16\pi^2} \mathcal{A} - \frac{m_{\lambda_i}}{2F} X \mathcal{R}^{-2} \right) \mathcal{W}_i^2 + \text{c.c.} \\ &\supset \frac{g_i^2 c_i^{\text{hid}}}{16\pi^2} \frac{a}{f_a} F^i \tilde{F}^i - \frac{m_{\lambda_i}}{2} \lambda_i \lambda_i \left(e^{-2ia/f_a} + \frac{g_i^2 c_i^{\text{hid}}}{4\pi^2} i \frac{a}{f_a} \right) \\ &\quad + \text{c.c.}, \end{aligned} \quad (5)$$

where \mathcal{W} is the field strength superfield ($r_{\mathcal{W}} = 1$) and i labels the SM gauge group, where we defined $g_1 = \sqrt{5/3}g_Y$ and $\tilde{F}^{i,\mu\nu} = 1/2\epsilon^{\mu\nu\rho\sigma} F_{\rho\sigma}^i$. The Majorana gaugino masses are of order $m_{\lambda_i} \approx m_{\text{soft}}$ by assumption. The coefficients c_i^{hid} encode the hidden-sector contributions to the mixed anomalies of the $U(1)_R$ with the SM gauge groups. For example, we get $c_i^{\text{hid}} = -N_{\text{mess}}$ for $i = 1, 2, 3$, for N_{mess} messengers chiral under $U(1)_R$ and in the $5 + \bar{5}$ of $SU(5)$ with zero R charge [in our NDA, $N_{\text{mess}} \sim (4\pi/g_*)^2$]. We encode the contributions to the anomalies from the MSSM fields in the full loop functions.

The interactions in the Higgs sector can be written as

$$\begin{aligned} \mathcal{L}_{\text{Higgs}} &= \int d^4\theta \left(\frac{\mu}{F} X^\dagger \mathcal{R}^{2-r_H} - \frac{B_\mu}{F^2} |X|^2 \mathcal{R}^{-r_H} \right) H_u H_d + \text{c.c.} \\ &\supset \mu \tilde{h}_u \tilde{h}_d e^{i(2-r_H)a/f_a} - B_\mu h_u h_d e^{-ir_H a/f_a} + \text{c.c.}, \end{aligned} \quad (6)$$

where $\tilde{h}_{u,d}$ are the Higgsinos and $h_{u,d}$ the Higgs doublets. We have assumed the μ term, in addition to B_μ , is generated by the hidden dynamics. The actual value of $r_H = r_{H_u} + r_{H_d}$ thus depends on the charge assignments in the hidden sector. The charge assignment of the visible sector fields is modified by higher-dimensional operators in the Kahler potential like $|H_{u,d}|^2 |\mathcal{R}|^2$, etc., which lead to g/g_* suppressed effects that will be neglected in what follows.

The coupling to the MSSM Higgses proportional to B_μ induces, after electroweak symmetry breaking, a small mixing between a and the MSSM Higgs boson A [27]

$$\delta = r_H \frac{v}{f_a} \frac{s_{2\beta}}{2} \frac{1}{1 - m_a^2/m_A^2} \simeq r_H \frac{v}{f_a} \frac{s_{2\beta}}{2}. \quad (7)$$

If we assume the Yukawa interactions in the superpotential are allowed in the limit of exact $U(1)_R$ ($r_{H_u} + r_Q + r_U = 2$, etc.), the mixing δ is the only source of couplings between a and the SM fermions and we get

$$\mathcal{L}_f = ir_H \frac{a}{f_a} [c_\beta^2 m_u \bar{u} \gamma_5 u + s_\beta^2 m_d \bar{d} \gamma_5 d + s_\beta^2 m_\ell \bar{\ell} \gamma_5 \ell]. \quad (8)$$

The same mixing induces

$$\mathcal{L}_{ahh} = \frac{\delta^2}{v} h (\partial_\mu a)^2, \quad (9)$$

where h is the SM-like Higgs, as well as extra interactions with the MSSM Higgses, whose phenomenological consequences we leave for future work [14]. Finally, the a couplings to sfermions also arise from its mixing with A and are proportional to the A terms. Since we assume all the sfermions to be

heavy and the A terms to be small, these couplings do not play any role in the R -axion phenomenology discussed here.

Phenomenology.—We focus on R -axion masses in the range between 2 GeV and 2 TeV, and we refer to [28] for a LHC study for masses of $O(100)$ MeV. For definiteness we fix $r_H = 2$, which allows for an R -symmetric μ term and a B_μ term from spontaneous $U(1)_R$ breaking. We will comment on the phenomenological differences of the $r_H = 0$ case, where the role of μ and B_μ is reversed. The Majorana gaugino masses cannot be arbitrarily larger than the scale of spontaneous R breaking, so we take $f_a \gtrsim 0.3$ TeV and fix for illustrative purposes the gaugino masses to the grand unified theory (GUT) universal values $m_{\lambda_{1,2,3}} = 0.7, 1.4, 3.6$ TeV (different values do not change the R -axion phenomenology as long as $m_{\lambda_i} > m_a/2$). For $f_a \lesssim 1$ TeV, obtaining such heavy gauginos present model building challenges which are beyond the scope of this Letter.

We now discuss the different production modes of the R -axion. For the purposes of this Letter we ignore R -axion production from SUSY decay chains. As for any axionlike particle, the single production modes scale with $1/f_a^2$ and double production ones with $1/f_a^4$.

(i) At the LHC, the resonant a (+SM) production is dominated by gluon fusion, which we determine using the leading-order prediction multiplied by a constant K factor of 2.4 [29] (see the Supplemental Material for details [10]).

(ii) Also at the LHC, we have double a production from Higgs decays driven by the coupling in Eq. (9).

(iii) At lepton colliders the R -axion can be single produced via its coupling to the Z , which is dominated by the anomaly in Eq. (5).

(iv) At flavor factories we consider R -axion production via $B \rightarrow K^{(*)} a$ and $\Upsilon \rightarrow \gamma a$ decays. The $\text{BR}(B \rightarrow K^{(*)} a)$ are computed from the general result of [30], accounting for the mixing of the R -axion with the CP -odd Higgs (7) [31], and choosing for reference $m_{H^\pm} = 1$ TeV (we take the form factor relevant for K^* from [32]). The $\text{BR}(\Upsilon \rightarrow \gamma a)/\text{BR}(\Upsilon \rightarrow ll)$ is computed using the standard Wilczek formula [33].

The R -axion decays to pairs of gauge bosons and of SM fermions, to Goldstini (invisible) and, if kinematically allowed, to supersymmetric particles. We refer the reader to the Supplemental Material for quantitative details [10].

In Fig. 1 we summarize the present constraints on the R -axion in the m_a - f_a plane as well as the most promising processes to search for it at future experiments. For $m_a \gtrsim m_h/2$, the most important bounds come from resonant a production at the LHC. The most distinctive feature of the R -axion is the invisible signal strength of Eq. (2), which is important for large m_a . This results in constraints from monojet searches at 8 and 13 TeV [34,35]. To draw them, we have determined the ratio of the a and $a + \text{jet(s)}$ production cross sections via a MADGRAPH [56,57] simulation, for the different missing energy cuts for which the bounds are given in [34,35] (we believe this approximation to be sufficient for our purposes).

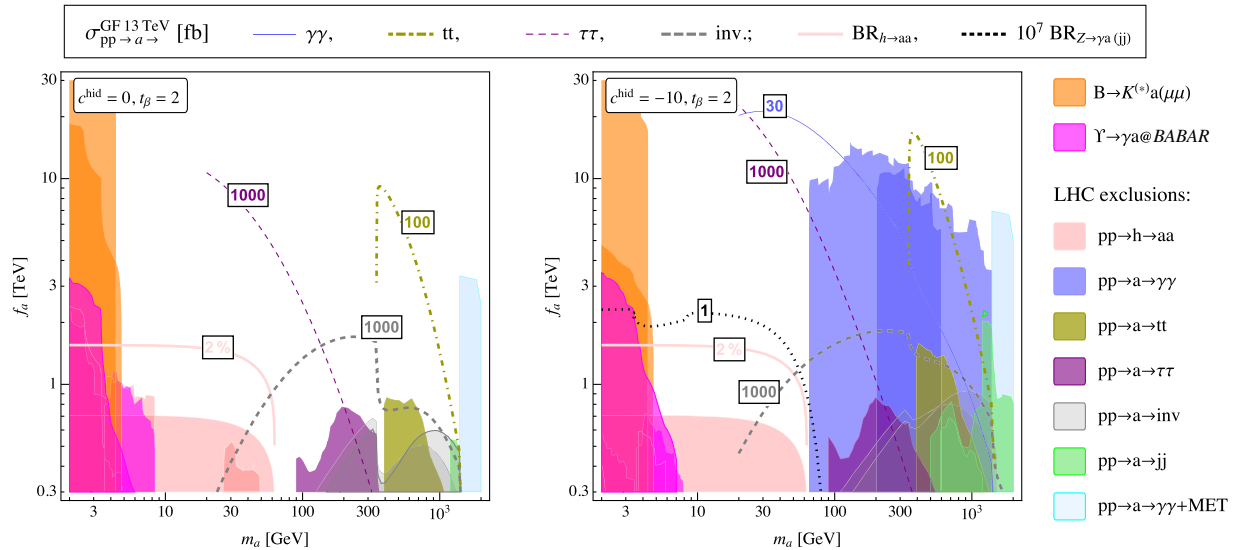

FIG. 1. Shaded areas show LHC8 and LHC13 [34–49], LHCb [50,51], BABAR [52–54], and Belle [55] exclusions. Contours show signal strengths at the LHC13 and Higgs and Z boson branching ratios. The tiny area in the lower right corner where $m_a \approx 4\pi f_a$ lies beyond the regime of validity of our effective description.

At $m_a > 1.4$ TeV the decay into bino pairs opens up, resulting in a $\gamma\gamma + \text{MET}$ final state via the prompt bino decay to $\gamma + G$. This is constrained by inclusive $\gamma\gamma + \text{MET}$ searches [36], which we translate in a bound $\sigma_{gg \rightarrow a \rightarrow \lambda_1 \lambda_1}^{8\text{TeV}} < 0.3$ fb.

For large anomalies, diphoton resonant searches [37–39] at 8 and 13 TeV dominate the collider phenomenology for $m_a > 60$ GeV [58]. Searches for a resonance decaying into dijet [40–42], into $t\bar{t}$ at 8 TeV [43,44], and into ditau at 13 TeV [45,46] give complementary bounds for $m_a > 500$ GeV, $m_a > 2m_t$, and $100 \text{ GeV} \lesssim m_a < 2m_t$, respectively.

For small anomalies the LHC constraints are sensibly weakened by the reduced production cross section and by the suppressed branching ratio in diphotons. A lower bound on f_a can still be derived from a combination of $t\bar{t}$, ditau, and monojet searches.

For $m_a \lesssim 2m_h$, the major constraint comes from the upper bound on $\text{BR}(h \rightarrow \text{untagged}) < 32\%$ [47]. This bound depends only on the mixing in Eq. (7) and applies to both cases with $N_{\text{mess}} = 10$ and $N_{\text{mess}} = 0$. We also include constraints arising from exclusive Higgs decays (e.g., $h \rightarrow aa \rightarrow 4\mu$ or $h \rightarrow aa \rightarrow 2\tau 2\mu$) [48,49]. Finally, LEP constraints [59–64] are not relevant for the f_a considered in this study.

For $m_a \lesssim 9$ GeV, stringent constraints on f_a come from BABAR searches of $\Upsilon \rightarrow a\gamma$, with a decaying into tau or muon pairs [52,53] or hadrons [54]. For $m_a \lesssim 4$ GeV, we consider LHCb [50,51] and Belle [55] bounds from $B \rightarrow K^* \mu\mu$. In particular, the recent LHCb limit $\text{BR}(B \rightarrow K^* \mu\mu) \lesssim 2 \times 10^{-9}$ [50] puts the strongest bound on f_a , among all the searches we considered, reaching $f_a \gtrsim 200$ TeV for $N_{\text{mess}} = 0$.

At large t_β , δ becomes smaller [see Eq. (7)], reducing the bounds from Higgs branching ratio measurements and $B \rightarrow K$ transitions. The couplings to quarks and leptons are also t_β dependent; most importantly, the $t\bar{t}$ signal strength is

reduced at large t_β . For $r_H = 0$ (and within our previous assumptions) the R -axion does not couple to SM fermions at the linear level. This makes it generically very difficult to be constrained for $m_a < m_h/2$. For larger values of m_a and irrespective of the values of t_β and r_H , diphoton constraints give $f_a \gtrsim 10$ TeV for large anomalies, while for small anomalies a milder bound on f_a is anyway given by monojet and dijet searches.

Promising signatures for future experimental programs are also shown in Fig. 1. The most distinctive one is the decay into two Goldstini, which gives a large invisible signal strength. This will be probed by monojet searches at the LHC (multijet + MET searches could also be relevant [65]) and constitutes a very good motivation for the high-luminosity LHC program. For large anomalies, the diphoton final state will be the most promising one at the LHC, while for small anomalies ditau and $t\bar{t}$ will be more important. For $m_a < m_h/2$ we show how an improvement of the Higgs coupling measurements down to 1%–2% (which is within the reach of ILC [66]) would probe f_a up to 1.5 TeV. Even bigger values of f_a are within the reach of machines like CLIC, CEPC, and FCC-ee, which plan to probe Higgs coupling with a precision of roughly 10^{-3} [66]. For large anomalies, an important probe of a light R -axion would be $Z \rightarrow \gamma a$ measurements at future lepton colliders. A naive rescaling of the LEP I analysis [62] indicates that $Z \rightarrow \gamma a(jj)$ branching ratios in the ballpark of 10^{-7} could be probed at the FCC-ee, if $O(10^{12})$ Z s will be produced. We notice that the mass window $10 \lesssim m_a \lesssim 65$ GeV is less constrained by the searches we considered. This could be improved by extending the coverage of resonance searches, in particular $\gamma\gamma$, to lower invariant masses.

To distinguish the R -axion from other scalar resonances, a jet + MET signal would certainly help in combination with

a pattern along the lines discussed above. Of course, to reinforce the R -axion interpretation of a possible signal, one would eventually need to find evidence for superpartners.

Conclusions.—The possibility that the R -axion could be the first sign of SUSY at colliders is well motivated from theoretical and phenomenological considerations, *a fortiori* given the strong LHC bounds on sparticles.

In this Letter we have investigated the low-energy dynamics of SUSY-breaking sectors with a light R -axion (and gravitino) coupled to the MSSM. Our results are summarized in Fig. 1, where we show how current and future colliders probe the space of R -axion masses and decay constants. We have also identified some promising signatures to cover the currently unconstrained part of the parameter space.

The R -axion constitutes a very interesting prototype of axionlike particles, with couplings that follow from well-defined selection rules of the theory, and whose mass can be safely considered a free parameter.

The rich phenomenology of the R -axion certainly deserves further investigation. The R -axion can give rise to nonstandard heavy Higgs decays or SUSY decay chains, it can be a further motivation for high-intensity experiments (in its light-mass window), and it could impact cosmological and astrophysical processes.

Finally, we wish to point out that other appealing features of SUSY, such as unification and dark matter, might find an interesting interplay with a light R -axion, opening new model-building avenues. We leave the exploration of this exciting physics for the future.

ABSTRACT: We initiate the study of gravitational wave (GW) signals from first-order phase transitions in supersymmetry-breaking hidden sectors. Such phase transitions often occur along a pseudo-flat direction universally related to supersymmetry (SUSY) breaking in hidden sectors that spontaneously break R -symmetry. The potential along this pseudo-flat direction imbues the phase transition with a number of novel properties, including a nucleation temperature well below the scale of heavy states (such that the temperature dependence is captured by the low-temperature expansion) and significant friction induced by the same heavy states as they pass through bubble walls. In low-energy SUSY-breaking hidden sectors, the frequency of the GW signal arising from such a phase transition is guaranteed to lie within the reach of future interferometers given existing cosmological constraints on the gravitino abundance. Once a mediation scheme is specified, the frequency of the GW peak correlates with the superpartner spectrum. Current bounds on supersymmetry are compatible with GW signals at future interferometers, while the observation of a GW signal from a SUSY-breaking hidden sector would imply superpartners within reach of future colliders.

1 Introduction

If supersymmetry is a property of our universe, how will it be discovered? Conventionally, searches for evidence of supersymmetry (SUSY) have focused on the Standard Model, looking for supersymmetric partners of Standard Model particles in direct production at colliders, scattering in dark matter experiments, and virtual effects in precision measurements. Thus far, no evidence has emerged of supersymmetry as it relates to the Standard Model, raising the prospect that it may lie outside the reach of the existing experimental program. Although this would pose a challenge to supersymmetry as a fully natural explanation for the scale of electroweak symmetry breaking, the abundance of remaining motivation (e.g. gauge coupling unification, dark matter, and straightforward string-theoretic embedding) favors continuing the search to shorter and shorter distances. While the LHC and proposed future colliders are promising tools in this search, the immense technical challenges of exploring energies far above the TeV scale in terrestrial experiments suggests casting a broader net. It invites identifying both new ways of accessing shorter distances and new sectors in which supersymmetry may be manifest.

A compelling avenue to shorter distances is to make use of the incredible energies of the Big Bang, searching for the imprint of supersymmetric phenomena on the early universe. In some sense, this is already the path taken by dark matter searches looking for the population of stable superpartners produced in the early universe, but it is not the only cosmological avenue for discovering SUSY. For example, spontaneous breaking of supersymmetry during inflation raises the prospect of observing signals in the three-point function of primordial curvature perturbations [1, 2], although the size of the signal depends on the strength of couplings between SUSY multiplets and the inflaton.

As for new sectors, at least one is *guaranteed* to exist in a supersymmetric universe: the sector responsible for breaking supersymmetry. Although there are many dynamical mechanisms for breaking supersymmetry, they typically possess a number of generic or universal features which can provide new ways of searching for supersymmetry even when superpartners of the Standard Model are decoupled. These include the goldstino, a goldstone fermion of spontaneous supersymmetry breaking (which becomes the longitudinal mode of the gravitino, the supersymmetric partner of the graviton, once gravity is accounted for), as well as a novel abelian global symmetry called the R -symmetry. The R -symmetry is generically spontaneously broken by the same dynamics that breaks supersymmetry, giving rise to a goldstone boson (the R -axion) and its scalar partner, a pseudo-modulus whose flat potential is protected by supersymmetry. In theories with low-energy supersymmetry breaking (LESB), in which the effects of SUSY breaking are communicated to the Standard Model by forces stronger than gravitation, these states may be accessible on their own. For example, the goldstino couples directly to Standard Model particles and may be produced at colliders, although the current reach of the LHC makes these searches less promising than continuing to look for Standard Model superpartners.

In this paper, we explore a new avenue for discovering supersymmetry in the physics of the early universe: using the stochastic gravitational wave background (SGWB) produced by a first-order phase transition to directly probe the sector responsible for breaking super-

symmetry [3]. This makes use of the extraordinary opportunities afforded by the detection of gravitational waves (GW) by the LIGO-Virgo collaboration [4], which has opened a new era in the exploration of the early universe. Sensitivity of current and proposed GW interferometers to stochastic gravitational wave backgrounds broadly motivates identifying beyond-the-Standard Model (BSM) scenarios whose first-order phase transitions may generate such a signal and exploring the complementarity of GW interferometry with other probes of new physics such as present and future colliders.¹

Among the most compelling scenarios for SGWB are those in which a first order phase transition (FOPT) is associated with the breaking of a global or gauge symmetry in the early universe [7–13]. As we will show, the supersymmetry-breaking sector is a natural candidate for such a phase transition because it generically possesses at least one pseudo-flat complex scalar direction, the pseudomodulus. In our constructions, the phase of this complex scalar direction is associated to the R -symmetry, which is in turn tied to the SUSY-breaking dynamics by many known theorems about SUSY quantum field theories [14–16]. This complex scalar direction is lifted by quantum corrections and the resulting potential is likely to possess a metastable minimum at the origin (where R -symmetry is preserved), which will then decay to the true minimum through a FOPT in the early universe. At the true minimum the R -symmetry is broken, consistently with a realistic SUSY spectrum featuring Majorana masses for the fermionic partners of Standard Model gauge bosons.

In our framework, the SUSY-breaking scale \sqrt{F} correlates directly with the frequency range of the SGWB, such that theories of low-energy SUSY breaking feature a peak frequency accessible at LIGO-Virgo or proposed GW interferometers such as the Laser Interferometer Space Antenna (LISA), Einstein Telescope (ET), Cosmic Explorer (CE), DECI-hertz Interferometer Gravitational wave Observatory (DECIGO), and the Big Bang Observatory (BBO). In fact, a consistent cosmological history (in which the production of gravitinos in the early universe is consistent with the present dark matter abundance and small-scale structure constraints) guarantees that low-energy supersymmetry-breaking phase transitions produce a peak frequency in the range accessible to current and future interferometers [17–20].

Once a mechanism is specified to mediate supersymmetry breaking to the Standard Model, the scale \sqrt{F} is also correlated with the spectrum of Standard Model superpartners, allowing the possibility of cross-correlating GW and collider signals. As we will see, the non-observation of SUSY particles at the LHC leaves open the opportunity for seeing SGWB signatures from low-energy SUSY breaking, making this a leading avenue for the discovery of supersymmetry. In return, the observation of a SGWB signal from a low-energy supersymmetry breaking phase transition would imply the SUSY spectrum to be within the reach of future colliders such as FCC-hh, SPPC, or a high-energy muon collider, highlighting the strong complementarity between such SGWB signals and proposed colliders.

Along the way, we identify a qualitatively new class of natural potentials capable of generating large GW signals from a first-order phase transition, corresponding to the scalar

¹Note that the LIGO-Virgo collaboration already places direct constraints on SGWB [5, 6] beyond existing indirect limits.

potential along the pseudo-flat direction associated with SUSY breaking. The size of the vacuum energy gap between the metastable and the true vacuum is set by the SUSY-breaking scale \sqrt{F} , which is necessarily smaller than the SUSY masses of other heavy fields in the sector in order to avoid tachyonic directions. As a consequence, the thermal corrections to the potential along the pseudomodulus direction are well described by a low- T expansion. Another distinctive feature of the pseudomodulus potential is the flatness at large field values, which is ensured by SUSY cancellations independently of the nature of SUSY-breaking deformations around the origin. These features combine to give strong first-order phase transitions, with the strongest transitions arising most naturally in models with two distinct SUSY-breaking scales. As we will discuss, a large amount of tuning would be necessary to realize a similar situation in non-SUSY scenarios, which explains why this possibility has not been explored so far in the literature (see for instance [21] for a collection of potentials giving rise to FOPT for the SM Higgs).

The organization of our paper is intended to highlight the qualitative connections between low-energy supersymmetry breaking, first-order phase transitions, and stochastic gravitational wave signals before progressing into explicit examples, and does not presume deep familiarity with spontaneous supersymmetry breaking. We begin in section 2 by giving a broad overview of the phenomenology of low-energy SUSY breaking, the parametrics of gravitational wave signals from first-order phase transitions, and the relationship between the frequency of the SGWB signal and spectrum of SUSY particles. In section 3 we discuss the general features of the pseudomodulus potential and the properties of a first-order phase transition along this direction, highlighting their novelty compared to commonly-studied potentials for FOPT. We present a simple toy model that captures the main features of concrete SUSY potentials, showing how a promising GW signal from FOPT requires multiple SUSY-breaking scales.

We then proceed to develop a series of increasingly realistic SUSY-breaking hidden sectors featuring FOPT in section 4. In section 4.1, we derive the phase diagram of the simple O’Raifeartaigh model. In section 4.2 we present the simplest single scale model featuring a FOPT, which is a simple deformation of the O’Raifeartaigh model with explicit R -symmetry breaking. Here, the FOPT takes place between the SUSY-breaking vacuum at the origin (which enjoys an unbroken R -symmetry) and the R -symmetry breaking minimum far away from the origin, where SUSY is restored unless coupled to an additional source of SUSY-breaking. In section 4.3, we develop a fully realistic model by introducing gauge interactions to the O’Raifeartaigh model, such that SUSY is broken in both the metastable vacuum at the origin and true vacuum. The presence of both F -term and D -term SUSY-breaking naturally gives rise to strong GW signals.

In section 5 we further comment on the phenomenology of our setup and the complementarity between GW observatories and colliders, highlighting the sense in which the observation of a SGWB signal in our models would ensure further evidence for SUSY at future colliders. We summarize our qualitative conclusions and future directions in section 6. Technical details are reserved for a series of appendices, including a review of the one-loop thermal effective potential in appendix A, approaches to the calculation of the bounce action in appendix B and inputs to our projections for GW interferometers in appendix C.

Figure 1. Parameter space of low energy SUSY-breaking models in the (\sqrt{F}, β_H) plane, with $\alpha = 0.3$ and $T_{r.h.} = \sqrt{F}$ (see section (2.2) for definitions). The GW reach is computed by requiring the strength of the SGBW signal at the peak frequency to intersect with the PLI curve of a given GW interferometer (see appendix C.1 for details). The *colored regions* show the reach for a signal generated from plasma waves which is generically the dominant one in our scenarios (see section 2.2). The *cyan region* with $\beta_H < 10$ implies a large fine-tuning in our setups (see discussion around eq. (2.18), the parametric discussion in section 3 and the explicit evaluation in the models of section 4). In the *red shaded region* gravitino pair production is excluded by a $\gamma + \text{MET}$ search at LEP with $\mathcal{L} = 0.24 \text{ fb}^{-1}$ [22], the gray region is excluded by ATLAS bounds $j + \text{MET}$ at $\sqrt{s} = 8 \text{ TeV}$ and $\mathcal{L} = 10.5 \text{ fb}^{-1}$ [23, 24]. The *dotted gray* and *dotted red* lines are the projection of the $\gamma + \text{MET}$ reach at FCC-hh with $\sqrt{s} = 100 \text{ TeV}$ and $\mathcal{L} = 30 \text{ ab}^{-1}$ and a future high energy lepton collider (HELIC) with $\sqrt{s} = 30 \text{ TeV}$ and $\mathcal{L} = 100 \text{ ab}^{-1}$. The *dark green shaded region* with *dark green arrows* indicates the bound on the SUSY-breaking scale derived from the LHC bound on gluinos $m_{\tilde{g}} > 2 \text{ TeV}$, requiring the messenger sector to be perturbative. The two *dark green* and *light green* bands show the impact of the present LHC bounds [25–28] and the future FCC-hh reach on gluinos [29] for perturbative messenger sectors with $g_M \in (0.01, 0.1)$ (see eq. (2.10) for a definition of g_M). The region between these two lines will be naturally populated by the model discussed in section 4.3 and section 5.2. The *dark blue arrows* on the right hand side shows the *ultralight gravitino window* where $m_{3/2} \leq 16 \text{ eV}$ and the gravitino does not poses any cosmological challenge with $\kappa = 1$ (see eq. (2.2) for a definition) and the *gravitino dark matter window* where $\kappa \ll 1$ and the full gravitino mass is heavier than the gravitino mass contribution set by \sqrt{F} . The *dark cyan region* marked as *inaccessible in LESB* is always excluded by a combination of gravitino overabundance [30] and BBN constraints [31] (see section 5 for details).

2 Detectable GW signals in low energy SUSY-breaking

In this section we illustrate the correlation between possible signals at present and future GW interferometers and the phenomenology of low energy SUSY-breaking (LESB). The underlying assumption is that the SGWB is produced through a first-order phase transition controlled by the SUSY-breaking hidden sector. As we will show, this connection is relatively insensitive to the details of the dynamics in the hidden sector. In section 2.1 we summarize the structure and the parametric predictions of LESB theories, while in section 2.2 we go through the field theory inputs that are necessary to compute the spectrum of GWs from a FOPT. In section 2.3 we combine the results of the preceding sections to delineate the parameter space of possible gravitational wave signals from low-energy supersymmetry breaking, illustrated in figure 1.

2.1 Low-energy SUSY-breaking

Here we briefly review the structure of LESB and its broad parametric predictions, remaining agnostic as to the particular model realization. This general discussion is buttressed by section 5, where we will present the predictions of a simple, explicit model which gives rise to GW signals. For the purposes of this paper, we adopt a phenomenological definition of low-energy SUSY breaking: LESB models are those in which *the gravitino is the lightest supersymmetric particle (LSP)*. This requirement has deep implications for collider searches, precision observables, and cosmology, which we summarize in turn.

The first ingredient in low energy SUSY-breaking scenarios is a hidden sector at a high scale m_* , which breaks supersymmetry (and R -symmetry) spontaneously. At energies much below m_* , the spontaneous breaking of both supersymmetry and the R -symmetry can be encoded in a model-independent manner through the F - and scalar components of a single chiral superfield

$$\langle X \rangle = \frac{f_a}{\sqrt{2}} e^{2ia/f_a} + \sqrt{2}\theta\tilde{G} + \theta^2 F, \quad (2.1)$$

where f_a is the order parameter for the R -symmetry breaking while \sqrt{F} is the SUSY breaking scale, corresponding to an R -charge $R_X = 2$ for the superfield X . The parameter θ is a constant, complex anti-commuting two-component spinor enabling component fields of different spin to be united into a single superfield. The Majorana fermion in the multiplet is the Goldstino \tilde{G} , the goldstone fermion associated with spontaneous SUSY-breaking, while the compact scalar field a is the R -axion, the goldstone boson associated with spontaneous R -symmetry breaking.

Switching on gravity, the Goldstino becomes the longitudinal component of the gravitino via the super-Higgs mechanism [32] while the R -axion is lifted by an unavoidable explicit symmetry-breaking contribution arising from the fine-tuning of the cosmological

constant [33, 34]. The gravitino and R -axion masses can be written as

$$m_{3/2} = \frac{F_0}{\sqrt{3}M_{\text{Pl}}} \simeq 24 \text{ keV} \left(\frac{1}{\kappa}\right) \left(\frac{\sqrt{F}}{10^7 \text{ GeV}}\right)^2, \quad (2.2)$$

$$m_a^{\text{grav.}} = m_{3/2} \left[\frac{6^{3/2}M_{\text{Pl}}}{f_a}\right]^{1/2} \simeq 5.2 \text{ GeV} \left(\frac{m_{3/2}}{24 \text{ keV}}\right) \left(\frac{10^7 \text{ GeV}}{\sqrt{F}}\right) \left(\frac{\sqrt{\epsilon_R}}{1}\right), \quad (2.3)$$

where $M_{\text{Pl}} = 2.4 \cdot 10^{18} \text{ GeV}$ is the reduced Planck scale and we have defined

$$\kappa \stackrel{\text{def}}{=} F/F_0, \quad \epsilon_R \stackrel{\text{def}}{=} 2F/f_a^2. \quad (2.4)$$

This reflects the fact that the gravitino mass is set by the sum of supersymmetry-breaking contributions from all sectors, corresponding to a total SUSY-breaking scale $\sqrt{F_0}$ that may be larger than the scale \sqrt{F} in the LESB sector under consideration (i.e. $\kappa \lesssim 1$). Similarly, the R -symmetry breaking scale f_a may exceed the scale of supersymmetry breaking \sqrt{F} (i.e. $\epsilon_R \lesssim 1$), as is often the case in calculable hidden sectors. In writing the gravity contribution to the R -axion mass in eq. (2.3) we saturated the upper bound on the superpotential vacuum expectation value (VEV) [35]. In the presence of a possible explicit R -symmetry breaking term in the hidden sector $\epsilon_{\mathcal{R}}$, the R -axion mass will receive an extra contribution

$$m_a^{\mathcal{R}} = \sqrt{\epsilon_{\mathcal{R}} F} \simeq 10^3 \text{ TeV} \left(\frac{\epsilon_{\mathcal{R}}}{0.01}\right)^{1/2} \left(\frac{\sqrt{F}}{10^7 \text{ GeV}}\right), \quad (2.5)$$

making the R -axion heavier than the superpartners of Standard Model fields and hence phenomenologically irrelevant.

Most of the universal phenomenological predictions of low-energy SUSY breaking follow from the gravitino's role as the LSP [36]. First, the gravitino is the endpoint of every superpartner decay. In particular, the lifetime of the next-to-lightest supersymmetric particle (NLSP) is determined by its decay into the gravitino plus a Standard Model state,

$$\tau_{\text{NLSP}} = \frac{48\pi}{c_{\text{NLSP}}} \frac{M_{\text{Pl}}^2 m_{3/2}^2}{m_{\text{NLSP}}^5} \simeq 10^2 \text{ sec} \left(\frac{1}{c_{\text{NLSP}}}\right) \left(\frac{m_{3/2}}{24 \text{ keV}}\right)^2 \left(\frac{500 \text{ GeV}}{m_{\text{NLSP}}}\right)^5, \quad (2.6)$$

where c_{NLSP} is an $\mathcal{O}(1)$ coefficient which depends on the particulars of the NLSP. Second, the gravitino may be directly produced in pairs with a rate controlled by dimension-eight contact operators suppressed by $1/F^2$ in the $m_{\text{soft}} \gg m_{3/2}$ limit [22, 37]. These operators lead to a total cross section at lepton colliders for pair production in association with a photon of the form

$$\sigma(e^+e^- \rightarrow \tilde{G}\tilde{G}\gamma) \simeq \frac{\alpha_{\text{em}} s^3}{160\pi^2 F^4} \left[\frac{247}{60} + \log\left(\frac{4E_{\text{min}}^2}{s}\right)\right] \log\left(\frac{1 - \cos\theta_{\text{min}}}{1 + \cos\theta_{\text{min}}}\right), \quad (2.7)$$

where \sqrt{s} is the beam energy, E_{min} is the minimal photon energy, and θ_{min} is the minimal photon angle with respect to the beam direction. Here we have expanded in $E_{\text{min}} \ll \sqrt{s}$ (see ref. [22] for the full formula). A similar formula can be derived for $\sigma(pp \rightarrow \tilde{G}\tilde{G}j)$ as shown in ref. [23]. Using these formulas and rescaling the Standard Model backgrounds to higher

energies and luminosities, we may determine the sensitivity of missing energy searches at future colliders gravitino pair production; see section 5 for details. These searches lead to projected direct constraints on the SUSY-breaking scale \sqrt{F} as shown in figure 1.

Finally, the stability of the gravitino LSP typically results in a cosmological hazard. This is the well known “gravitino problem” of LESB theories [38–40]. For sufficiently high reheating temperature (i.e. $T_{\text{r.h.}} > 45m_{3/2}^2 M_{\text{Pl}}/M_3^2$, where M_3 is the soft mass of the gluino), the gravitino is in thermal equilibrium with the Standard Model bath. At freeze-out, the gravitino is still relativistic and its abundance is bounded from above by small-scale cosmological observables [41, 42]. The latter imply $m_{3/2} \lesssim 16$ eV, which corresponds to $\sqrt{F} < 260$ TeV. Alternately, if the reheating temperature is low enough, the gravitino is never in equilibrium with the Standard Model bath but is typically overproduced by a combination of UV scattering contributions [43–47], freeze-in from the decays of superpartners [48], and decay of the NLSP relic abundance after freeze-out [49, 50].

In order for SUSY-breaking sectors to generate sizable GW signals, the hidden sector needs to be reheated after inflation. Fixing the reheating temperature $T_{\text{r.h.}} = \sqrt{F}$ and requiring the gravitino to not overclose the universe implies

$$C_{\text{UV}} \frac{M_3^2 T_{\text{r.h.}}}{m_{3/2}} + C_{\text{F.O.}} \frac{m_{3/2} m_{\text{NLSP}}}{\alpha_{\text{eff}}^2} \lesssim 0.27 T_{\text{eq}} M_{\text{Pl}}, \quad (2.8)$$

where $C_{\text{UV}} = 45\sqrt{5}f_3/(8\pi^{13/2}g_*^{3/2}) \simeq 4 \cdot 10^{-5}$, $g_* \simeq 230$, and $f_3 \simeq 18$ encodes the thermal corrections as computed in ref. [46]; $C_{\text{F.O.}} = x_{\text{F.O.}}/(4\pi\sqrt{g_*}) = 0.12$ for $x_{\text{F.O.}} = 23$, and $\alpha_{\text{eff}} \simeq 0.01$ is chosen to match the correct dark matter relic abundance in the pure Higgsino case [51]. Eq. (2.8) reflects a similar expression in ref. [30], although here we have dropped the freeze-in contribution from superpartner decays because it is always subdominant compared to UV scattering contributions.

For $\kappa = 1$, the only region where the gravitino is not overabundant for $T_{\text{r.h.}} = \sqrt{F}$ corresponds to $\sqrt{F} < 260$ TeV, while for $\kappa \ll 1$ one can decouple the gravitino mass and push the SUSY-breaking scale to be as high as $\sqrt{F} \simeq 5 \cdot 10^7$ GeV. In this case, the upper bound is obtained by combining the overclosure bound, LHC bounds on Standard Model superpartner masses, and the BBN bounds on NLSP decays into the gravitino through the universal two-body decay in eq. (2.6) as derived in ref. [31]. This bound could slightly vary depending on the NLSP type and the detailed features of the spectrum, but this does not alter the primary message: requiring a reheating temperature $T_{\text{r.h.}} = \sqrt{F}$ to obtain sufficiently strong gravitational wave signals implies a quite stringent upper bound on \sqrt{F} as long as the gravitino is required to be the LSP.

Thus far, our discussion has not correlated the scale \sqrt{F} of supersymmetry breaking with the mass spectrum of Standard Model superpartners. Supersymmetry breaking in the hidden sector is transmitted to the visible sector (which we will take to be the minimal supersymmetric Standard Model, or MSSM, in this paper) through a mediation mechanism. The simplest possibility is to assume that a certain number of messengers N_{mess} in a given representation of the SM gauge group are coupled to the SUSY-breaking field X via the superpotential $W_{\text{mess}} = y_{\text{mess}} X \Phi \tilde{\Phi}$. Given this coupling, the R -symmetry breaking scale f_a controls the masses of the fermionic messengers, while the SUSY-breaking scale \sqrt{F} gives

an off-diagonal mass to the scalar messengers. The non-supersymmetric splitting between scalar and fermionic messengers is then transmitted to MSSM superfields via Standard Model gauge interactions. The resulting gaugino and squark masses are those of standard gauge mediation [36],

$$M_I = \frac{\alpha_I N_{\text{mess}} s_M}{4\pi} \left(\frac{\sqrt{2}F}{f_a} \right), \quad m_{\tilde{f}}^2 = \sum_I C_{\tilde{f}}(I) \left(\frac{\alpha_I N_{\text{mess}}}{4\pi} \right)^2 \left(\frac{\sqrt{2}F}{f_a} \right)^2, \quad (2.9)$$

where $C_{\tilde{f}}(I)$ is the quadratic Casimir of the representation of the MSSM sfermion \tilde{f} under the I th Standard Model gauge group and for simplicity we have considered messengers in the $5 + \bar{5}$ representation of $SU(5)$. The additional coefficient $s_M \lesssim 1$ appearing in the gaugino masses accounts for the phenomenon of “gaugino screening” [16, 52, 53]. In the simple scenarios discussed here, the ratio between the gluino and squark soft masses $M_3/m_{\tilde{q}} \simeq \sqrt{N_{\text{mess}}} s_M \lesssim 1$, so that the most relevant collider bounds at current and future colliders can be framed purely in terms of the gluino mass, assuming the squarks to be decoupled and the lightest gaugino to be the next-to-lightest SUSY particle (NLSP).

Writing the R -symmetry breaking VEV as in eq. (2.4), the final gluino mass can be simply written in terms of underlying parameters as

$$m_{\tilde{g}} \simeq 7 \text{ TeV} \left(\frac{g_M}{0.1} \right) \frac{\sqrt{F}}{10^7 \text{ GeV}}, \quad g_M \stackrel{\text{def}}{=} N_{\text{mess}} \sqrt{\epsilon_R} s_M \left[1 + \frac{\alpha_3}{4\pi} \left(9 + 6 \log \frac{Q}{M_3} \right) \right], \quad (2.10)$$

where we have collected various coefficients into a model-dependent prefactor g_M which encodes i) the suppression of the gaugino masses due to $f_a \gg \sqrt{F}$ (i.e. $\sqrt{\epsilon_R} \ll 1$), ii) the enhancement for $N_{\text{mess}} \gg 1$, iii) the gaugino screening controlled by $s_M \lesssim 1$, and iv) the relation of the gluino soft mass to its pole mass, correctly accounting for the one loop running of the gluino soft mass at low energies in the limit of heavy squarks [54, 55].

Broadly speaking, eq. (2.10) establishes an interesting relation between the SUSY-breaking scale and the present and future collider bounds on the gluino. Given the current LHC bound on gluino masses, which ranges between $m_{\tilde{g}} \gtrsim 2 - 2.5 \text{ TeV}$ [25–28], eq. (2.10) indicates the lowest values of the SUSY-breaking scale \sqrt{F} consistent with data.

Depending on the model, g_M can span many orders of magnitude, but there are three parametric regimes of interest:

- $1 \ll g_M \lesssim 160$, which is realized in strongly-coupled messenger sectors that are at the boundary of perturbativity. The upper bound on g_M is indeed obtained by requiring the SM gauge couplings and y_{mess} to be perturbative at the scale of the hidden sector.
- $g_M \simeq 1$, which is realized in weakly-coupled messenger sectors if $M_{\text{mess}} \simeq \sqrt{F}$ and the gaugino masses are not screened. The latter requirement requires non-trivial dynamics in the hidden sector, as shown in ref. [16].
- $g_M \ll 1$, which is typical of models where the soft masses are suppressed compared to the SUSY-breaking scale because $f_a \gg \sqrt{F}$ and the gaugino masses may be further screened compared to the squark masses. As we will show in section 5, this is the typical situation in simple, explicit setups featuring SGWB signals.

One of the most appealing features of LESB mediated via gauge interactions is the flavor-preserving nature of the MSSM superpartner spectrum. This is because the flavor-blind contributions to superpartner masses transmitted by gauge interactions vastly exceeds the omnipresent, flavor-violating “gravity-mediated” contributions. However, these gravity-mediated contributions reflect *all* contributions to SUSY breaking, while the gauge-mediated contributions reflect only the SUSY-breaking in the sector of interest. Thus when the gravitino mass is enhanced by $\kappa \ll 1$, the contribution from gravity mediation increases relative to the contribution from gauge mediation, and may eventually run afoul of bounds on flavor violation. In particular, this implies that κ is bounded from below by bounds from flavor-changing neutral currents (FCNCs). For instance, considering the slepton contributions to $\mu \rightarrow e\gamma$ [56, 57] and the squark contributions to Δm_K [58, 59] leads to the bounds

$$\kappa|_{\mu \rightarrow e\gamma} \gtrsim 10^{-9} \cdot \left(\frac{1}{\epsilon_R}\right), \quad \kappa|_{\Delta m_K} \gtrsim 10^{-9} \cdot \left(\frac{\sqrt{F}}{10^7 \text{ GeV}}\right) \cdot \left(\frac{1}{\epsilon_R}\right)^{3/4}, \quad (2.11)$$

where κ and ϵ_R are defined in eq. (2.4) and we set $\text{BR}(\mu \rightarrow e\gamma) < 4.2 \cdot 10^{-13}$ and $\Delta m_K = (3.479 \pm 0.001) \cdot 10^{-12}$ MeV, asking for the squark contribution to be less than present experimental uncertainty. These constraints give a robust upper bound on the gravitino mass in our framework. Finally, even in the absence of flavor violating effects, the electric dipole moments arising from the relative phase between gaugino and higgsino masses can be probed in precision experiments such as ACME [60, 61]. The current limits are already challenging a CP-violating phase of order 10^{-2} with gauginos below the TeV scale and the future experimental program will sensibly improve this reach making it one of the most interesting indirect probes of LESB [62, 63].

2.2 First order phase transitions and SGWB

Phase transitions in field theory are triggered by the nucleation of vacuum bubbles and their subsequent percolation in the space-time volume. The vacuum bubbles can be found in Euclidean signature as the stationary minimum-energy bounce solutions interpolating between the false and true vacuum [64, 65]. In all cases we consider here, the thermal fluctuations will dominate so that the total decay rate per unit volume can be approximated as

$$\Gamma(T) \simeq T^4 \left(\frac{S_3}{2\pi T}\right)^{\frac{3}{2}} \exp(-S_3/T), \quad (2.12)$$

where S_3 is the 3 dimensional Euclidean action for the $O(3)$ -symmetric bounce [66, 67]. The decay rate encodes the probability of true vacuum bubbles to be nucleated in a spacetime region where the false vacuum dominates.

The time evolution of the phase transition can be described in terms of different temperatures. First of all, a necessary condition for nucleation is that the universe reaches temperatures below the critical temperature T_c , where the false and true vacuum are degenerate. At the nucleation temperature $T_n < T_c$, one bubble will nucleate per Hubble

volume, corresponding to²

$$\frac{\Gamma(T_n)}{H(T_n)^4} = 1 \quad \Rightarrow \quad \frac{S_3(T_n)}{T_n} \simeq -9.2 \log \frac{g_*}{230} + 4 \log \frac{M_{\text{Pl}}}{T_n} + \frac{3}{2} \log \frac{S_3(T_n)}{T_n}, \quad (2.13)$$

where we assumed that the phase transition happens during radiation domination so that $H^2(T) = \frac{\pi^2 g_* T^4}{90 M_{\text{Pl}}^2}$ and normalized g_* to the number of the degrees of freedom in the MSSM. In all the cases we will consider, the last term in eq. (2.13) can be neglected together with the constant term, so that solving

$$\frac{S_3(T_n)}{T_n} \simeq \mathcal{C}(T_n), \quad \mathcal{C}(T_n) \stackrel{\text{def}}{=} 104 \log \left(\frac{10^7 \text{ GeV}}{T_n} \right) \quad (2.14)$$

is always a good approximation. Since $\mathcal{C}(T)$ is a slowly-varying function of T , we can further simplify this equation assuming $\mathcal{C}(T_n) \simeq \mathcal{C}(T_c)$; this number is always going to be $\mathcal{O}(10^2)$ in the temperature range of interest.

After one bubble per volume has been nucleated at T_n , the bubbles expand to fill the space-time volume. The phase transition is considered to be completed at the percolation temperature T_p , when a small fraction of the total volume remains in the false vacuum. For fast phase transitions like the ones discussed here, one can show that $T_p \simeq T_n$ so that we can neglect this difference and take T_n as the temperature at which the phase transition completes. This sets the relevant dimensionful scale controlling the frequency range of the SGWB spectrum.

The shape and amplitude of the SGWB spectrum strongly depends on the amount of energy released into GWs during the FOPT, the duration of the phase transition, and the behavior of the bubbles in the cosmic fluid. The two first ingredients can be easily quantified in terms of field theory data via the quantities

$$\alpha(T_n) = \frac{30}{\pi^2 g_* T_n^4} \left(\Delta V(T_n) - T_n \left. \frac{d\Delta V(T)}{dT} \right|_{T=T_n} \right), \quad (2.15)$$

$$\beta_H(T_n) \stackrel{\text{def}}{=} \frac{\beta(T_n)}{H(T_n)} = T_n \frac{d}{dT} \left(\frac{S_3}{T} \right) \Big|_{T=T_n}, \quad (2.16)$$

where $\Delta V(T_n)$ is the potential energy difference between the true and the false vacuum at T_n . The amount of energy released into GWs is quantified by α , the latent heat relative to the radiation energy density $\rho_R = \frac{\pi^2 g_* T^4}{30}$ [68]. The duration of the phase transition is quantified by β_H , the inverse of the typical timescale of the transition normalized with respect to Hubble; it is defined under the assumption that the nucleation rate rises exponentially [66, 67] as $S(t) = e^{\beta_H H(t)(t-t_n)}$. Using the approximate nucleation condition in eq. (2.14) we can write

$$\beta_H(T_n) \simeq S'(T_n) - \mathcal{C}, \quad (2.17)$$

where $S'(T_n) \gtrsim \mathcal{C}$ in order for the nucleation rate to rise as a function of time, and $\beta_H \gtrsim \mathcal{C} \sim 100$ unless there is some measure of fine-tuning between the first and the second

²The nucleation temperature is formally defined by the integral $1 = \int_{T_n}^{T_c} \frac{dT}{T} \frac{\Gamma(T)}{H(T)^4}$, which is well approximated by eq. (2.13) since $\Gamma(T)$ depends exponentially on the temperature.

terms of the above expression. To evaluate the fine-tuning associated with β_H in explicit models, we define

$$\Delta_{\beta_H} \stackrel{\text{def}}{=} \text{Max}_{\{p_i\}} \Delta_{\beta_H}^{p_i} = \text{Max}_{\{p_i\}} \left| \frac{d \log \beta_H}{d \log p_i} \right|, \quad (2.18)$$

where $\Delta_{\beta_H}^{p_i}$ are the individual tunings with respect to the underlying parameters of the theory p_i . As we will discuss in section 3, the parametric dependence of the fine-tuning can be derived for our general class of models and then computed explicitly in the models of section 4. As a result, obtaining $\beta_H < 10$ would imply a large amount of fine tuning (in the sense of being a non-generic prediction of a given model). This is illustrated in figure 1, where it provides a meaningful bound on the parameter space of GW signals in LESB. The dominant production mechanism of gravity waves during the first-order phase transition depends on the dynamics of the bubbles in the cosmic fluid. If the mean free path of the particles is much longer than the width of the bubble wall, the velocity of the wall v_w can be determined by equilibrating the pressure on the bubble wall induced by the difference in potential energy ΔV with the friction forces exerted by the surrounding plasma [69–71]. The latter are induced by states whose mass changes in passing from the false to the true vacuum. For $v_w \rightarrow 1$, the total pressure can be derived in a quasi-classical approximation [71–73] and reads

$$p = \Delta V - \Delta P_{\text{LO}} - \Delta P_{\text{NLO}}, \quad \Delta P_{\text{LO}} = \frac{\Delta m^2 T^2}{24}, \quad \Delta P_{\text{NLO}} \simeq \frac{1}{16\pi^2} \gamma g^2 \Delta m_V T^3, \quad (2.19)$$

where the Lorentz gamma factor is $\gamma = 1/\sqrt{1 - v_w^2}$ and the leading-order plasma friction P_{LO} depends on the change in the masses-squared Δm^2 of all the states in the thermal bath [72]. Since $\Delta m^2 = m_{\text{true}}^2 - m_{\text{false}}^2$, the approximate expression in eq. (2.19) is only valid when both $\gamma T \gtrsim m_{\text{true}}$ and $T \gtrsim m_{\text{false}}$. The first condition ensures that particles in the false vacuum have enough energy to pass through the wall, while the second forestalls Boltzmann suppression of the pressure [71]. The next-to-leading order radiation pressure P_{NLO} is instead induced by the change in mass of the vector bosons and it is γ -enhanced for $v_w \rightarrow 1$, as first derived in [73].

The pressure in eq. (2.19) determines both how much the bubble wall accelerates as a function of the bubble radius [74, 75], and the fraction of the FOPT energy which is in the bubble wall at the time of collision T_* (traditionally called k_{coll}). Since we will be dealing with fast phase transitions, we take $T_* \simeq T_p \simeq T_n$.

In the absence of friction, the acceleration of the bubble wall grows linearly with the bubble radius until the gamma factor reaches a terminal value

$$\gamma_* \simeq \frac{2 R_*}{3 R_0} \simeq 2.6 \cdot 10^8 \sqrt{\frac{230}{g_*(T_n)}} \left(\frac{100}{\beta_H} \right) \left(\frac{10^7 \text{ GeV}}{T_n} \right) \left(\frac{\Delta V(T_n)}{T_n^4} \right)^{1/3}, \quad (2.20)$$

where we took the initial radius to be $R_0 \simeq R_c = \left(\frac{3}{2\pi} \frac{S_3(T_n)}{\Delta V(T_n)} \right)^{1/3}$ estimated in the thin wall approximation [64], estimated R_* as in ref. [76], and assumed radiation domination. The last term is $\mathcal{O}(1)$ in phase transitions which do not have a supercooling phase since $\Delta V(T_n)/T_n^4 < 75.6(g_*/230)$.

In the FOPTs discussed here, the bubble growth is generically stopped by plasma effects from heavy states. This is due to a novel effect in which the relevant energy scale for particles interacting with the wall reaches values $\sim \gamma T_n$ much larger than the intrinsic scales associated with the bubble. This is particularly relevant for SUSY-breaking hidden sectors, where there is a large separation of scales that can be spanned by these ultra-relativistic effects. In particular, the bubbles expand and accelerate linearly with the radius until the boost factor is large enough to allow heavy states of mass $m_{\text{true}} \gg T_n$ to cross the bubble wall. The significant mass change of these states induces a new source of LO friction,

$$\Delta P_{\text{LO}}^{\text{heavy}} \simeq \frac{1}{24} (m_{\text{true}}^2 - m_{\text{false}}^2)^2 T_n^2 e^{-m_{\text{false}}/T_n}. \quad (2.21)$$

If $\Delta V - \Delta P_{\text{NLO}}^{\text{heavy}} \leq 0$, the gamma factor of the bubble wall and the bubble radius at equilibrium are approximately

$$\gamma_{\text{eq}}^{\text{heavy}} \simeq \frac{m_{\text{true}}}{T_n}, \quad R_{\text{eq}}^{\text{heavy}} \simeq \frac{3}{2} \gamma_{\text{eq}}^{\text{heavy}} R_c. \quad (2.22)$$

This effect is very similar to the pressure term from mixing discussed in ref. [77], but here we typically pay the Boltzmann suppression of m_{false} .

The resulting fraction of the energy in the bubble wall at the time of collisions is generically very suppressed,

$$k_{\text{coll}} \simeq \frac{R_{\text{eq}}}{R_*} \left(1 - \frac{\Delta P_{\text{LO}}}{\Delta V}\right) \simeq 4 \cdot 10^{-9} \gamma_{\text{eq}}^{\text{heavy}} \left(\frac{2.6 \times 10^8}{\gamma_*}\right) \left(1 - \frac{\Delta P_{\text{LO}}}{\Delta V}\right). \quad (2.23)$$

As such, most of the energy released in the FOPT goes into the plasma, giving rise to sound waves propagating through the cosmic fluid. These sound waves source gravitational waves from the motion of the plasma with an efficiency determined by

$$k_{\text{sw}} \simeq \frac{\alpha}{0.73 + 0.083\sqrt{\alpha} + \alpha}, \quad (2.24)$$

where we have expanded the general formula of refs. [78, 79] for $k_{\text{coll}} \ll 1$. The resulting GW spectral density is

$$\Omega_{\text{sw}}^* = 3.8 \left(\frac{1}{\beta_H^2}\right) \left(\frac{\kappa_{\text{sw}} \alpha}{1 + \alpha}\right)^{3/2} \left(\frac{f}{f_{\text{sw}}^*}\right)^3 \left[1 + \frac{3}{4} \left(\frac{f}{f_{\text{sw}}^*}\right)^2\right]^{-7/2}, \quad f_{\text{sw}}^* = 1.2 \beta_H^* H_*, \quad (2.25)$$

where $H_*^2 = \frac{\pi^2 g_*(T_*)}{90} \frac{T_*^4}{M_{\text{Pl}}^2} (1 + \alpha)$ to account for the reheating of the plasma and β_H^* is normalized accordingly following eq. (2.16). The sound wave spectrum is a broken power law which drops like $\Omega_{\text{sw}}^* \sim f^3$ for $f \ll f_{\text{sw}}^*$, as expected from causality in a radiation dominated universe, and as $\Omega_{\text{sw}}^* \sim f^{-4}$ for $f \gg f_{\text{sw}}^*$. The high frequency behavior of the spectrum is likely to be affected by the turbulence contribution, whose size is still subject to large theoretical uncertainties [11, 80]. Here, we include for simplicity only the sound waves contribution to the GW spectrum in eq. (2.25), which will mainly determine the

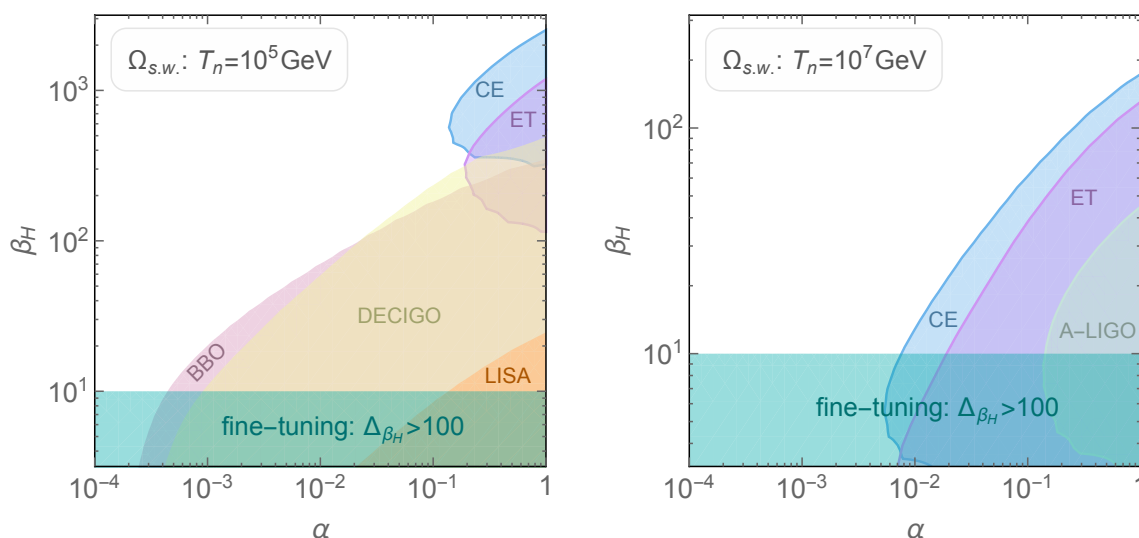

Figure 2. The reach of future GW interferometers in the (α, β_H) plane for two different scales of FOPTs, assuming the signal is dominated by sound waves given by eq. 2.25. The shaded regions are obtained by requiring the signal at the peak in eq. (2.28) to be inside the PLI curve of a given experiment. *Left:* $T_n = 10^5$ GeV corresponds to LESB scenarios with an ultralight gravitino LSP and $\kappa = 1$. *Right:* $T_n = 10^7$ GeV corresponds to LESB scenarios with gravitino DM and $\kappa \ll 1$. We will exhibit calculable scenarios of this type in section 4.

detectability of a given GW signal. After redshift is taken into account, assuming that the entropy per comoving volume remains constant [68], the GW spectrum today reads

$$\Omega_{\text{sw}}^0 h^2 = \left(\frac{a_*}{a_0}\right)^4 \left(\frac{H_*}{H_0}\right)^2 \Omega_{\text{sw}}^* = 2.8 \cdot 10^{-5} \left(\frac{230}{g_*}\right)^{1/3} \Omega_{\text{sw}}^*, \quad (2.26)$$

where the peak frequency and the power at the peak frequency scale as

$$f_{\text{sw}}^0 = f_{\text{sw}}^* \left(\frac{a_*}{a_0}\right) = 1.1 \times 10^2 \text{ Hz} \left(\frac{g_*}{230}\right)^{1/6} \left(\frac{\beta_H}{50}\right) \left(\frac{T_n}{10^7 \text{ GeV}}\right) \left(\frac{1.3}{1+\alpha}\right)^{1/4}, \quad (2.27)$$

$$\Omega_{\text{GW}}^{\text{sw},0} h^2 \simeq 10^{-10} \left(\frac{230}{g_*}\right)^{1/3} \left(\frac{50}{\beta_H}\right)^2 \left(\frac{\kappa_{\text{sw}} \alpha}{0.08}\right)^{3/2} \left(\frac{1.3}{1+\alpha}\right)^{3/2}. \quad (2.28)$$

Here we have taken $T_* \simeq T_n$ and normalized the scalings for $\alpha = 0.3$, $\beta_H = 100$ and $T_n = 10^7$ GeV, which will be the typical values for FOPTs related to fully calculable SUSY-breaking hidden sectors explored in the following sections.

Having derived the expected GW spectrum, we can determine the region in the (α, β_H) plane where we expect the SBGW to be detectable at future interferometers. Given the fraction of energy density in GWs today in eq. (2.26), the sensitivity of a given interferometer is controlled by the time integrated signal-to-noise ratio

$$\rho^2 = t_{\text{obs}} \int_{f_{\text{min}}}^{f_{\text{max}}} \left[\frac{\Omega_{\text{GW}}(f, \alpha, \beta, v_w)}{\Omega_{\text{noise}}(f)} \right]^2, \quad (2.29)$$

where $\Omega_{\text{noise}}(f)$ is the effective noise of the interferometer within a given frequency band ($f_{\text{min}}, f_{\text{max}}$) and t_{obs} is the observation time. A detectable stochastic GW background is defined to have $\rho > 10$. The Power Law Integrated (PLI) curves are generated by considering a power law function of the frequency f for the GW signal shape in eq. (2.29). The PLI curves for each GW interferometer considered here are given in appendix C for completeness.

In figure 2 we show the regions in the (α, β_H) plane where the power at the peak frequency in eq. (2.28) lies within the reach of future interferometers for two different nucleation temperatures. Low nucleation temperatures such as $T_n = 10^5$ GeV can be probed over a wide frequency range depending on β_H (i.e. the duration of the FOPT) while high nucleation temperatures such as $T_n = 10^7$ GeV will be accessible only at future high frequency interferometers such as Advanced LIGO (A-LIGO) [17], the Einstein Telescope (ET) [18] and the Cosmic Explorer (CE) [19, 20]. In the next section we show that $T_n \sim \sqrt{F}$ in our LESB scenarios, so that high nucleation temperatures in fully calculable SUSY-breaking scenarios correspond to superpartners lying out of the reach of the LHC.

2.3 LESB in the future: GW interferometers vs. colliders

We are now ready to establish a connection between the SGWB signals and SUSY-breaking phenomenology described in the previous two sections. The first step is to relate the nucleation temperature relevant for the SGWB signal to the scales in a SUSY-breaking hidden sector. As we will see, the nucleation temperature is essentially set by the SUSY-breaking scale \sqrt{F} in our scenarios.

Focusing on FOPT where the barrier between the false and the true vacuum is present at $T = 0$, S_3 is bounded from below by a constant and we can define T_{min} as the temperature where

$$\beta_H|_{T=T_{\text{min}}} = 0 \quad \Rightarrow \quad T_{\text{min}} < T_n < T_c. \quad (2.30)$$

If $S_3(T)$ is monotonic for $T > T_{\text{min}}$, the solution of the equation above is unique. The nucleation temperature is then bounded from above by T_c , where $\beta_H \rightarrow \infty$ and α in eq. (2.15) is suppressed and dominated by $\frac{d\Delta V(T_n)}{dT}$. It is further bounded from below by T_{min} where $\beta_H \rightarrow 0$ and α is dominated by $\Delta V(T_n)$.

More importantly, T_n can be directly related to the SUSY-breaking scale \sqrt{F} which sets the size of the $O(3)$ -symmetric bounce action. A simple way of seeing this is to note that the bounce action at T_n is itself set by the scale of relevant features in the potential,

$$S_3(T_n) \simeq c_3 \sqrt{F} \quad \Rightarrow \quad T_n = \frac{c_3}{\mathcal{C}} \sqrt{F}, \quad (2.31)$$

where c_3 is a model-dependent function of the parameters controlling the shape of the potential which we assume to be temperature independent for simplicity (an approximation that is certainly justified if T_n is close enough to T_{min}). Here we assume that $c_3/\mathcal{C} \sim \mathcal{O}(1)$, an assumption that will turn out to be justified analytically in section 3 and numerically in the explicit models of section 4.

Having established a relation between T_n and the SUSY-breaking scale \sqrt{F} , we identify two different viable regions of the LESB parameter space satisfying the following simple requirements:

- the gravitino is the lightest supersymmetric particle (LSP) as required by LESB, and
- the reheating temperature $T_{\text{r.h.}}$ is as high as \sqrt{F} to generate GW signals from the hidden sector. We take $T_{\text{r.h.}} = \sqrt{F}$ in figure 2.11 to maximize the allowed parameter space.

The two viable regions satisfying the above requirements are

Gravitino dark matter window: where $260 \text{ TeV} < \sqrt{F} \lesssim 50 \text{ PeV}$ and $\kappa \ll 1$ so that the gravitino mass is larger than the nominal value set by the F -term in Eq (2.1). The upper bound on the SUSY-breaking scale is obtained by combining the constraints on gravitino overabundance in eq. (2.8), BBN constraints on NLSP decays, and the LHC bound on the gluino mass $m_{\tilde{g}} > 2 \text{ TeV}$. The precise upper bound is potentially dependent on further model-building epicycles; the value here is meant to be indicative. In this window, the gravitino abundance can match the observed dark matter relic abundance today, while the soft masses are still dominated by the gauge mediation contributions in eq. (2.9) so that flavor constraints are under control when eq. (2.11) is satisfied. Perturbative gauge mediation models with $f_a \gtrsim \sqrt{F}$ and gaugino screening will naturally live in the upper end of this window for $\sqrt{F} \simeq 1 - 50 \text{ PeV}$. As shown in figure 1, the future reach on gluinos at FCC-hh [29] could provide a further direct test of these models. Future interferometers in the LIGO frequency band such as A-LIGO [17], ET [18] and CE [19, 20] have the unique opportunity to probe these scenarios as long as the thermal transition to the SUSY-breaking vacuum is associated with a sufficiently strong FOPT (see figure 2). In the rest of the paper, we discuss explicit scenarios of this type.

Ultralight gravitino window: where $m_{3/2} < 16 \text{ eV}$ and $\sqrt{F} < 260 \text{ TeV}$. This region has no cosmological issues for $\kappa = 1$, but it requires $g_M \gtrsim 1$ to satisfy the LHC bound on the gluino mass given the low SUSY-breaking scale (see eq. (2.10) for definition and comments). A lower bound on the gravitino mass can be derived from direct searches for gravitino pair production at LEP in $\gamma + \text{MET}$ and at the LHC in $j + \text{MET}$. As shown in figure 1, present direct bounds on the gravitino are not competitive with the bound on \sqrt{F} obtained by requiring $m_{\tilde{g}} > 2 \text{ TeV}$ and perturbativity in the messenger sector. The HL-LHC will not improve much on that. Future colliders — in particular, high energy lepton colliders (HELCS) — can drastically improve the reach on gravitino pair production and meaningfully probe this window even if MSSM superpartners remain inaccessible. As shown in figure 2, these scenarios can be probed across a wide frequency range by future GW interferometers depending on the strength and the duration of the FOPT. Building explicit calculable models in this window presents challenges [81, 82], and we leave a study of possible GW signals for a future work.

3 Anatomy of the SUSY-breaking phase transition

In this section we describe the generic features of FOPT occurring in calculable SUSY-breaking hidden sectors. First, we discuss how a large class of perturbative hidden sectors can be encoded in the effective field theory of the *universal pseudomodulus*, which is the scalar component x of the chiral superfield X in eq. (2.1), universally related to the spontaneous breaking of supersymmetry [14–16].

Second, we show how the flatness of the pseudomodulus potential gives rise to a new class of FOPTs with a very distinctive feature: the nucleation temperature is generically small compared to the SUSY mass scale, $T_n \leq m_*$, so that the thermal potential is well approximated in the low- T expansion. As we will discuss, non-supersymmetric realizations of this class of FOPT typically entail a large amount of fine-tuning.

Finally, we derive parametric estimates for T_n , α and β_H for this new class of FOPTs using the triangular barrier approximation [83, 84] and comment on a universal feature of bubble dynamics in our FOPTs. The observations of this section will find a concrete realization in the working examples of section 4.

3.1 The SUSY-breaking pseudomodulus

The existence of flat directions is a trademark of hidden sectors with spontaneous SUSY breaking. Here we focus on a large class of SUSY breaking sectors where the dynamics of both SUSY and R -symmetry breaking can be embedded in a single chiral superfield X parametrized as in eq. (2.1)

$$X = \frac{x}{\sqrt{2}} e^{2ia/f_a} + \sqrt{2}\theta\tilde{G} + \theta^2 F, \tag{3.1}$$

where the R -charges of the components are respectively $R[x] = 2, R[\tilde{G}] = 1, R[F] = 0$. The scalar component x (the *universal pseudomodulus*) tracks the breaking of the R -symmetry, while $\langle F \rangle$ sets the SUSY breaking scale.³ The phase transition occurs along x from a local minimum at the origin $x = 0$ (where R -symmetry is preserved) to the $T = 0$ vacuum of the theory where $\langle x \rangle = f_a$ and R -symmetry is broken. Hence $\langle x \rangle = f_a$ is the order parameter of the phase transitions of interest here, parameterizing the spontaneous breaking of the R -symmetry.

In hidden sectors which admit a weakly coupled description, the phase transition can be fully described by studying the effective potential of the pseudomodulus x , whose mass is typically well below the mass m_* of the heavy SUSY states in the hidden sector. As we will see, the unique features of the pseudomodulus potential leave a strong imprint on the properties of the phase transition. The full effective potential for the pseudomodulus can be written as

$$V_{\text{eff}}(x) = V_0(x) + V_T(x), \tag{3.2}$$

where $V_0(x)$ encodes the zero-temperature quantum corrections and $V_T(x)$ the thermal ones.

The zero-temperature part of the effective potential $V_0(x)$ is flat at tree level, up to explicit R -symmetry breaking effects. Along this so-called F -flat direction, the size of the potential energy is set by supersymmetry breaking, $V \sim F^2$. Interactions that explicitly violate the R -symmetry typically destabilize the origin and give a slope to the pseudomodulus potential at tree level, but these features are usually small compared to the scale \sqrt{F} . At one loop, quantum corrections lift the pseudomodulus potential; these corrections are

³In more general scenarios there could be multiple different field directions associated to SUSY-breaking and R -symmetry breaking [16] or even multiple pseudo-flat directions from multiple sources of F -term SUSY breaking [85].

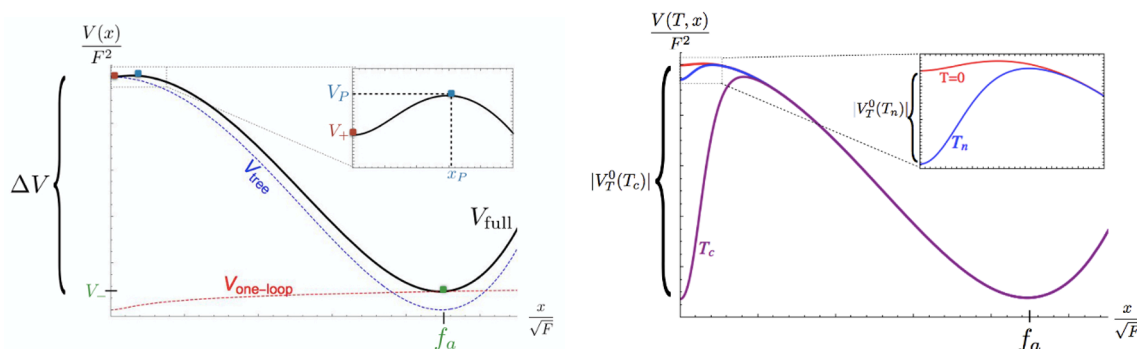

Figure 3. Qualitative features of the pseudomodulus potential relevant to the FOPT in SUSY-breaking hidden sectors. *Left:* sketch of the zero-temperature potential as described in section 3.1, exhibiting the following features: i) the distance between the two minima is larger than their potential difference, $f_a^4 \gtrsim \Delta V$, and ii) the height of the peak between the two minima is loop-suppressed compared to the potential difference, $V_P \ll \Delta V$. An explicit realization of this potential is presented in section 3.4. The tree level potential (*dashed blue*) generated by explicit R -symmetry breaking destabilizes the origin, giving rise to a minimum at $\langle x \rangle = f_a$ where the R -symmetry is further spontaneously broken by the VEV of x . Quantum corrections (*dashed red*) generate a local minimum at origin. *Right:* behavior of the temperature corrections described in eq. (3.5) at $T = 0$, $T = T_c$, and $T = T_n$. The thermal corrections give a contribution to the potential at the origin which at T_n is typically much smaller than F^2 . The barrier and the true vacuum are essentially unchanged. The approximations in section 3.2 are then justified.

present even in the absence of explicit R -symmetry breaking. The combination of tree-level explicit R -symmetry breaking and one-loop quantum corrections give rise to the schematic zero-temperature potential shown in figure 3. Assuming the quantum corrections exceed the R -symmetry breaking effects, at zero temperature this creates a metastable vacuum at the origin that is separated by a barrier from the true vacuum at $\langle x \rangle_{\text{true}} = f_a$. The energy difference between the two vacua ΔV is proportional to the SUSY-breaking scale. The barrier is located at a distance x_P from the origin; at this point, the barrier height is V_P . The essential features characterizing the zero temperature potential are:

- *The potential is flat.* This means that the distance f_a in field space between the false vacuum and the true vacuum is larger than the size of the potential energy difference ΔV :

$$f_a^4 > \Delta V, \quad (3.3)$$

where this hierarchy assumes that R -symmetry breaking effects are parametrically smaller than the loop corrections. This will be manifest in the toy model of section 3.4. Under this assumption, the flatness of the potential is a direct consequence of the fact that SUSY loop corrections asymptote to a logarithm at large field values (see for instance [86]). Obtaining similar quantum corrections in non-supersymmetric theories with a field-independent mass gap is notoriously difficult without fine-tuning.⁴

⁴A well studied example of a flat potential is that of the dilaton of spontaneously broken conformal symmetry. Here, however, the mass gap is field-dependent and as a consequence the theory becomes strongly coupled at the origin [87]. The features of the dilaton phase transition are consequently very different from the one described here.

- *The barrier between the two vacua is small.* Given that the potential is generated by loop effects (and subleading R -symmetry breaking effects), the size of the barrier V_P is one-loop suppressed with respect to the energy difference between the true and the false vacuum ΔV :

$$\frac{V_P}{\Delta V} = \frac{\lambda_{\text{eff}}^2}{16\pi^2}, \tag{3.4}$$

where $\lambda_{\text{eff}} \sim \mathcal{O}(1)$ should be thought of as the effective coupling determining the height of the barrier. The position of the barrier x_P is model-dependent, but will not play a critical role in the determination of the bounce action as long as eq. (3.3) is satisfied.

We now turn to the finite temperature corrections. First, as it is well known, finite temperature effects break SUSY and thus significantly modify the pseudo-modulus potential. The thermal effects are dominated by the loops of heavy fields in the SUSY hidden sector coupled to x , whose mass is of order m_* . Since m_* is by construction larger than the SUSY-breaking scale \sqrt{F} setting the zero-temperature potential, the relevant temperatures for the phase transition are smaller than the mass scale m_* of the particles running in thermal loops. This implies that the correct approximation of the thermal potential is the *low temperature expansion* (see appendix A for explicit formulas). This makes the finite-temperature potential of the pseudomodulus qualitatively different from ordinary non-SUSY models, where the high temperature approximation applies since the typical scalar potential curvature is of the same order of the highest mass scale in the theory.

The effect of thermal corrections on the pseudomodulus potential takes the schematic form

$$V_T(x) \simeq -N T^4 \left(\frac{\lambda^2 x^2 + m_*^2}{(2\pi T)^2} \right)^{3/4} e^{-\sqrt{\frac{\lambda^2 x^2 + m_*^2}{T^2}}}, \tag{3.5}$$

where we assumed the presence of N degrees of freedom with masses-squared $\sim \lambda^2 x^2 + m_*^2$. Notice that N counts all the heavy degrees of freedom, both bosonic and fermionic, which contribute with the same sign to the thermal potential. This enhances the importance of thermal effects compared to zero-temperature loops, where cancellations occur between states of different statistics.

The thermal correction constitutes a negative contribution to the potential which is maximal (in absolute value) at the origin of the pseudomodulus, when $x \sim 0$ and the Boltzmann suppression factor is minimized. As a consequence, thermal corrections in our scenarios have an exponentially larger impact at the origin relative to the true vacuum or the barrier. This behavior is explicitly shown in the right panel of figure 3. As we will show in section 4 small deviations from this generic feature can be induced by heavy states becoming lighter at large field values of the pseudomodulus.

3.2 First order phase transitions in the low- T expansion

Given the shape of our potential as shown in figure 3, we can approximate the bounce action in the triangular barrier approximation [83, 84]. Within this approximation, we will be able to capture the parametric behavior of the FOPTs analytically and in section 4 we

will show how the full analytical solution in explicit models reflects the general features explored here. A more in-depth discussion about the computation of the bounce action in the various cases can be found in appendix B.

Taking the false vacuum to be at the origin of field space, we can write the bounce action in the triangular barrier approximation as

$$\frac{S_3}{T} = \frac{144\sqrt{2}\pi}{5} \frac{(V_P - V_+)^{5/2}}{(V_P - V_-)^3} \frac{f_a^3}{T} f(r_\lambda), \quad \text{for } \frac{f_a}{x_P} > g(r_\lambda), \quad (3.6)$$

where we have defined the variables

$$r_\lambda \stackrel{\text{def}}{=} \frac{\lambda_-}{\lambda_+}, \quad \lambda_- \stackrel{\text{def}}{=} \frac{V_P - V_-}{f_a - x_P}, \quad \lambda_+ \stackrel{\text{def}}{=} \frac{V_P - V_+}{x_P}, \quad (3.7)$$

and the functions

$$f(r_\lambda) = \frac{r_\lambda^3(1+r_\lambda)}{3\sqrt{3}(3+2r_\lambda-3(1+r_\lambda)^2/3)^{3/2}} \underset{r_\lambda \rightarrow 0}{\simeq} 1 + \frac{5}{3}r_\lambda, \quad (3.8)$$

$$g(r_\lambda) = 1 + \frac{r_\lambda}{3+2r_\lambda-3(1+r_\lambda)^{2/3}} \underset{r_\lambda \rightarrow 0}{\simeq} \frac{3}{r_\lambda} + \frac{7}{3}. \quad (3.9)$$

The expansion for $r_\lambda \rightarrow 0$ is justified as long as both eq. (3.3) and eq. (3.4) are satisfied and the true vacuum VEV f_a sets the largest scale in the pseudomodulus potential. The triangular barrier approximation can be extended beyond the region set by $f_a/x_P > g(r_\lambda)$, but the range of validity of eq. (3.6) is sufficient to capture the parametrics of the phase transitions of interest. We give the full expression of the triangular barrier approximation in appendix B.

The triangular barrier approximation depends in general on only five parameters characterizing the potential: the three values of the potential at the critical points, V_\pm, V_P , and the position of the two critical points, f_a, x_P . For a given theory we can compute these temperature-dependent quantities explicitly, and find that the bounce action in eq. (3.6) is an excellent match to the full numerical result.⁵

At the leading order in the $r_\lambda \rightarrow 0$ expansion, the bounce action is independent of x_P ; our analytical estimates will assume that this holds. To further simplify our analytical treatment, we approximate the thermal potential in eq. (3.5) by only including thermal corrections at $x = 0$, where the exponential suppression is minimized, and neglecting the temperature dependence of V_- and V_P . Within this approximation we obtain

$$V_+ = V_T^0, \quad V_T^0 \stackrel{\text{def}}{=} V_T(x=0), \quad V_- = -\Delta V, \quad (3.10)$$

where we set V_+ to be exactly zero at zero temperature so that its (strictly negative) value is purely controlled by the thermal corrections at the origin. The value of the potential at the true vacuum is $-\Delta V$, and independent of temperature in this approximation.

With these approximations, the bounce action becomes simply

$$\frac{S_3}{T} \simeq \frac{144\sqrt{2}\pi}{5T} \frac{(V_P - V_T^0)^{5/2} f_a^3}{(\Delta V)^3}, \quad \frac{3V_T^0}{\Delta V} + 1 > 0, \quad (3.11)$$

⁵Throughout this paper we make use of the Mathematica package FindBounce [88] for our numerical analysis, which we further validate using CosmoTransitions [89].

and we are now ready to describe the shape of S_3/T as a function of T . First we define the critical temperature T_c , where the thermal corrections at the origin balance the zero-temperature potential difference between the two minima:

$$|V_{T_c}^0| \simeq \Delta V \quad \Rightarrow \quad T_c \simeq \frac{2}{5} \frac{m_*}{\mathcal{W}\left(0.13 \left(N \frac{m_*^4}{F^2}\right)^{2/5}\right)}, \quad (3.12)$$

where $\mathcal{W}(x)$ is the Lambert function, defined as the solution to the equation $\mathcal{W}(x)e^{\mathcal{W}(x)} = x$. At large x the function $\mathcal{W}(x)$ behaves approximately like $3/4 \log(1+x)$, and this simple approximation can be used for all practical purposes here (see appendix A for a short summary of the properties of the Lambert function). Using this, the low- T expansion will apply in regions of parameter space where

$$T_c \lesssim m_* \quad \Rightarrow \quad \sqrt{F} \lesssim 0.8 \left(\frac{N}{10}\right)^{5/8} m_*, \quad (3.13)$$

where we have normalized the number of degrees of freedom in the thermal loops to the typical order of magnitude we will find in the explicit examples of section 4. The low- T approximation is then valid whenever eq. (3.13) is satisfied, making it a generic feature of the pseudomodulus potential where the vacuum energy is protected from quantum corrections induced by heavy SUSY states.

From the definition of T_c in eq. (3.12), we can immediately see that the triangular approximation in eq. (3.11) breaks down in this regime and should be extended (see appendix B). However, the nucleation temperature in our setup is generically very far from T_c , so that eq. (3.11) is always a good approximation at the temperatures relevant for the FOPT. As the temperature decreases below $T < T_c$, S_3/T decreases as long as $|V_T^0| > V_P$, since $|V_T^0|$ decreases exponentially with the temperature. When the temperature approaches T_{\min} defined in eq. (2.30), then $|V_T^0| \simeq V_P$ and S_3/T attains a minimum value. As the temperature decreases further below T_{\min} , S_3/T grows as $1/T$.

Plugging the simplified bounce action in eq. (3.11) into the T_{\min} definition in eq. (2.30), we can easily obtain an analytic expression for T_{\min} which reads

$$T_{\min} = \frac{2m_*}{3} \frac{1}{\mathcal{W}\left(\frac{5^{2/3}}{3\pi} \left(N \frac{m_*^4}{V_P}\right)^{2/3}\right)} \quad \Rightarrow \quad \frac{T_{\min}}{T_c} \lesssim 0.2, \quad (3.14)$$

where to obtain the first expression we assumed $T_{\min} \lesssim 0.48m_*$ and the second inequality follows from approximating the Lambert function $\mathcal{W}(x) \simeq 3/4 \log(x+1)$, assuming $N \sim \mathcal{O}(10)$ and using the eq. (3.4) for the scaling of V_P with $\lambda_{\text{eff}} \sim \mathcal{O}(1)$ and $\Delta V \sim F^2$. Higher values of λ_{eff} or a suppressed value of ΔV will lead to a reduction of the hierarchy between T_{\min} and T_c . The latter cases are less interesting from the point of view of the expected GW signal.

We are now ready to verify that there exists a nucleation temperature T_n where S_3/T satisfies the nucleation condition eq. (2.14). As discussed in eq. (2.30), the nucleation temperature is always within the interval (T_{\min}, T_c) . Scenarios where T_n is closer to T_{\min}

have a larger α (see eq. (2.15)) and a smaller β_H (see eq. (2.16)), favorable for generating an observable GW signal. Understanding the scaling of T_n with respect to T_{\min} and T_c thus provides valuable information about the strength of the FOPT.

Even approximating the nucleation condition in eq. (2.14) with a constant \mathcal{C} , solving the equation analytically with respect to T using S_3/T given by eq. (3.11) is not possible. We may, however, expand in $V_P/|V_T^0| \ll 1$ and solve for T_n order by order in this expansion. This is always a good approximation as long as T_n does not approach T_{\min} too closely. At first order, writing $T_n = T_n^0(1 + \delta T_n^1)$ we find

$$T_n \simeq T_n^0 \left(1 - \frac{7}{\mathcal{C}^{2/5}} \frac{V_P}{m_*^4} \left(\frac{T_n^0}{m_*} \right)^{3/5} \left(\frac{f_a m_*^3}{\Delta V} \right)^{6/5} \right), \quad (3.15)$$

where

$$T_n^0 = 0.48 m_* \frac{1}{\mathcal{W} \left(0.32 \left(\frac{N^5}{\mathcal{C}^2} \right)^{2/21} \left(\frac{f_a m_*^3}{\Delta V} \right)^{4/7} \right)}, \quad (3.16)$$

and we have again assumed $T_n^0 < 0.48 m_*$. Given that the argument of the Lambert function is much larger than one, T_n^0 depends only logarithmically on the parameters $N, \mathcal{C}, f_a, \Delta V$, and can be taken proportional to m_* for simplicity.

The leading scaling of T_n with respect to the parameters shaping the potential is captured by the leading corrections proportional to V_P in (3.15). Indeed, we observe that by increasing V_P (i.e. the height of the barrier), or by increasing f_a , the nucleation temperature decreases, approaching the region of parameter space where nucleation does not occur. The border between the nucleation and the non-nucleation areas is the portion of parameter space which is optimal for gravitational waves, since it is where β_H is minimal. This behavior is in good agreement with the numerical results of section 4, and one can verify that eq. (3.15) reproduces the behavior of the full numerical result when properly matched to the models in section 4 up to an overall scaling of the bounce action.

3.3 α , β_H and fine-tuning

Now we can use our prediction for T_n to compute the parameters characterizing the FOPT:

- Within our analytical approximation, the temperature corrections only affect the potential at the origin of field space and are exponentially suppressed for $T < m_*$. Therefore, we approximate α as

$$\alpha \simeq \frac{30}{g_*(T_n) \pi^2} \frac{\Delta V}{T_n^4}, \quad (3.17)$$

where the scaling of T_n can be obtained by using (3.15). Within this approximation, ΔV is temperature-independent and the largest values of α correspond to T_n closer to T_{\min} .

- The inverse time scale of the phase transition can be computed explicitly from (3.11), giving

$$\beta_H \simeq \mathcal{C} \left(\frac{1.1N}{\mathcal{C}^{2/5}} e^{-\frac{m_*}{T_n}} \left(\frac{T_n}{m_*} \right)^{11/10} \left(\frac{f_a m_*^3}{\Delta V} \right)^{6/5} - 1 \right). \quad (3.18)$$

One can easily verify that if $T_n = T_{\min}$, then $\beta_H \simeq 1$ within the small V_P expansion. Moreover, the exponential dependence on T_n makes β_H very sensitive to the underlying parameters.

We now use the approximate β_H formula in eq. (3.18) to estimate the β_H -tuning defined in eq. (2.18). We compute first the tuning with respect to V_P , which is encoded in eq. (3.18) through the dependence of T_n on V_P . At leading order in $V_P/m_*^4 \ll 1$ we obtain

$$\left| \frac{d \log \beta_H}{d \log V_P} \right| = \left| \left(1 - \frac{\beta_0}{\beta_H} \right) \right| \gtrsim \left| 4 \frac{\mathcal{C}}{\beta_H} \right| \quad (3.19)$$

where in the last step we used the fact that

$$\beta_0 \simeq \mathcal{C} \left(-1 + \frac{5 m_*}{2 T_n^0} \right) \gtrsim 4\mathcal{C} \quad (3.20)$$

since $T_n^0 < \frac{10}{21} m_*$ and $\beta_H \lesssim \mathcal{C}$ in the interesting region of parameter space. The tuning associated with the barrier height is the dominant one, given that the tuning with respect to vacuum distance f_a is suppressed by an extra factor of T_n^0/m_* . As in eq. (2.17), we see that the natural value of β_H is $\beta_H \simeq \mathcal{C}(T_n) \simeq 100$ for the scales of interest in this study. Smaller values of β_H can be obtained at the price of fine-tuning the barrier height at the percent level. This might imply an even larger tuning with respect to the fundamental parameters of a given model, as we will show in a concrete example in section 4.2.

3.4 A toy example: fine-tuning vs. single SUSY-breaking scale

We now present a simple toy model which captures most of the features of the pseudomodulus potential in the explicit SUSY-breaking hidden sectors we will encounter in section 4. We take the zero-temperature potential to be

$$V_0(x) = \kappa_D^2 \left(F - \epsilon_{\mathbb{R}} x^2 \right)^2 + \frac{\lambda^2}{32\pi^2} |F|^2 \log \left(\frac{\lambda^2 x^2 + m_*^2}{m_*^2} \right), \quad (3.21)$$

which reproduces the shape of the potential sketched in figure 3. The first term captures tree-level effects, while the second term captures one-loop quantum corrections. The x potential is flat at tree-level up to R -symmetry breaking operators parametrized by $\epsilon_{\mathbb{R}}$.⁶ SUSY-breaking corrections induced by heavy fields lift the x potential around the origin, giving a mass to the pseudomodulus, but ultimately become subdominant for $x \gg \sqrt{F}$ where SUSY is restored in the direction associated to the F -term. This large-field behavior is a unique characteristic of SUSY models.

As long as the explicit R -symmetry breaking is parametrically small, the position of the true vacuum and the zero temperature difference energy between the true vacuum and false vacuum are

$$\langle x \rangle_{\text{true}} = f_a = \sqrt{\frac{F}{\epsilon_{\mathbb{R}}}}, \quad \Delta V = (\kappa_D F)^2, \quad (3.22)$$

⁶As shown in section 4.2, the potential controlled by $\epsilon_{\mathbb{R}}$ can be obtained from a marginal operator breaking R -symmetry in the superpotential. Similarly, one could study explicit R -breaking operators of arbitrary dimension in the superpotential $\mathcal{W}_{\mathbb{R}} = \frac{\epsilon_{\mathbb{R}} X^n}{n \Lambda^{n-3}}$ which correspond to tree level potentials of the form $V(x) = \left(F - \frac{\epsilon_{\mathbb{R}} x^{n-1}}{\Lambda^{n-3}} \right)^2$. These types of operators would naturally be generated by UV dynamics as in ref. [90].

where we have introduced the parameter κ_D to allow the scale controlling the difference in vacuum energy to vary relative to the scale controlling the loop corrections along the pseudomodulus potential. We will exhibit a concrete realization of such a model in section 4.3. Requiring the potential to be flat as in eq. (3.3) requires $\epsilon_{\mathcal{R}} < 1/\sqrt{\kappa_D}$.

Following the triangular barrier prescription, we need to find the position of the barrier and the value of the potential at the barrier; for the toy model these take the form

$$x_P \simeq \frac{\lambda}{8\pi\kappa_D} f_a, \tag{3.23}$$

$$V_P \simeq \frac{\lambda^2 F^2}{32\pi^2} \left(2 \log \left(\frac{\lambda^2 f_a}{8\pi\kappa_D m_*} \right) - 1 \right). \tag{3.24}$$

From the last equation we see that the loop suppression of the zero-temperature barrier V_P , as assumed in Eq (3.4), is here an automatic consequence of the fact that the pseudomodulus direction is lifted by quantum corrections. For a single-scale model (i.e. $\kappa_D = 1$) the position of the peak x_P is fixed in terms of the one of the true vacuum f_a , while for a two-scale model, $\kappa_D \gg 1$ can enhance the hierarchy between x_P and f_a .

We are now ready to use the triangular barrier approximation in eq. (3.6) to compute the bounce action and the features of the FOPT between the origin and the true vacuum. For $\epsilon_{\mathcal{R}} < 1/\sqrt{\kappa_D}$, f_a is the largest scale in the problem and the approximation in eq. (3.11) is justified. If the general features of the bounce action characterize the FOPT in the low- T expansion discussed above, this simple toy model allows us to say something more precise about the scaling of the energy released during the FOPT. From eq. (3.17) we have

$$\alpha = \frac{30}{g_*(T_n)\pi^2} \left(\frac{\kappa_D F}{T_n^2} \right)^2 \sim 10^{-2} \kappa_D^2 \left(\frac{F}{m_*^2} \right)^2 \left(\frac{230}{g_*(T_n)} \right), \tag{3.25}$$

where we normalized the number of relativistic degrees of freedom at T_n to be close to the MSSM value and we substituted $T_n \sim T_n^0 \sim 0.5m_*$, which is the natural value of the nucleation temperature unless either V_P or f_a are tuned to suppress it (see eq. (3.15)). In a single-scale model where $\kappa_D = 1$, tuning $T_n \ll \sqrt{F}$ is the only way to enhance the strength of the FOPT. The same tuning will allow β_H to be small. Conversely, in a two-scale model of SUSY-breaking, having $\kappa_D \gg 1$ can compensate the suppression in eq. (3.25) without any tuning. We will show an explicit example of this class of hidden sectors in section 4.3. These are clearly the best candidates to be probed by future GW interferometers.

4 Explicit models

In this section we provide two working examples of the general idea described in the previous sections. Both models are straightforward deformations of the minimal O’Raifeartaigh model, which is the simplest theory of chiral superfields that breaks SUSY spontaneously [91]. The O’Raifeartaigh model involves three chiral superfields, namely the SUSY-breaking field X containing the pseudomodulus and two messenger fields $\Phi_{1,2}$. The dynamics are determined by three parameters: the SUSY-breaking scale \sqrt{F} , the SUSY-preserving mass m of the messengers, and the coupling λ between the three fields. To set the stage

for our analysis, we begin in section 4.1 by determining the phase diagram of the minimal O’Raifeartaigh model which can be described as a function of the dimensionless parameter

$$y_F \stackrel{\text{def}}{=} \frac{\lambda F}{m^2}. \tag{4.1}$$

The model exhibits a rich phase structure as a function of temperature and the underlying parameters; for $y_F \sim 1$ the origin of the pseudomodulus is the global minimum at all T and no interesting phase transitions occur, while for $y_F \ll 1$ a second minimum develops away from the origin that may become the global minimum at intermediate temperatures, leading to a variety of phase transitions. Unfortunately, as we will see, none of these phase transitions are sufficiently strongly first-order to generate an observable GW signal. However, this minimal O’Raifeartaigh model serves as the foundation for SUSY-breaking hidden sectors that *do* generate observable GW signals.

In section 4.2, we present the simplest SUSY-breaking hidden sector featuring a strong FOPT like the ones describe in section 3. This hidden sector involves a marginal deformation in the superpotential of the minimal O’Raifeartaigh model, breaking the R -symmetry explicitly and obtaining a pseudomodulus potential very similar to the one described in the toy model in section 3.4. We show that in such a simple single-scale model, α will be generically suppressed as predicted in eq. (3.25), and discuss quantitatively the fine-tuning of β_H defined in eq. (2.18). Phenomenologically, this model is unsatisfactory since the global minimum restores SUSY, although this may be remedied by the introduction of external SUSY-breaking effects.

In section 4.3, we show how both the shortcomings of the simple model of section 4.2 are resolved in hidden sectors with two SUSY-breaking scales, in keeping with our expectations from section 3.4. We make this concrete by gauging a $U(1)$ flavor symmetry of the messengers in the minimal O’Raifeartaigh model, which admits an additional source of SUSY breaking via the Fayet-Iliopoulos term. This additional “ D -term” supersymmetry breaking provides a second SUSY-breaking scale, which both ensures that supersymmetry is broken everywhere on the pseudomoduli space and increases α , leading to observable GW signals.

4.1 Warm up: the O’Raifeartaigh model at finite temperature

In the minimal O’Raifeartaigh model, the pseudo-modulus is stabilized at the origin by quantum corrections. Since the R -symmetry is unbroken in the global minimum at $T = 0$, one would expect that including finite temperature corrections will not induce any phase transitions. Instead, the dynamics of the O’Raifeartaigh model at finite temperature presents rich features that we discuss here in detail (see refs. [92, 93] for earlier works on related issues).

Having in mind applications to gauge mediated SUSY breaking, we consider the vector-like version of the minimal O’Raifeartaigh model, which is described by the superpotential

$$W = -FX + \lambda X \Phi_1 \tilde{\Phi}_2 + m(\Phi_1 \tilde{\Phi}_1 + \Phi_2 \tilde{\Phi}_2), \tag{4.2}$$

encoding the interactions of the SUSY-breaking chiral superfield X and two vector-like sets of messenger superfields $\Phi_i, \tilde{\Phi}_i$ ($i = 1, 2$). The first term is a tadpole ensuring that supersymmetry is broken at the scale \sqrt{F} , while the second term encodes interactions among the

fields with strength λ . We take the masses of the two pairs of messengers to be equal for simplicity. The superpotential above enjoys an unbroken R -symmetry under which X carries $R[X] = +2$, as well as a $U(1)_D$ flavor symmetry under which the messengers Φ and $\tilde{\Phi}$ have opposite charges (see figure 4 right for a summary table with the full charge assignment).

The potential for the scalar components of the chiral superfields is

$$V = |F - \lambda\phi_1\tilde{\phi}_2|^2 + |\lambda X\tilde{\phi}_2 + m\tilde{\phi}_1|^2 + |\lambda X\phi_1 + m\phi_2|^2 + |m\phi_1|^2 + |m\tilde{\phi}_2|^2, \quad (4.3)$$

where $X = \frac{x}{\sqrt{2}}$ denotes the scalar component of the pseudomodulus in the notation of eq. (3.1). For $\lambda F \leq m^2$, the tree level vacuum of the theory is at $\phi_i = \tilde{\phi}_i = 0$ with x undetermined, and SUSY is broken at a scale \sqrt{F} . Radiative corrections from loops of the messenger fields ϕ and $\tilde{\phi}$ generate a potential for x that stabilizes it at the origin, and thus the global vacuum at zero temperature lies at $\phi_i = \tilde{\phi}_i = 0$ and $\langle x \rangle = 0$. Note that the one-loop corrections have the shape described in section 3, being polynomial close to the origin of the pseudomodulus potential and logarithmic for large field values. Expanding for $y_F \equiv \frac{\lambda F}{m^2} \sim 1$ we obtain

$$V_{x \rightarrow 0}^{1\text{-loop}} \simeq \frac{\lambda^3 F}{16\pi^2} (\log 4 - 1) x^2 - \frac{\lambda^4}{384\pi^2} (12 \log 2 - 7) x^4 + O(x^6), \quad (4.4)$$

$$V_{x \rightarrow \infty}^{1\text{-loop}} \simeq \frac{\lambda^2 F^2}{16\pi^2} \log\left(\frac{x^2}{m^2}\right), \quad (4.5)$$

where we have fixed the renormalization scale to the messenger mass m . The thermal corrections to the x potential can be added with standard formulas that we review in the appendix A.

The shape of the thermal corrections is set by the x dependence of the mass eigenvalues for the scalar and fermionic components of the messengers. From (4.2) we can distinguish two classes of mass-squared eigenvalues: i) the ones growing quadratically with x , and ii) the ones decreasing as $1/x^2$ and asymptotically going to zero in the large- x region. Specifically, the fermionic eigenvalues scale as

$$m_{\pm}^2 = m^2 + \frac{\lambda^2 x^2}{4} \left(1 \pm \sqrt{1 + \frac{8m^2}{\lambda^2 x^2}} \right) = \begin{cases} m & \text{for } x \rightarrow 0 \\ \sim x^{\pm 2} & \text{for } x \rightarrow \infty \end{cases}, \quad (4.6)$$

and the bosonic eigenvalues are split in pairs around the fermionic ones, e.g. at the origin the bosonic eigenvalues are $\{m^2, m^2, m^2 + \lambda F, m^2 - \lambda F\}$. The behavior of the full spectrum as a function of x is shown in figure 4 (right). We also observe that at large x , the spectrum asymptotes to a supersymmetric one.

For low temperatures (i.e. $T < m$), the induced thermal corrections are a decreasing function of x , since they are mainly controlled by the lightest eigenstates. These corrections are mildly Boltzmann suppressed at large x and modify the pseudo-modulus potential as soon as $T^4 \sim \frac{\lambda^2 F^2}{16\pi^2}$. For larger temperatures, the contribution from the other mass eigenstates and in particular from the ones growing with x become relevant, and the thermal potential is a growing function of x . Hence at temperatures $T \sim m$ we expect the global minimum to be at the origin of the field space. However, for intermediate temperatures

Figure 4. *Left:* behavior of the hidden sector spectrum in the simple O’Raifeartaigh model as a function of the pseudomodulus direction x . The *dashed dark red/blue* line indicates the fermionic eigenvalues growing/going to zero like $x^{\pm 2}$ (see eq. (4.6)). The two *pink* and *light blue* solid lines indicate the scalar mass states splitted in pairs around the fermionic ones. The *dashed light magenta* line indicates the states that remain independent on x . The *dashed peach* line shows T_\star for this particular benchmark, where the new vacuum induced by thermal corrections becomes degenerate with the origin (see eq. (4.7)). *Right:* unbroken symmetries of the chiral superfields in the O’Raifeartaigh model superpotential in eq. (4.2). The model enjoys a $U(1)_R$ symmetry and an extra $U(1)_D$ flavor symmetry. The first will be explicitly broken in the model in section 4.2 while the second one will be gauged in the model in section 4.3.

the thermal corrections can make the origin of the field space unstable, leading to a very rich evolution of the potential with temperature.

The thermal corrections compete with the loop corrections in the large x region (see eq. (4.5)), eventually leading to a minimum of the potential at

$$x_\star \simeq \frac{2\sqrt{2}\pi T}{\lambda y_F}, \quad T_\star \sim 0.23\sqrt{y_F}m, \quad (4.7)$$

where x_\star is obtained using the high- T expansion for the thermal potential up to T^2 , assuming 2 bosons and 2 fermions with masses-squared $\simeq \frac{2m^4}{\lambda^2 x^2}$, and T_\star is an estimate of the temperature where the new minimum can be the global one. The latter is estimated by requiring the temperature corrections at x_\star to be comparable to the height of the one loop potential. If T_\star is close to m , then the neglected contributions from the states whose masses grow with x^2 lifts again the minimum at x_\star , which will then never be the global minimum at any temperature. In conclusion, we expect that depending on the hierarchy between λF and m^2 , the minimum at x_\star could become the global minimum in a certain temperature range around T_\star . This complicated phase diagram is well summarized in figure 5, where we have fixed the ratio $\frac{F}{m^2}$ to a representative value and explore the dynamics of the model as a function of the temperature and coupling λ .

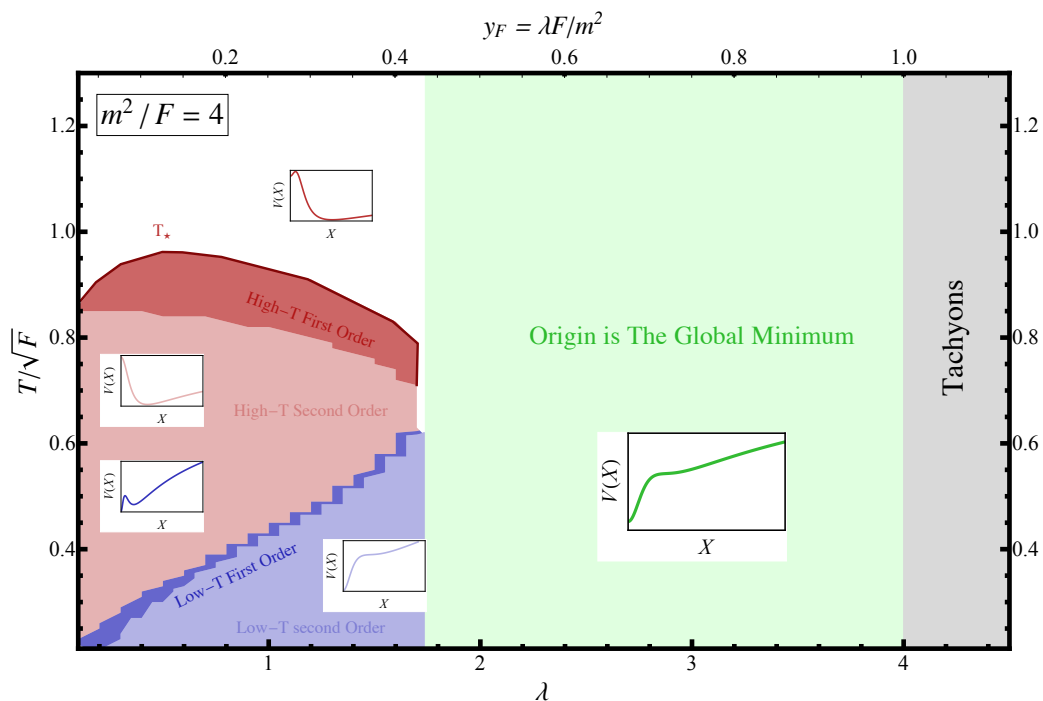

Figure 5. Phase diagram of the O’Raifeartaigh model at fixed $F/m^2 = 4$. For *large* λ the quantum corrections dominate and the origin is the global minimum at all temperatures. For *small* λ , at $T = T_*$ a new vacuum develops as a consequence of the interplay between the thermal and the loop corrections as shown in eq. (4.7). In *dark red* we show the range of temperatures where a barrier is present between the origin and the true minimum, in *light red* we show the range of temperatures where the barrier disappears. At lower temperatures, the origin again becomes the global minimum, and the second minimum decays back into the origin. In *blue* we show the range of temperatures where a barrier separates the two minima and in *light blue* the region when the barrier disappears.

For large λ , corresponding to $y_F \sim 1$, the minimum at X_* is never the global minimum of the scalar potential (green region in the plot). For small λ , i.e. $y_F \ll 1$ two phase transitions occur while lowering the temperature. Specifically, at very high temperature the global minimum is at the origin, as explained above. At intermediate temperatures the global minimum is at X_* , and finally at zero temperature the global vacuum is again at the origin. The corresponding two phase transitions can be first or second order. We have explored the parameter space of the model for different values of y_F and λ , and found that these phase transitions are never strongly first order (i.e. small β_H and large α) in the regime of perturbative λ .

Although the minimal O’Raifeartaigh model is itself not a good candidate for a strong FOPT, it nonetheless provides the foundation for simple variations that are. We explore these variations in the following subsections, restricting our attention to the region of parameter space in which the minimal O’Raifeartaigh model exhibits a simple thermal history corresponding to the green region in figure 5. Deformations of the minimal O’Raifeartaigh model will endow this region with phase transitions as a function of temperature, while avoiding the complications of new minima arising from the interplay of thermal and loop corrections shown in the red and blue regions.

4.2 O’Raifeartaigh model with explicit R -symmetry breaking

Now we turn to a simple, concrete realization of a SUSY-breaking hidden sector whose pseudomodulus potential exhibits the properties explored in section 3. This model simply amounts to deforming the minimal O’Raifeartaigh model studied in the previous section with the following marginal, R -symmetry-breaking term in the superpotential:

$$W_{\mathcal{R}}(X) = \frac{1}{3}\epsilon X^3. \quad (4.8)$$

The complete tree-level scalar potential of the model is

$$V = |-F + \epsilon X^2 + \lambda\phi_1\tilde{\phi}_2|^2 + |\lambda X\tilde{\phi}_2 + m\tilde{\phi}_1|^2 + |\lambda X\phi_1 + m\phi_2|^2 + |m\phi_1|^2 + |m\tilde{\phi}_2|^2 \quad (4.9)$$

and assuming $y_F \leq 1$, the global minimum sits at $\langle x \rangle_{\text{true}} = \sqrt{\frac{2F}{\epsilon}}$ and $\phi_i = \tilde{\phi}_i = 0$. In contrast to the minimal O’Raifeartaigh model, the R -symmetry-breaking deformation destabilizes the origin at tree level and restores supersymmetry in the true vacuum.

The radiative corrections are identical to the ones in the O’Raifeartaigh at zeroth order in ϵ , and they tend to stabilize the pseudo-modulus at $x = 0$, competing with the tree-level contributions induced by the ϵ deformation. Close to the origin, the effective potential for the pseudomodulus obtained by integrating out the ϕ_i and $\tilde{\phi}_i$ fields reads (up to quartic order)

$$V_0(x) \underset{x \rightarrow 0}{\simeq} F^2 + \frac{m_{\text{eff}}^2}{2}x^2 - \frac{\lambda_{\text{eff}}}{4}x^4, \quad \begin{cases} m_{\text{eff}}^2 = \left(\frac{\lambda^3}{8\pi^2}(\log 4 - 1) - 2\epsilon\right)F \\ \lambda_{\text{eff}} = \frac{\lambda^4}{96\pi^2}(12\log 2 - 7) - \epsilon^2 \end{cases}, \quad (4.10)$$

where again we have approximated the loop corrections in the leading order in $y_F = \frac{\lambda F}{m^2} \sim 1$. For $\epsilon < \frac{\lambda^3}{16\pi^2}(\log 4 - 1)$, the radiative corrections are sufficient to create a metastable vacuum at the origin of x . In this regime, the ϵ contribution to the quartic is always negligible. Along the pseudomodulus direction, there is now a true vacuum created by the R -symmetry-breaking deformation and a false vacuum created by radiative corrections. The height and location of the barrier between these two vacua may be approximated as

$$V_P - V_+ \simeq \frac{m_{\text{eff}}^4}{4\lambda_{\text{eff}}} \sim \frac{24\pi^2}{\lambda^4} \left(\frac{\lambda^3}{8\pi^2}(\log 4 - 1) - 2\epsilon\right)^2 F^2 \quad x_P \simeq \frac{m_{\text{eff}}}{\sqrt{\lambda_{\text{eff}}}}, \quad (4.11)$$

This approximation is valid if $x_P \lesssim \frac{m}{\lambda}$, that is if there is a cancellation between the two terms in m_{eff}^2 such that $m_{\text{eff}}^2 \lesssim \frac{\lambda^3}{96\pi^2}F$. The global minimum far away from the origin is not modified by the quantum corrections since SUSY is effectively restored there (we will come back to this point in section 4.2.2) and stays at $\langle x \rangle_{\text{true}} = \sqrt{\frac{2F}{\epsilon}}$, so that $\Delta V = F^2$.

In summary, this hidden sector provides a concrete realization of the toy model discussed in section 3.4. A direct consequence of having a single SUSY-breaking scale \sqrt{F} is that the potential difference ΔV and the quantum corrections determining the barrier are both controlled by the same scale. This corresponds to $\kappa_D = 1$ in the toy model of section 3.4, and typically leads to suppressed α as we will show below. The formulae above allow straightforward matching of the model parameters onto the variables entering in the triangular barrier bounce action of section 3.2. In the following, we will compare our analytical expectations with the full numerical analysis of the FOPT from the origin to the $\langle x \rangle_{\text{true}}$ vacuum.

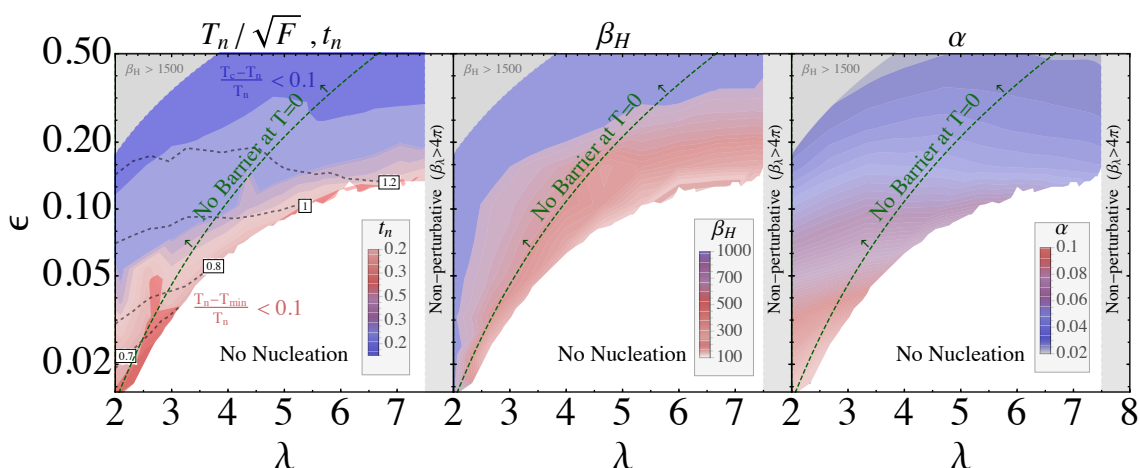

Figure 6. From the left to the right, we show the behavior of T_n/\sqrt{F} , β_H and α in the O’Raifeartaigh model with explicit R -symmetry breaking described in eq. (4.8). We fix $y_F = 3/4$ and $F = 30$ PeV so that the entire parameter space of the model can be shown in the (λ, ϵ) plane. The *black dashed contours* in the left plot show T_n/\sqrt{F} . The *red-to-blue* gradients show contours of t_n as defined in eq. (4.12) (left), of β_H as defined in eq. (2.16) (center) and of α as defined in eq. (2.15) (right). The GW signal weakens going from red to blue. Above the *green dashed* line, the barrier separating the false and true vacua disappears at zero temperature. The *grey* regions are not considered in our numerical scan because β_H is too large (top left) or λ is non-perturbative. In the *white* region the nucleation condition in eq. (2.13) cannot be satisfied.

4.2.1 First order phase transition dynamics

We now study the model at finite temperature with an eye towards the dynamics of the phase transition associated to R -symmetry breaking. The thermal corrections to the X potential are equivalent to the ones that we studied in the simplest O’Raifeartaigh model, up to small corrections proportional to ϵ . The main difference is that the thermal effects are added on top of a zero-temperature potential described in the previous section, where the global minimum is far away from the origin. If we restrict to the parameter space where $\lambda F/m^2 \sim 1$ (the green region of figure 5), the role of the thermal corrections is to stabilize the origin at high temperature. Lowering the temperature, the thermal history is very similar to the one described in section 3: the negative thermal contributions at the origin decrease in absolute value until we reach T_c , where the minimum at $x = 0$ is degenerate with the minimum at x_{true} . An analytic estimate of this temperature can be obtained following eq. (3.12). By further lowering the temperature, the thermal corrections become more and more negligible and one recovers the zero-temperature potential with a local minimum at the origin separated from the true vacuum by a loop-induced barrier.

Bounce action and nucleation temperature. The next step in determining the phase transition dynamics is to compute the bounce action and the nucleation temperature. In the left panel of figure 6, we show the numerical result for the nucleation temperature T_n as a function of the two dimensionless couplings of the model, having fixed $y_F \equiv \lambda F/m^2 = 3/4$

and the scale of SUSY breaking to $\sqrt{F} = 30$ PeV for concreteness. Numerically we see that $T_n \sim \sqrt{F}$ as assumed in the general discussion around eq. 2.31. As can be seen from the explicit formula in eq. 3.15, this feature is a consequence of the fact that F cannot be arbitrarily decoupled from m^2 if we require $y_F \sim 1$ and perturbativity of λ .

Keeping ϵ fixed, we see that the nucleation temperature T_n decreases when λ increases, up until reaching the no-nucleation zone. Indeed, increasing λ makes the barrier between the two vacua higher, and the bounce action larger, decreasing the likelihood that the phase transition completes. When the bounce action increases, the nucleation temperature lowers, approaching T_{\min} at the border of the no-nucleation region. Conversely, decreasing λ at fixed ϵ shifts the nucleation temperature towards T_c . In figure 6 we plot the quantity

$$t_n \stackrel{\text{def}}{=} \min\left(\frac{T_c - T_n}{T_c}, \frac{T_n - T_{\min}}{T_{\min}}\right), \quad (4.12)$$

which indicates whether T_n is closer to T_c or T_{\min} . As we will see this quantity is strongly correlated with the strength of the signal.

The main effect of ϵ on the pseudomodulus potential is to set the distance in field space between the origin and the true vacuum. The barrier is also ϵ -dependent, but away from the region where the effective mass in eq. (4.10) changes sign, the effect of varying ϵ is negligible. Decreasing ϵ makes $x_{\text{true}} = f_a$ larger. From eq. (3.11) we see that the bounce action grows, making it more difficult for the phase transition to occur. This explains why lowering ϵ at fixed λ causes the nucleation temperature to decrease until the no-nucleation region is reached.

The interesting area of the parameter space is the sliver between the no-nucleation region and the region where there is not a barrier at $T = 0$. Within this sliver, $\frac{\lambda^3}{16\pi^2} \sim \epsilon$ and the effective mass of the pseudomodulus in eq. (4.10) is small and positive (in units of $\sqrt{F} \sim \Delta V^{1/4}$). The whole region shrinks for small ϵ because the true vacuum is pushed to large field values, and there is no nucleation unless the effective mass at the origin is tuned to be small.

The scaling of T_n/\sqrt{F} with the Lagrangian parameters can be captured by the analytic approximations presented in section 3. We match the generic parameterization of section 3 using the expressions in (4.10) and (4.11), giving

$$T_n \sim \frac{40\sqrt{\lambda F}}{63} \frac{1}{\log\left(1 + 0.76 \frac{\lambda^{6/7}}{\mathcal{C}^{4/21} \epsilon^{2/7}}\right)} \left(1 - 0.015 \left(\frac{\lambda^9}{\mathcal{C}^2 \epsilon^3}\right)^{1/5}\right), \quad (4.13)$$

where we have approximated the radiative corrections for $y_F \sim 1$. This expression qualitatively reproduces the left panel of figure 6, up to an overall normalization of the bounce action (corresponding to a shift in \mathcal{C}).

For large ϵ , the rightmost term in parentheses in (4.13) is always $\mathcal{O}(1)$, and hence the variation of T_n is largely controlled by the prefactor. The $\sim \sqrt{\lambda}$ scaling of the numerator is balanced by the $\log \lambda$ scaling in the denominator, and the resulting prefactor of T_n is essentially flat in λ and only decreases with decreasing ϵ . In the small ϵ region, the rightmost term in parentheses in (4.13) becomes smaller than 1 and controls the shapes of the T_n contours, in agreement with the left panel of figure 6.

α , β_H and fine-tuning. The microscopic properties of the FOPT dynamics are encoded in the two parameters α and β_H , which correspond to the energy release and the duration of the phase transition. In the central and rightmost panels of figure 6, we show the behavior of β_H and α in the (λ, ϵ) plane. Here the scaling of α is essentially dictated by the scaling of T_n/\sqrt{F} , since $\alpha \sim \frac{30}{g_*\pi^2} \frac{\Delta V}{T_n^4}$ and $\Delta V \sim F^2$. We see that in the parameter space explored here, we cannot reach large values of α except in the thin sliver towards small ϵ and λ where $T_n \sim T_{\min}$ and T_{\min} is minimized with respect to \sqrt{F} . This unfortunate feature is a generic prediction of a single-scale SUSY-breaking hidden sector, as discussed in section 3.4.

As shown in figure 6, β_H is small in the regions of the parameter space at the border of the no-nucleation zone where $T_n \sim T_{\min}$. Getting closer and closer to this boundary, one can achieve $\beta_H \lesssim 100$ at the price of a large tuning of the model parameters as discussed in section 2.2. The fine-tuning is dominated by the tuning of the barrier V_P between the two minima. Substituting the dependence of V_P on the Lagrangian parameters, we can estimate the tuning of β_H with respect to λ as

$$\frac{\partial \log \beta_H}{\partial \log \lambda} \gtrsim 8 \left(\frac{\mathcal{C}(T_n)}{\beta_H} \right). \tag{4.14}$$

The same fine-tuning can be computed numerically using the prescription of eq. (3.19). We show the results in figure 7, where we see that $\beta_H \lesssim 100$ corresponds to $\Delta_{\beta_H} \sim 10^3$, which is larger than the estimate derived above. The numerical results also confirm our expectation that the tuning associated with the λ parameter (setting the height of the barrier) dominates relative to the tuning associated with the ϵ parameter (setting the location of the true vacuum). Comparing the left and right panels in figure 7, it is apparent that the tuning grows in the region of small ϵ , where α is larger.

4.2.2 Phenomenological challenges

As discussed in the previous section, the model presented here is not optimal for generating a sizable SGWB signal. Indeed, by comparing the resulting values of α and β_H in figure 6 to the values displayed in figure 2, it is clear that the typical value of α is too small to lead to a detectable signal. Of course, this issue can be resolved by going in a tuned region of the parameter space where a very small ϵ and an appropriately fine-tuned λ give $T \sim T_{\min}$ and a suppressed T_{\min} compared to \sqrt{F} . However, it is fair to say that, in general, a perturbative single-scale SUSY-breaking hidden sector cannot lead to strong SGWB signals. For this reason, we do not display the SGWB for this model, although it may easily be inferred from the α, β_H, T_n plots in figure 6.

As shown in the simple toy model of section 3.4, the suppression of α is a consequence of the fact that in a single-scale SUSY-breaking hidden sector one cannot significantly separate ΔV from T_n^4 . Notice that this conclusion hinges on requiring $y_F \sim 1$, which is necessary to avoid the region shown in figure 5 where thermal corrections at high temperatures induce new minima. A more careful study of the dynamics of single scale models for $y_F \ll 1$ is left for future work.

In addition to the α suppression, the true vacuum in this model restores SUSY, so that the phase transition is not genuinely a ‘‘SUSY-breaking phase transition’’; this sector,

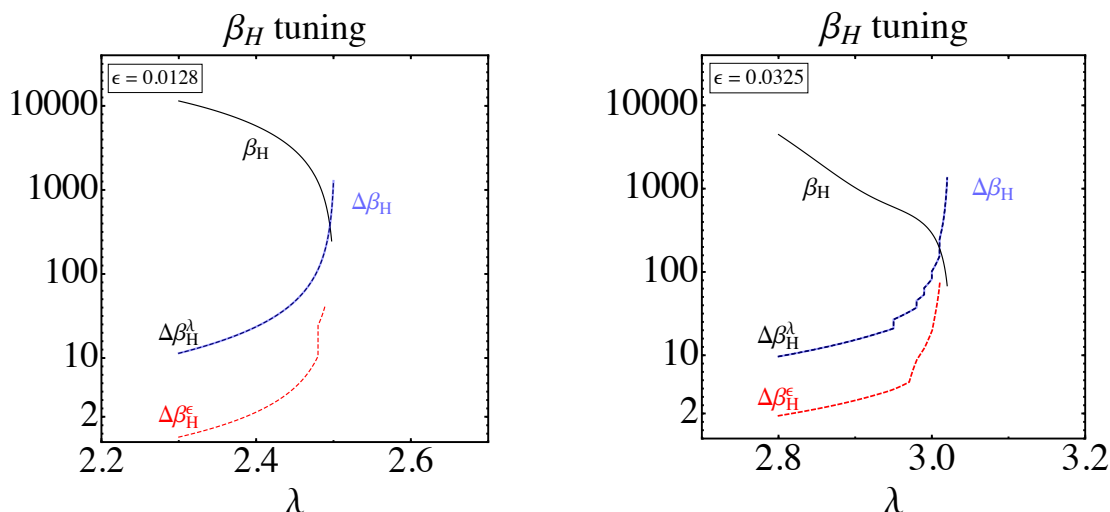

Figure 7. Behavior of β_H (black solid curve) and the associated fine-tunings defined in eq. (2.18) as a function of λ for $m^2/F = 4$ and $\sqrt{F} = 30$ PeV. The left and right plots correspond to two different values of ϵ . The black dashed curve shows the fine tuning w.r.t. λ , which dominates over the fine tuning w.r.t. ϵ shown as a red dashed curve. The λ fine-tuning corresponds to the total fine-tuning $\Delta\beta_H$ shown as a light blue solid line.

as presented, cannot be responsible for the SUSY breaking transmitted to the MSSM. However, this is not a fatal obstruction, as the vacuum energy in the true vacuum far from the origin can be easily lifted by coupling to another source of SUSY breaking, very much in the spirit of [94]. If we require the new source of SUSY-breaking to not significantly affect the dynamics of the phase transition, the parametrics of the model will not significantly deviate from those presented here and the resulting α will be still suppressed. Interestingly, our analysis seems to point towards SUSY-breaking hidden sectors with multiple dynamical field directions and scales. In the next section, we will exhibit the simplest model of this type, leaving a more thorough exploration of the different possibilities for future study.

4.3 O’Raifeartaigh model with gauge interactions

In the previous subsection we analyzed a simple model displaying a first order phase transition associated with the breaking of the R -symmetry. However, there were two aspects that were not completely satisfactory: i) SUSY breaking in the global minimum had to be added as a further deformation, and ii) the phase transition was generically not strong enough to generate a sizable signal. Both issues were related to the fact that there was only one SUSY breaking scale in the problem. In this subsection we resolve these issues in a hidden sector where the global minimum breaks both SUSY and R -symmetry spontaneously and the presence of two SUSY breaking scales leads to a strong FOPT from the origin to the true minimum.

It is well-known that adding gauge interactions to SUSY breaking models with chiral superfields modifies the potential and typically leads to a new SUSY- and R -symmetry-breaking vacuum at large field values (see e.g. [15]). As a prototype of this class of models

we consider the simplest realization, which consists of the vector-like O’Raifeartaigh model of the previous sections where the anomaly-free $U(1)_D$ flavor symmetry defined in the right panel of figure 4 is gauged. The model we consider has been studied at zero temperature in [95]. The qualitative features that we find here are generic to models where SUSY is broken through the interplay of F - and D -term effects.

The field content and superpotential are the same as those introduced in (4.2). The gauging of the $U(1)_D$ symmetry contributes new terms in the scalar potential from the D -term contribution. The F - and D -term contributions to the potential together give

$$V_F + V_D = |F - \lambda\phi_1\tilde{\phi}_2|^2 + |\lambda X\tilde{\phi}_2 + m\tilde{\phi}_1|^2 + |\lambda X\phi_1 + m\phi_2|^2 + |m\phi_1|^2 + |m\tilde{\phi}_2|^2 + \frac{g^2}{2} \left(\frac{D}{g} + |\phi_1|^2 - |\tilde{\phi}_1|^2 + |\phi_2|^2 - |\tilde{\phi}_2|^2 \right)^2, \quad (4.15)$$

where g is the gauge coupling of the $U(1)_D$ symmetry and we have also included a UV Fayet-Iliopoulos (FI) term D/g . This FI term contributes a second source of SUSY breaking that will strengthen the GW signal. Note that the model contains, in addition to the O’Raifeartaigh degrees of freedom, a gauge boson and gaugino associated with the $U(1)_D$ vector multiplet. We focus on the regime where $y_F \lesssim 1$ and we do not discuss the origin of the FI term here.⁷

The scalar potential at zero temperature. As a first step, we analyze the zero-temperature vacuum structure and map it onto the parameterization of section 3. Neglecting the gauge dynamics, the tree-level potential has a minimum at $\phi_i = \tilde{\phi}_i = 0$ where SUSY is broken everywhere along the F -flat pseudomoduli space parameterized by X . Including the gauge interactions, the minimization of the D -term part of potential favors configurations where the $\tilde{\phi}_i$ fields acquire a VEV to compensate for the FI term D/g . This results in a tension between the minimization of the F -term and D -term contributions to the potential. While the F -term can never be set to zero, one can find a runaway direction in field space which leads, asymptotically, to the vanishing of the D -term.

First, we can solve for the F -terms of Φ_1 and $\tilde{\Phi}_2$ by taking

$$\tilde{\phi}_1 = -\frac{\lambda}{m} X \tilde{\phi}_2, \quad \phi_2 = -\frac{\lambda}{m} X \phi_1. \quad (4.16)$$

On this solution the scalar potential simplifies to

$$V = |F^2 - \lambda\phi_1\tilde{\phi}_2|^2 + |m\phi_1|^2 + |m\tilde{\phi}_2|^2 \quad (4.17)$$

$$+ \frac{g^2}{2} \left[|\phi_1|^2 \left(\frac{\lambda^2 |X|^2}{m^2} + 1 \right) - |\tilde{\phi}_2|^2 \left(\frac{\lambda^2 |X|^2}{m^2} + 1 \right) + \frac{D}{g} \right]^2. \quad (4.18)$$

Note that $\phi_1, \tilde{\phi}_2$ have vanishing R -charge, so the only direction where the R -symmetry is spontaneously broken is along x . In order to visualize the shape of the scalar potential

⁷The inclusion of a fundamental FI term is not strictly required to obtain a strong FOPT. A very similar potential for the pseudomodule can be obtained by considering two different masses for the messengers and working in the regime where $\lambda F > m_1 m_2$. Models with multiple F -terms would also lead to similar conclusions.

and the approach to the runaway, we show in figure 8 the tree level scalar potential as a function of x , as well as the values of ϕ_1 and $\tilde{\phi}_2$ as a function of x .

The scalar potential is flat around the origin and then turns to the runaway direction along which the D -term diminishes. The turning point along x is where the fields ϕ_1 and $\tilde{\phi}_2$ acquire a non-vanishing VEV. The VEV of ϕ_1 is different from zero since the potential energy is most efficiently minimized if ϕ_1 partially cancels the first term in (4.18) as well as minimizing the D -term. The VEV of ϕ_1 is suppressed by a factor $\sim \frac{gF}{\lambda D}$ with respect to the VEV of $\tilde{\phi}_2$. An analytic estimate of the scalar potential can then be captured by working at zeroth order in the VEV of ϕ_1 . In this approximation, and focusing on the parameter region where $gD/m^2 < 1$, the effective mass-squared for the $\tilde{\phi}_2$ field is X -dependent,

$$m_{\tilde{\phi}_2}^2 = m^2 - gD - \frac{\lambda^2 gD}{2m^2} x^2 \quad \Rightarrow \quad x_{\text{trans}}^2 \simeq \frac{2m^2(m^2 - gD)}{\lambda^2 gD} \quad (4.19)$$

and turns negative at the transition point x_{trans} where the field $\tilde{\phi}_2$ develops a VEV.

The potential for x is flat for $x \leq x_{\text{trans}}$, while for $x \geq x_{\text{trans}}$ it can be obtained by integrating out $\tilde{\phi}_2$,

$$V_{\text{tree}}(x) \simeq \begin{cases} F^2 + \frac{1}{2}D^2 = V_+ & x < x_{\text{trans}} \\ F^2 + \frac{1}{2}D^2 - \frac{\lambda^4 D^2 (x^2 - x_{\text{trans}}^2)^2}{2(2m^2 + \lambda^2 x^2)^2} & x > x_{\text{trans}} \end{cases} . \quad (4.20)$$

Since we work in the small- g regime, radiative corrections from the gauge sector may be neglected, such that the 1-loop corrections are the same as the ones discussed in the previous sections (see eq.s (4.4) and (4.5)). They have two effects, namely i) they create a local minimum at the origin, and ii) they generate a global minimum at large x values along the D -flat direction.

The barrier between the two vacua is approximately at $x \simeq x_{\text{trans}}$ where we can estimate the one-loop potential simply by the large field behaviour in (4.5), giving

$$V_P - V_+ \simeq \frac{\lambda^2 F^2}{16\pi^2} \log \left(\frac{x_{\text{trans}}^2}{m^2} \right), \quad x_P \simeq x_{\text{trans}} . \quad (4.21)$$

Combining the approximate tree level potential in (4.20) with the loop corrections in (4.5), we find that the true vacuum at large field values lies at

$$\langle x \rangle_{\text{true}} = f_a \simeq \frac{4\sqrt{2}\pi}{\lambda y_F} \sqrt{\frac{D}{g}}, \quad \Delta V \simeq \frac{1}{2}D^2, \quad (4.22)$$

where the difference in potential energy between the two minima is dominated by the D -term contribution. This completes the matching of the potential of this model to the general discussion of section 3. Note that here the SUSY-breaking F -term controls the height of the barrier in eq. (4.21), while the SUSY-breaking D -term sets the potential energy difference as in eq. (4.22). This implies that the phase transition can have sizable values of α , as we will see in the numerical analysis.

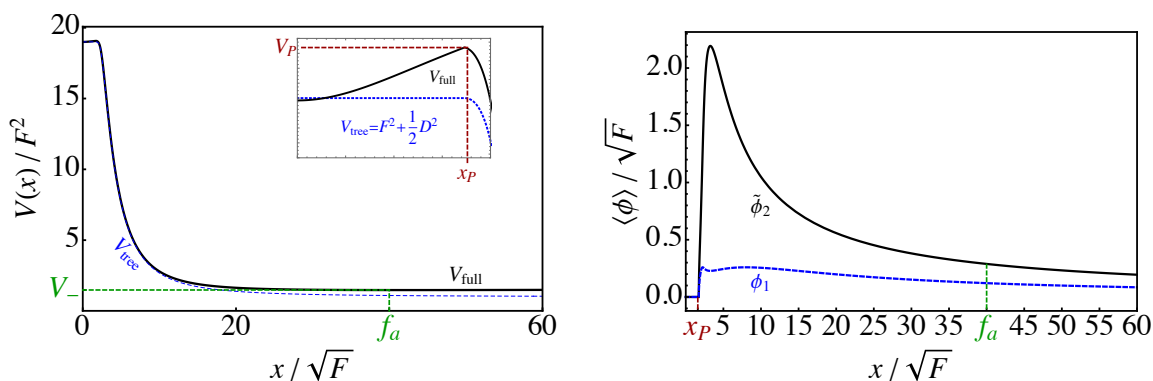

Figure 8. *Left:* tree level and one-loop scalar potential as a function of the pseudomodulus direction x minimizing the directions ϕ_1 and $\tilde{\phi}_2$. The *dashed blue* line shows the tree level potential which is flat around the origin and develops a runaway at $x_P \simeq x_{\text{trans}}$ (see Eq. (4.19)). Quantum corrections generate a local minimum at the origin as shown by the *black solid* line in the small quadrant and a global minimum far away in field space indicated with a *green dashed* line. The difference in energy density is $\Delta V \simeq \frac{1}{2}D^2$. *Right:* the VEVs of the fields ϕ_1 and $\tilde{\phi}_2$ while moving along the x -direction. Interestingly, both VEVs increase only at the barrier and they are otherwise quite small compared to \sqrt{F} . For reference, the benchmark used in both plots has $(F = 1, m = 2, D = 6, \lambda = 2.9, g = 1)$.

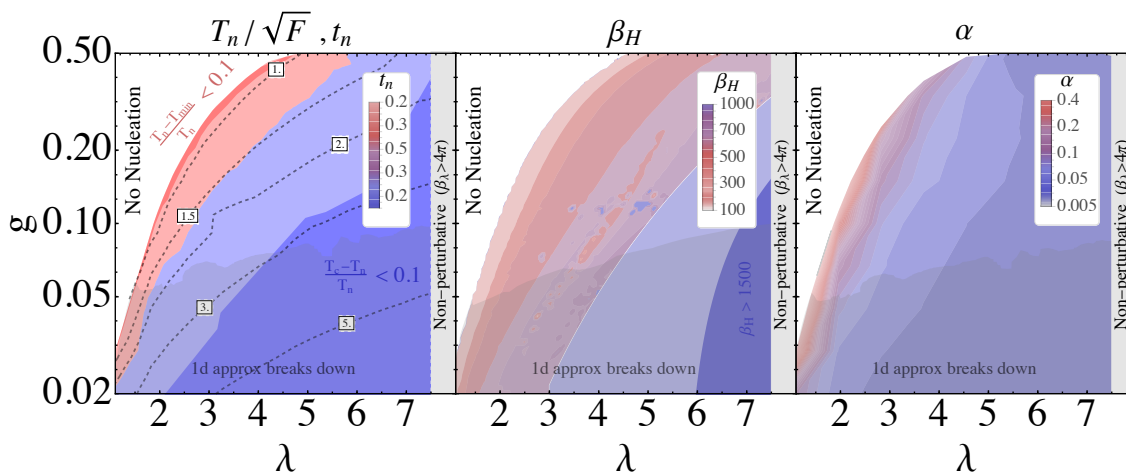

Figure 9. From the left to the right we show the behavior of T_n/\sqrt{F} , β_H and α in the O’Raifeartaigh model with gauge interactions described in eq. (4.18). We fix $F = 30$ PeV, $y_F = 3/4$ and $y_D = 1/5$ so that the entire parameter space of the model can be shown in the (λ, g) plane. The *black dashed contours* in the left plot show T_n/\sqrt{F} . The *red-to-blue* gradients show contours of t_n as defined in eq. (4.12) (left), of β_H as defined in eq. (2.16) (center) and of α as defined in eq. (2.15) (right). The GW signal weakens going from red to blue. In the *gray shaded* region at the bottom $R_{1d/3d} > 0.5$ and as described in eq. (4.23) our *1d* approximation is expected to break down. The *gray* region on the left is excluded by the perturbativity of λ below m . In the *white* region the nucleation condition in eq. (2.13) cannot be satisfied.

4.3.1 First order phase transition dynamics

We now turn to the finite-temperature corrections and compute the parameters associated with the phase transition. Note that the spectrum is similar to the O’Raifeartaigh model with the addition of the gauge boson and the gaugino of the $U(1)_D$ symmetry. These additional states are massless in the false vacuum and massive in the true vacuum, so they contribute to making the origin the global minimum at high temperatures.

We numerically evaluate the one-loop and the thermal corrections to the scalar potential, and then compute the bounce action for tunneling from the false vacuum to the true vacuum. In appendix B.1.2 we present the triangular barrier approximation for this model and compare it with the full numerics. Even though the bounce profile in field space involves three different fields, i.e. $(x, \phi_1, \tilde{\phi}_2)$, in our numerical scan, we approximate the bounce as one-dimensional, neglecting the contribution from the $\phi_1, \tilde{\phi}_2$ directions. As detailed in appendix B.2, we checked the single field approximation against the full $3d$ bounce action computed numerically with both FindBounce [88] and CosmoTransitions [89]. As a result, the single field approximation gives a good description of the bounce as long as $\phi_1, \tilde{\phi}_2$ are smaller than X at the bounce release point (defined as the starting point of the tunneling set at $r = 0$, where the kinetic terms of all the fields are exactly zero). In order to estimate where we expect sizable deviations from the multidimensional contribution, we borrow some intuition from the triangular barrier approximation, where S_3/T scales as $\sim X^3$, and define

$$R_{1d/3d} \stackrel{\text{def}}{=} \frac{X^3(r)}{\left(X^2(r) + \phi_1^2(r) + \tilde{\phi}_2^2(r)\right)^{3/2}} \Bigg|_{r=0}, \quad (4.23)$$

where $X(0)$, $\phi_1(0)$ and $\tilde{\phi}_2(0)$ are the field distances from the origin computed at the release point $r = 0$. In figure 9 we show the region where $R_{1d/3d} > 0.5$ and we expect deviations of 50% or more from our one-dimensional estimate of the bounce action. As we can see, this region is not phenomenologically relevant since it is quite far from the interesting region for GW signals.

The parameter space of this model can be explored at fixed F , after fixing the two ratios

$$y_F \stackrel{\text{def}}{=} \frac{\lambda F}{m^2}, \quad y_D \stackrel{\text{def}}{=} \frac{gD}{m^2}. \quad (4.24)$$

In figure 9 we show the behavior of T_n , α , and β_H in the (λ, g) plane, having fixed $\sqrt{F} = 30$ PeV and $y_F = 3/4$ as in the previous model and set $y_D = 1/5$. Keeping fixed the ratios in eq. (4.24), the triangular barrier parameters scale as

$$f_a \sim \frac{1}{g\sqrt{\lambda}}, \quad \frac{\Delta V}{F^2} \sim \frac{\lambda^2}{g^2}, \quad \frac{V_P}{F^2} \sim \lambda^2, \quad \frac{m_*}{\sqrt{F}} \sim \sqrt{\lambda}. \quad (4.25)$$

As a consequence of these scalings, using eq. (3.11) it is straightforward to see that for fixed λ the boundary of the nucleation region is reached for large g , while for fixed g the boundary lies at small λ . The shape of the nucleation temperature T_n can be captured by

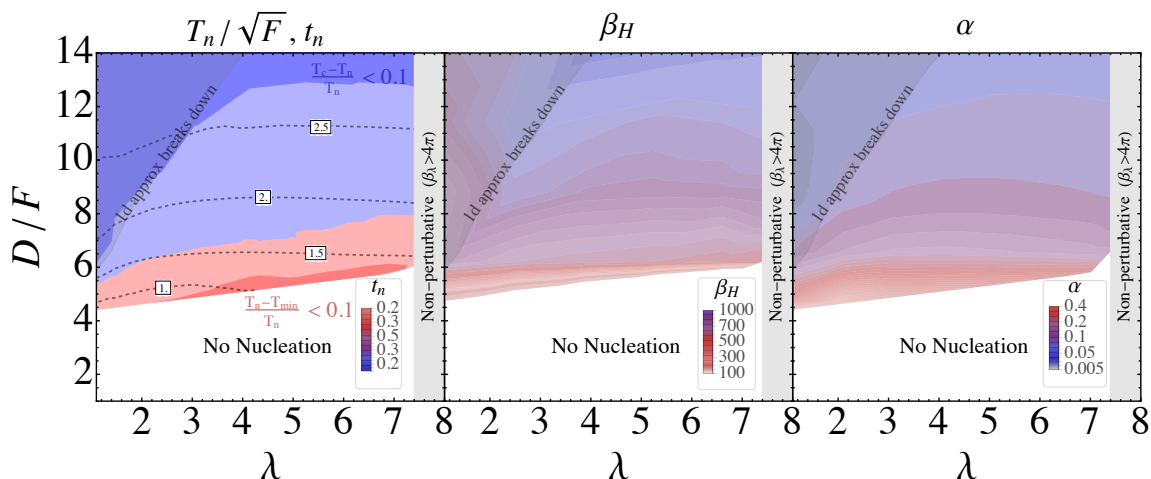

Figure 10. Same as in figure 9 but in the $(\lambda, D/F)$ plane, fixing $F = 30$ PeV, $y_F = 3/4$ and $g = 0.1$.

a simple analytic formula after rewriting eq. (3.15) in terms of the theory parameters:

$$T_n \sim 0.73\sqrt{\lambda F} \frac{1}{\log\left(1 + \frac{22.5}{c^{4/21}} \left(\frac{g}{\lambda}\right)^{4/7}\right)} \left(1 - 20.5 \left(\frac{g^6}{c^2 \lambda^6}\right)^{1/5}\right). \quad (4.26)$$

This expression reproduces the contours in figure 9 (left) up to overall normalization.

In the middle and right panels of figure 9 we show the contours for β_H and α , respectively. The main difference compared to the model in section 4.2 is that even if $T_n \sim \sqrt{F}$, it is possible to obtain sizable values of α because ΔV is here controlled by the D -term. Approaching the boundary of the nucleation zone without fine-tuning the theory parameters by more than $\mathcal{O}(1)$ we can reach $\beta_H \sim 100$ and $\alpha \sim 0.3 - 0.4$, which we use as a benchmark for our summary plot in figure 1.

The interplay of the two SUSY-breaking scales \sqrt{F} and \sqrt{D} is an essential ingredient for a strong FOPT. This is illustrated in figure 10, where we show the behavior of T_n , α , and β_H in the $(\lambda, D/F)$ plane, having again set $\sqrt{F} = 30$ PeV and $y_F = 3/4$, and now fixing $g = 0.1$. In this scaling the FOPT is essentially independent of λ , and one can see clearly that the separation of D from F is the crucial ingredient for a sufficiently strong phase transition. Notice that the required separation is $\mathcal{O}(1)$ and therefore not obviously in tension with theoretical bounds on large D -terms [96]. Strictly speaking, these bounds do not apply to our simple model, where a tree level Fayet-Iliopoulos term makes the Ferrara-Zumino multiplet not gauge invariant [97]. However they would have applied if we were to UV complete this model to a full-fledged model of dynamical SUSY-breaking or for instance if we were to explore the second branch of the model with two different messengers masses and $\lambda F > m_1 m_2$.

4.3.2 Gravitational wave spectrum and phenomenology

Having shown that a strong FOPT can be achieved without fine-tuning in a SUSY-breaking hidden sector with at least two SUSY-breaking scales, we now turn to the gravitational

Figure 11. Predicted SGWB in the O’Raifeartaigh model with gauge interactions. We show the prediction for various values of the SUSY-breaking scale $\sqrt{F} = 1, 10, 30$ PeV and choose the theory parameters such that $\alpha \simeq 0.3$ and $\beta_H \simeq 50$. As discussed in the text, achieving these values does not require any tuning in this model. The SUSY-breaking scale correlates with the peak frequency of the GW spectrum, which is always dominated by sound waves as shown in eq. (4.28).

wave signal itself, again using the simple model presented in the previous section as a benchmark. As discussed in section 2.2, computing the SGWB signal requires understanding the macroscopic dynamics of the vacuum bubbles expanding in the plasma. This is essentially determined by the balance of the energy ΔV released in the FOPT and the pressure effects from the plasma (see eq. (2.19)). If pressure effects stop the bubbles before they collide, most of the SGWB signal will be sourced by the energy released in the plasma.

In section 2.2 we described a quite unique friction mechanism at work in our class of models. This mechanism is a direct consequence of two peculiar features of the pseudomodulus potential: i) the nucleation temperature $T_n \sim \sqrt{F}$ is set by exponentially suppressed temperature corrections to be smaller than the typical scale of the heavy states in the theory m , and ii) the true vacuum VEV is typically the larger scale in the problem and controls the mass variation $\Delta m^2/m^2 \sim \lambda^2 f_a^2/m^2 \gg 1$ of the heavy states from the false to the true vacuum. These two properties together imply that when the vacuum bubbles accelerate enough, $\gamma T_n > m_{\text{true}}$ and the heavy states can cross the bubble wall. Their crossing switches on a new pressure effect which is generically larger than ΔV and immediately stops the bubble runaway.

This last statement can be checked explicitly with the parametric dependence of the simple model described here. The heavy state pressure term in eq. (2.21) scales as

$$\Delta P_{\text{LO}}^{\text{heavy}} \sim \frac{4\pi^2}{3y_F^2 g} F D e^{-m_{\text{false}}/\sqrt{F}}, \quad (4.27)$$

where we used the scaling of the true vacuum as a function of the theory parameters in eq. (4.22) and approximated $T_n \simeq \sqrt{F}$ for simplicity (this approximation is numerically correct up to an $\mathcal{O}(1)$ factor as shown by the dashed contours in figure 9). Inside the exponential, we should take the lightest heavy states in the plasma $m_{\text{false}} \sim \sqrt{m^2 - \lambda F}$ which are of course less Boltzmann suppressed and dominate the friction. Comparing this quantity with the energy released in the phase transition $\Delta V = D^2/2$ we can get the range of the gauge coupling g such that this friction prevents the bubble runaway,

$$g \lesssim \frac{8\pi^2 F}{3y_F D} e^{-m_{\text{false}}/\sqrt{F}}. \quad (4.28)$$

Plugging in the typical numbers for our phase transition ($F/D \sim 1/5$, $y_F \sim 3/4$ and $m_{\text{false}}/\sqrt{F} \lesssim \sqrt{\lambda} \lesssim 2.5$) indicates that the vacuum bubbles are always stopped in the range of interest for the gauge coupling g for perturbative values of λ . The predicted boost factor at equilibrium in this case is

$$\gamma_{\text{eq}}^{\text{heavy}} = \frac{m_{\text{true}}}{T_n} \sim \frac{\lambda f_a}{\sqrt{F}}, \quad (4.29)$$

where again f_a is defined in this model by eq. (4.22). As a final remark, we notice that the NLO friction induced by gauge degrees of freedom radiated through the wall never dominates over the one from heavy states in the interesting range of the gauge coupling g .

Given that the bubble runaway is always prevented, the dominant SGWB comes from sound waves in the plasma. The predicted energy fraction as a function of frequency at GW interferometers has been discussed in eq. (2.25) and below. Putting everything together, in figure 11 we compare our model predictions with the PLI curves for future GW interferometers derived in appendix C.1. This clearly demonstrates that SUSY-breaking hidden sectors with multiple SUSY-breaking scales can generate stochastic signals detectable at future GW interferometers. Moreover, it makes explicit the expected correlation between the SUSY-breaking scale and the peak frequency of the resulting SGBW. All that remains is to explore the full range of viable SUSY-breaking scales (and hence signal frequencies), as well as the correlation between signals at GW interferometers and other experiments. In the next section, we will bound the SUSY-breaking scale from above around \sim few tens of PeV by computing the gravitino cosmological abundance. By specifying a mediation mechanism, we will also use the explicit hidden sector presented here to show how the SUSY-breaking scale determines the spectrum of MSSM superpartners, thereby correlating signals at GW interferometers and future colliders.

5 Phenomenology

Having demonstrated that the first-order phase transition in a SUSY-breaking hidden sector can generate an observable GW signal, we now turn to complementary aspects of hidden

sector phenomenology that shape the motivated parameter space and suggest additional experimental tests in the event of a signal at GW interferometers. We begin with universal features that are intrinsic to the hidden sector itself and independent of the mediation mechanism that connects the hidden sector to the MSSM. This includes key aspects of gravitino cosmology, where we will see that the requirement $T_{\text{r.h.}} = \sqrt{F}$ implies an upper bound on \sqrt{F} even if $m_{3/2}$ receives extra contribution from other SUSY-breaking sectors as in eq. (2.2). We also explore the prospects for collider searches for the gravitino (independent of the MSSM spectrum), finding that future high energy lepton colliders could probe almost the entirety of the light gravitino window (i.e. $m_{3/2} < 16$ eV) by directly producing gravitino pairs. We then relate the parameters of the hidden sector to the spectrum of the MSSM, which requires specifying details of the mediation mechanism. Here we consider the prototypical example of gauge mediation via vector-like messengers, where the parameter space for observable GW signals generates a superpartner spectrum within reach of future proton-proton colliders such as FCC-hh.

5.1 Gravitino cosmology vs future colliders

The gravitino overabundance is a well known problem of LESB scenarios [38–40]. This problem is exacerbated in our setup, because having sizeable GW signals from the SUSY-breaking hidden sector requires the reheating temperature $T_{\text{r.h.}}$ to be at least as high as the SUSY-breaking scale, enhancing the gravitino production from scattering as detailed in eq. (2.8). In light of this tension, here we delve into further detail about the two viable scenarios sketched section 2.3. Since $T_{\text{r.h.}} \sim \sqrt{F}$, which is much larger than the scale of the soft masses, the main player in determining the final gravitino abundance is the production from UV scattering computed in [43–46]. The final yield can be written as

$$Y_{3/2}^{\text{UV}} = C_{\text{UV}} \frac{M_3^2 \sqrt{F}}{m_{3/2}^2 M_{\text{Pl}}}, \quad C_{\text{UV}} = \frac{45\sqrt{5}f_3}{8\pi^{13/2}g_*^{3/2}} \simeq 4 \times 10^{-5}, \quad (5.1)$$

where the production through gluon-gluino scattering dominates over the other channels and we have substituted $T_{\text{r.h.}} \simeq \sqrt{F}$, which is the lowest reheating temperature compatible with our scenario. Following eq. (2.2), we assume that the gravitino mass $m_{3/2}$ is set by an independent SUSY-breaking scale $F_0 = F/\kappa$, possibly higher than the one setting the soft spectrum (i.e. $\kappa \ll 1$).

Ultralight gravitino window vs. pair production at future colliders. If the gravitino mass and the soft spectrum are set by the same SUSY-breaking scale \sqrt{F} , the yield scales as $Y_{3/2}^{\text{UV}} \sim M_{\text{Pl}}/\sqrt{F}$. For sufficiently low SUSY-breaking scales, the yield becomes just the equilibrium one, $Y_{3/2}^{\text{UV}} > Y_{\text{eq}}$, where $Y_{\text{eq}} = n_{3/2}^{\text{eq}}/s = 1.8 \times 10^{-3}$. The gravitino is a thermal relic as long as $\sqrt{F} \lesssim \left(\frac{3}{45}M_{\text{Pl}}M_3^2\right)^{1/3}$, which corresponds to $\sqrt{F} \lesssim 8.6 \times 10^7$ GeV for $M_3 = 2$ TeV. Moreover, since $\sqrt{F} \gg m_{3/2}$, the gravitino is relativistic at freeze-out and its abundance today is constrained by measurements of the matter power spectrum at short scales [41, 42]. The current bounds imply

$$m_{3/2} \lesssim 16 \text{ eV}, \quad F \lesssim 260 \text{ TeV}. \quad (5.2)$$

Figure 12. Parameter space of low energy SUSY-breaking in the $(m_{3/2}, \sqrt{F})$ plane. The *gray shaded* region is excluded by gravitino overabundance and the requirement $m_{3/2} < m_{\text{NLSP}}$, having fixed $m_{\text{NLSP}} = 500$ GeV. The red dashed line shows the region where $\Omega_{3/2} = \Omega_{\text{DM}}$ for different values of the gluino soft mass. The colored regions show the sensitivities of different GW interferometers to signals with fixed $\alpha = 1$ and $\beta_H = 50$. The two *dark green* and *light green* bands show the impact of the present LHC bounds [25–28] and the future FCC-hh reach on gluinos [29] for perturbative messenger sectors with $g_M \in (0.01, 0.1)$ (see eq. (2.10) for a definition of g_M). The *dark blue dashed* lines show the values of $\kappa = F/F_0$, the ratio between the total SUSY-breaking scale F_0 and one controlling the soft masses (see eq. (2.2)). As discussed in eq. (2.11), we expect constraints on flavor changing neutral currents to exclude $\kappa \lesssim 10^{-8}$ as indicated by the *dark blue arrows*. The *dark magenta thick* line indicates the BBN bound on the higgsino NLSP decaying to gravitino plus hadrons as obtained in [31].

The above requirement identifies the *ultralight gravitino window*. Although it is unquestionably challenging to decouple the soft spectrum from the LHC in this window (see [81, 82] for attempts in this direction), it is interesting to ask whether future colliders can test this window in a model-independent fashion through direct pair production of the longitudinal component of the gravitino, the goldstino. This production rate depends directly on \sqrt{F} even when the MSSM superpartners are decoupled, and so provides a direct experimental test of the SUSY-breaking sector.

The projected sensitivity to gravitino pair production at both hadron and lepton colliders is displayed in figure 1. For the bound at future lepton colliders, we consider a high energy lepton collider operating at $\sqrt{s} = 30$ TeV. Assuming minimal cuts on the photon

kinematics ($E_\gamma > 50 \text{ GeV}$, $|\eta_\gamma| < 2.4$), the signal cross section from eq. (2.7) is

$$\sigma_{30\text{TeV}}(\ell^+\ell^- \rightarrow \tilde{G}\tilde{G}\gamma) \simeq 487 \text{ fb} \left(\frac{10 \text{ TeV}}{\sqrt{F}} \right)^8. \quad (5.3)$$

Applying the same minimal cuts on the photon, the SM background (estimated with MadGraph5 [98, 99]) is $\sigma_{SM} \simeq 2\text{pb}$. In contrast to LEP, at high energy lepton colliders the SM background is dominated by WW fusion while the Drell-Yan process with an ISR photon is negligible. We can then derive a lower bound on the scale of SUSY breaking as displayed in figure 1 given an assumed integrated luminosity, namely

$$\sqrt{F} \gtrsim 25 \text{ TeV} \left(\frac{\mathcal{L}}{100 \text{ ab}^{-1}} \right)^{1/16}, \quad (5.4)$$

which is still an order of magnitude away from entirely closing the ultralight gravitino window. However, improved analyses and new cosmological data could strengthen the gravitino mass bound by an order of magnitude, potentially closing the ultralight gravitino window completely. For instance, ref. [100] already claims a bound on the gravitino mass of $m_{3/2} < 4.7 \text{ eV}$; although the robustness of this bound is subject to interpretation, improved limits from Planck data are likely to be comparable.

In order to estimate the reach of future hadron colliders, we perform a rescaling of the limits discussed in [24], based on the mono-photon search of ATLAS [101], which constrain $\sqrt{F} \gtrsim 850\text{GeV}$ with 20.3fb^{-1} at $\sqrt{s} = 8 \text{ TeV}$.⁸ As at lepton colliders, the signal cross section for gravitino pair production in association with a photon $\sigma(pp \rightarrow \tilde{G}\tilde{G}\gamma)$ scales as s^3/F^4 at hadron colliders [23]. To estimate the limit attainable at $\sqrt{s} = 100 \text{ TeV}$, we first compute the ratio of the signal cross sections at $\sqrt{s} = 100 \text{ TeV}$ and $\sqrt{s} = 8 \text{ TeV}$, taking the partonic signal cross section to scale as $\sigma_{\text{sig}} \sim \hat{s}^3/F^4$ and assuming that the $p_{T,\gamma} \geq 125 \text{ GeV}$ cut at $\sqrt{s} = 8 \text{ TeV}$ is increased to $p_{T,\gamma} \geq 1 \text{ TeV}$ at $\sqrt{s} = 100 \text{ TeV}$. We additionally compute the ratio of background cross sections, assuming the partonic background cross section scales as $\sigma_{\text{bkg}} \sim 1/\hat{s}$. Using the $\sqrt{s} = 8 \text{ TeV}$ signal and background predictions in [101] and the above ratios, we find the expected limit at $\sqrt{s} = 100 \text{ TeV}$ to be

$$\sqrt{F} \gtrsim 12 \text{ TeV} \left(\frac{\sqrt{s}}{100 \text{ TeV}} \right)^{3/4} \left(\frac{\mathcal{L}}{30 \text{ ab}^{-1}} \right)^{1/16}, \quad (5.5)$$

which is the one displayed in figure 1. Even with this aggressive estimate, the reach of high energy hadron colliders is limited compared to the reach of high energy lepton colliders because the signal cross section at the former only grows with \hat{s}^3 , while at the latter it grows as s^3 .

Gravitino dark matter window. If the SUSY-breaking scale $\sqrt{F_0}$ setting the gravitino mass exceeds the scale \sqrt{F} of the hidden sector, we can treat $m_{3/2}$ as a free parameter and access an interesting region where the gravitino is never in thermal equilibrium with the SM.

⁸The bounds from mono-jet searches are comparable [24], but involve backgrounds from a mix of both quark- and gluon-initiated processes that are less amenable to simple rescaling. Thus we focus on the mono-photon signal for simplicity.

This could arise naturally from additional sequestered sectors that break supersymmetry at higher scales. As shown in figure 12, we also require this new source of SUSY-breaking to not spoil the defining phenomenological features of LESB, namely i) the gravitino is still the LSP, and ii) the soft masses are dominated by the flavor-diagonal contribution from gauge mediation.

Requiring the gravitino avoid thermalization, $Y_{3/2}^{\text{UV}} < Y_{\text{eq}}$, we obtain an upper bound on \sqrt{F} at fixed gravitino mass which can be cast as an upper bound on the ratio between the two SUSY-breaking scales, $\kappa = F/F_0$:

$$Y_{3/2}^{\text{UV}} < Y_{\text{eq}} \quad \Rightarrow \quad \kappa < 0.02 \left(\frac{F}{10^7 \text{ GeV}} \right)^{1/4} \left(\frac{0.1}{g_M} \right), \quad (5.6)$$

Here we have used the expression for the gravitino mass in eq. (2.2) and the one for the gluinos in eq. (2.10), where the parameter g_M encodes the model-dependence of the latter. If the gravitino is never in thermal equilibrium, we can assume (as usual in freeze-in scenarios) that the gravitino sector is not directly reheated after inflation and the gravitino abundance is frozen-in through scattering of SM states with their superpartners. Setting the gravitino abundance to explain the DM abundance today, we can predict the gluino mass in the $(m_{3/2}, \sqrt{F})$ plane,

$$M_3 \simeq 2 \text{ TeV} \left(\frac{10^7 \text{ GeV}}{\sqrt{F}} \right)^{1/2} \left(\frac{m_{3/2}}{2.5 \text{ GeV}} \right)^{1/2} \simeq 2 \text{ TeV} \left(\frac{\sqrt{F}}{10^7 \text{ GeV}} \right)^{1/2} \left(\frac{10^{-5}}{\kappa} \right), \quad (5.7)$$

which corresponds to the red lines of figure 12 where the gravitino accounts for the total DM abundance today at fixed gluino mass. The current LHC bounds on the gluino mass set a boundary of our parameter space, which is shown in figure 12.⁹ The second scaling in eq. (5.7) shows the value of κ required to achieve a given gluino mass. As shown in figure 12, the parameter space of interest has κ between $(10^{-8}, 10^{-4})$, where smaller values of κ would not open up more parameter space and in any event would be in tension with FCNC constraints as discussed in eq. (2.11).

The bound at larger gravitino masses (the gray band on the r.h.s. on figure 12) is given by the requirement that the gravitino be the LSP. A stronger bound is derived from BBN constraints on the freeze-out abundance of the NLSP decaying into gravitinos. We have computed the NLSP freeze-out abundance assuming the NLSP is a pure higgsino NLSP and applied the BBN bound of ref. [31] given the NLSP lifetime in eq. (2.6). The triangular-shaped region where the gravitino could be DM can be probed by both GW interferometers and future colliders, as shown in figure 12. This highlights the potential for future colliders to determine whether a SUSY-breaking phase transition is the source of a SGWB signal observed at GW interferometers.

5.2 A complete model of gauge mediation

Finally, we can correlate the GW signals of the SUSY-breaking hidden sector with the superpartner spectrum of the MSSM by specifying a mediation mechanism. In order to

⁹Strictly speaking, the gluino mass here is the soft mass at computed at the high scale; since the low-scale pole mass will be larger, we generously show the parameter space up to $M_3 = 1 \text{ TeV}$.

embed the model of section 4.3 into a successful model of gauge mediation, we work in terms of a simple generalization of the gauged O’Raifeartaigh model which allows a natural embedding of both the gauged $U(1)_D$ symmetry and the SM gauge group into the flavor symmetry of the messengers. This requires M copies of the vector-like messengers Φ and $\tilde{\Phi}$ coupled to the singlet X , so that the superpotential is identical to the one of the O’Raifeartaigh model in eq. (4.2), but where now the fields are intended as vectors with M components. The minimal setup requires $M = 6$ so that the superpotential enjoys an $SU(6)$ symmetry, where a $U(1)$ subgroup of the $SU(6)$ is the gauged $U(1)_D$ with a non vanishing Fayet-Iliopoulos term, while the SM gauge group lies inside the remaining global $SU(5)$ such that the messengers can be taken to transform in the $5 + \bar{5}$ representation of $SU(5)$ as in standard gauge mediation scenarios [36].

The mass matrix of the messenger fields is

$$\mathcal{M}_{\text{mess}} = \begin{pmatrix} \frac{\lambda f_a}{\sqrt{2}} & m \\ m & 0 \end{pmatrix}, \tag{5.8}$$

where f_a is the VEV of the pseudomodulus given in eq. (4.22). Integrating out the messengers, one can compute the soft masses for the MSSM following the general formulas in [102]. The scalar masses follow the standard gauge mediation scaling discussed in eq. (2.9), while it is worth explicitly writing the parametric dependence of the gluino soft mass in the notation of eq. (2.9):

$$M_3 = \frac{\alpha_3}{4\pi} \frac{\sqrt{2}F}{f_a} s_M, \quad s_M = \frac{y_F^2}{6}. \tag{5.9}$$

Here we have expanded in $\lambda f_a \gg m \gtrsim F$ and identified the gaugino screening factor s_M in this model. Since we typically have $y_F \sim 1$ in our scenarios (in order to remain in the green region of figure 5) the gaugino screening factor does not provide significant suppression, but interestingly it is generic for models like ours where the messengers mass matrix is never singular along the pseudomodulus direction [16, 53]. Abandoning this requirement, one could avoid gaugino screening at the price of opening up messenger field directions where the SM gauge group is spontaneously broken in the UV [103].

Substituting the value of f_a in eq. (4.22) and taking as benchmark values a typical point with $\alpha \sim 0.3$ and $\beta_H \sim 100$ from figure 9, the gaugino pole mass is

$$m_{\tilde{g}} \simeq 2 \text{ TeV} \left(\frac{F}{30 \text{ PeV}} \right)^{1/2} \left(\frac{y_F}{0.75} \right)^3 \left(\frac{F}{2.5D} \right)^{1/2} \left(\frac{\lambda}{4} \right) \left(\frac{g}{0.4} \right). \tag{5.10}$$

This shows that the band between the present exclusion at the LHC and the future reach of FCC-hh can be populated with simple, concrete models featuring strong SGWB signals within the reach of future high-frequency interferometers such as A-LIGO, ET and CE.

6 Conclusions

We began by asking if future gravity wave detectors could provide a new window into supersymmetry by probing SUSY-breaking hidden sectors in a region not yet excluded by

LHC searches. The answer to this question is well summarized in figure 1, which shows the complementarity of future gravitational wave interferometers and colliders in probing scenarios of low-energy supersymmetry breaking (LESB). Fortuitously, the cosmological history of the gravitino — a key degree of freedom in LESB scenarios — bounds the SUSY-breaking scale from above, so that the viable parameter space lies within reach of both high-frequency GW interferometers and high-energy colliders.

The underlying assumption in figure 1 is that the SUSY-breaking hidden sector actually undergoes a strong first-order phase transition. The remainder of the paper has been devoted to demonstrating, on general grounds, the circumstances under which strong FOPTs can be produced in SUSY-breaking hidden sectors. We have focused on phase transitions along the pseudomodulus direction, which as a universal feature of spontaneous SUSY-breaking is guaranteed to exist in a vast class of SUSY-breaking hidden sectors. Remarkably, the generic features of the pseudomodulus potential gave rise to a parametrically new way of realizing strong first-order phase transitions in field theory.

The novelty of the pseudomodulus FOPT is a consequence of the flatness of the tree-level potential accompanied by the presence of a mass gap for the heavy states, which makes the theory calculable everywhere in field space. Since the mass gap is supersymmetric, it does not destroy the flatness of the potential at large field values. The two resulting features of this setup are that i) the nucleation temperature is well below the scale of the heavy states, so that the low- T expansion applies, and ii) the pressure from Boltzmann-suppressed heavy states in the plasma is responsible for stopping the vacuum bubble runaway. The dominant GW signal then comes from the energy released in the plasma during the phase transition.

The strength of the GW signal depends on finer details of the hidden sector dynamics. However, we found that multiple SUSY-breaking scales in the hidden sector are a necessary condition for generating strong GW signals without fine tuning of the theory parameters. This result is quite general and can be obtained analytically without reference to a specific model. For the sake of concreteness, we presented an explicit model for a hidden sector generating a strong GW signal, where SUSY is broken by both an F -term and a D -term. Detailed predictions for the GW signal and superpartner spectrum in this model substantiate the general phenomenological observations of figure 1.

Acknowledgments

We thank Tomer Volansky for collaboration at the initial stage of this project. We thank Andrea Tesi for asking if there was a non-SUSY realization of our phase transitions. In trying to answer this question we realized how special these SUSY-breaking phase-transitions were. We also thank Daniele Barducci, Toby Opferkuch for interesting discussions. We thank Victor Guada for assistance with the FindBounce package. DR would like to thank the Galileo Galilei Institute for Theoretical Physics (GGI) for its hospitality, and Patrick Fox for useful discussions therein.

EOS” — be.h project n.30820817. NC is supported in part by the Department of Energy under the award DE-SC0011702. NL would like to thank the Milner Foundation for the award of a Milner Fellowship.

A The effective potential

The effective scalar potential is given by a sum of quantum and thermal contributions

$$V_{\text{eff}}(x, T) = V_0(x) + V_T(x, T). \quad (\text{A.1})$$

The temperature independent potential can be written as $V_0(x) = V_{\text{tree}}(x) + V_{\text{CW}}(x)$, where $V_{\text{CW}}(x)$ is the one loop Coleman-Weinberg potential at zero temperature which in the $\overline{\text{MS}}$ scheme is given by

$$V_{\text{CW}}(x) = \sum_i (-1)^F \frac{g_i m_i^4(x)}{64\pi^2} \left(\log \frac{m_i^2(x)}{m_0^2} - c_i \right), \quad (\text{A.2})$$

where $F = 1$ (0) for fermions (bosons), the number of degrees of freedom associated with the particle i is $g_i = 1/2/3$ for real scalars, fermions and vectors, respectively, and $c_i = \frac{3}{2}$ ($\frac{5}{2}$) for scalars/fermions (vectors). The thermal one-loop potential is given by

$$V_T(x, T) = \frac{T^4}{2\pi^2} \sum_i (-1)^F g_i J_{\text{B/F}} \left(\frac{m_i^2(x)}{T^2} \right), \quad (\text{A.3})$$

where the thermal functions for both species are

$$J_{\text{B/F}}(z^2) = \int_0^\infty dx x^2 \log[1 \mp \exp(-\sqrt{x^2 + z^2})], \quad (\text{A.4})$$

with $z_i \equiv m_i/T$. These functions can only be fully evaluated numerically, but admit analytical approximations for large and small $|z^2|$. In the high-temperature limit, $|z^2| \ll 1$ and the thermal functions are

$$\begin{aligned} J_B(z^2) &\approx J_B^{\text{high-}T}(z^2) = -\frac{\pi^4}{45} + \frac{\pi^2}{12} z^2 - \frac{\pi}{6} z^3 - \frac{1}{32} z^4 \log\left(\frac{z^2}{a_b}\right), \\ J_F(z^2) &\approx J_F^{\text{high-}T}(z^2) = \frac{7\pi^4}{360} - \frac{\pi^2}{24} z^2 - \frac{1}{32} z^4 \log\left(\frac{z^2}{a_f}\right), \quad \text{for } |z^2| \ll 1, \end{aligned} \quad (\text{A.5})$$

where $a_b = \pi^2 \exp(3/2 - 2\gamma_E)$ and $a_f = 16\pi^2 \exp(3/2 - 2\gamma_E)$. The low temperature limit (i.e. $|z^2| \gg 1$) can be approximated in terms of modified Bessel functions of the second kind

$$\begin{aligned} J_B(z^2) &= \tilde{J}_B^{(m)}(z^2) = -\sum_{n=1}^m \frac{1}{n^2} z^2 K_2(zn), \\ J_F(z^2) &= \tilde{J}_F^{(m)}(z^2) = -\sum_{n=1}^m \frac{(-1)^n}{n^2} z^2 K_2(zn), \quad \text{for } |z^2| \gg 1, \end{aligned} \quad (\text{A.6})$$

where m is high enough such that the series converge. For T low enough, we can take only the first term in the series and further expand the modified Bessel function to the leading order $K_\nu(z) \underset{z \rightarrow \infty}{\simeq} \sqrt{\frac{\pi}{2z}} e^{-z}$ to get

$$J_B(z^2) = -J_F(z^2) \underset{z \rightarrow \infty}{\simeq} - \left(\frac{\pi z^3}{2} \right)^{1/2} e^{-z}. \tag{A.7}$$

Within this approximation we can obtain a simple expression for $V_{\text{th}}(x, T)$ which is valid at the leading order in the low- T expansion:

$$V_T(x, T) \simeq -T^4 \sum_{\text{B/F}} g_i \left(\frac{m_i(x)}{2\pi T} \right)^{3/2} e^{-m_i(x)/T}, \tag{A.8}$$

where it is important to notice that bosons and fermions contribute with the same (negative) sign to the effective potential. The approximation above is used in section 3 to derive an analytical scaling of the dynamics of FOPTs.

Lambert function. As a consequence of the low- T expansion the equations we will be dealing with have the typical form

$$Az^{-a} e^{-z} - B = 0, \quad z = a\mathcal{W} \left[\frac{1}{a} \left(\frac{A}{B} \right)^{1/a} \right], \tag{A.9}$$

where $\mathcal{W}(z)$ is the Lambert function, which is defined such that $\mathcal{W}(z)e^{\mathcal{W}(z)} = z$. Without entering into the details of the interesting properties of this function, we restrict our interest to finding a good approximation for it using simpler functions. First, we will consider $\mathcal{W}(z)$ for strictly positive arguments. Second, we note that $\mathcal{W} \rightarrow 0$ for $z \rightarrow 0$ and that $\mathcal{W}(z) \sim \log z$ for $z \rightarrow \infty$. By inspection one finds that a good approximation of $\mathcal{W}(z)$ is given simply by

$$\mathcal{W}(z) \simeq \frac{3}{4} \log(1+z). \tag{A.10}$$

The relative difference between the Lambert function and the approximation with the logarithm in (A.10) is at most $\sim 1/4$ (for $z \rightarrow 0$ and $z \rightarrow \infty$) and smaller (in absolute value) in intermediate regions. For practical purposes in analytic estimations of relevant quantities, we will hence often consider the approximation in (A.10).

B Bounce action computation schemes

The transition of a quantum system from a meta-stable vacuum state to the true vacuum can be driven either by quantum tunneling or by thermal fluctuations. In the FOPTs describe in this paper the latter are always dominant. The probability of thermal tunnelling is described semi-classically by eq. 2.12 and it is exponentially dependent on the classical $O(3)$ -symmetric bounce solution [66, 67]. In this appendix we review both the analytical and the numerical approaches we used to study the behavior of the $O(3)$ -symmetric bounce in our FOPTs.

First, in section B.1, we describe in detail the triangular barrier approximation introduced in ref. [83] and its generalization to the $O(3)$ -symmetric case [84]. We compare this approximation with the behavior of the full bounce action computed numerically with the FindBounce package [88, 104] and the CosmoTransitions code [89]. In section B.1.1 we discuss an optimization of the triangular barrier approximation which leads to excellent agreement with the full numerical computation. In section B.1.2 we consider the O’Raifeartaigh model with gauge interactions of section 4.3 as our main case study.

Second, in section B.2 we discuss the single field approximation of the bounce action in the model of section 4.3. We study numerically the behavior of the bounce action in the full three-dimensional field space and compare it with the single field approximation, deriving where we expect the latter to deviate sensibly from the full solution.

B.1 Triangular barrier approximation of the bounce action

The d -dimensional Euclidean action for n scalar fields ϕ_i is

$$S_d = \Omega_d \sum_i \int_0^\infty r^{d-1} dr \left[\frac{1}{2} \dot{\phi}_i^2 + V(\phi_i) \right], \tag{B.1}$$

where $\Omega_d = 2\pi^{d/2}/\Gamma(d/2)$ and the equations of motion for ϕ_i are

$$\ddot{\phi}_i + \frac{(d-1)}{r} \dot{\phi}_i = V'(\phi_i). \tag{B.2}$$

The boundary conditions defining the bounce solution are

$$\dot{\phi}_i(r=0) = 0, \quad \phi_i(r \rightarrow \infty) = \phi_{i_f} \quad \text{and} \quad \dot{\phi}_i(r \rightarrow \infty) = 0, \tag{B.3}$$

where the conditions at $r \rightarrow \infty$ ensures that the solution starts with zero kinetic energy from the false vacuum and stops at $r = 0$ with zero kinetic energy. Here, we are interested in solving this equation for a single field ($n = 1$) and in $d = 3$.

The idea behind the triangular barrier approximation is to approximate the potential as a piecewise linear function anchored at three points: the false vacuum, the top of the barrier and the true vacuum. In the following, we review in some details the derivation of the 3d bounce action in the triangular barrier approximation, and we refer to the original paper [83] for more details and to [105] for the derivation in arbitrary dimensions.

Following the notation of [83], we define the false vacuum to be at the field position ϕ_+ with potential V_+ ; the peak of the triangular barrier to be at ϕ_P with potential V_P ; and the true vacuum to be at ϕ_- with potential V_- . It is then convenient to define the magnitudes of the gradients of the potential by

$$\lambda_\pm \stackrel{\text{def}}{=} \frac{\Delta V_\pm}{\Delta \phi_\pm}, \tag{B.4}$$

so that $V'(\phi) = \pm \lambda_\pm$ on either side of the barrier, precisely

$$V(\phi) = \begin{cases} V_+ + \lambda_+(\phi - \phi_+) & \text{for } \phi < \phi_P \\ V_- + \lambda_-(\phi - \phi_-) & \text{for } \phi > \phi_P \end{cases} \tag{B.5}$$

In order to solve the equation of motions we have to specify the boundary conditions. At a large radius R_+ the field attains the false vacuum, so we have

$$\phi(R_+) = \phi_+ \quad \dot{\phi}(R_+) = 0, \quad (\text{B.6})$$

Then, we have to specify the boundary conditions at the start of the tunneling. There are two possibilities:

1. The field immediately start to roll at $r = 0$ and hence we impose

$$\phi(0) = \phi_0 \quad \dot{\phi}(0) = 0, \quad (\text{B.7})$$

where the initial field value ϕ_0 is the undetermined release point. This is the valid regime if one finds that $\phi_0 \leq \phi_-$.

2. Otherwise, the field sits in the true vacuum for $r < R_0$ and then starts rolling. In this second case the boundary conditions are

$$\phi(r) = \phi_- \quad 0 < r < R_0 \quad (\text{B.8})$$

$$\phi(R_0) = \phi_- \quad \dot{\phi}(R_0) = 0, \quad (\text{B.9})$$

We begin with the analysis of the first case. Imposing the previous boundary conditions one finds the following solutions for the equations of motion in the different radius intervals

$$\phi(r) = \begin{cases} \phi_R(r) = \phi_0 - \frac{\lambda_-}{6} r^2 & 0 < r < R_P \\ \phi_L(r) = \phi_+ + \frac{\lambda_+}{6} \left(r^2 - 3R_+^2 + 2\frac{R_+^3}{r} \right) & R_P < r < R_+ \end{cases} \quad (\text{B.10})$$

Then we impose that the two solutions match at R_P and also that their first derivatives match at R_P , obtaining the following conditions

$$\phi_0 = \phi_P + \frac{\lambda_+ R_P^2}{6} \quad (\text{B.11})$$

$$R_P^3 = (1 + r_\lambda) R_+^3 \quad (\text{B.12})$$

$$R_P^2 = \frac{6\Delta\phi_+^2}{\left[3 + 2r_\lambda - 3(1 + r_\lambda)^{2/3} \right] \Delta V_+} \quad (\text{B.13})$$

where we have introduced $r_\lambda \equiv \frac{\lambda_-}{\lambda_+}$. Then we insert into the action the solutions (B.10) and we integrate from $r = 0$ to $r = R_+$ with the appropriate potential (see (B.5)). From this computation we have to subtract the action for the case in which the field sits at the false vacuum from $r = 0$ to $r = R_+$, that is we compute all in all

$$S_3^{TBA} = S_3[\phi(r)] - S_3[\phi_+] \quad (\text{B.14})$$

Using the equations in (B.13) we can rewrite the result as a function of the parameters of the potential to obtain

$$\left(\frac{S_3}{T} \right)_{\text{TBA}} = \frac{16\sqrt{6}\pi}{5} \frac{1}{T} \frac{(1 + r_\lambda)}{\left[3 + 2r_\lambda - 3(1 + r_\lambda)^{2/3} \right]^{3/2}} \left(\frac{\Delta\phi_+^3}{\sqrt{\Delta V_+}} \right), \quad (\text{B.15})$$

The condition to select the first case (i.e. $\phi_0 > \phi_-$) can also be rewritten by employing again formula (B.13) as

$$\frac{\Delta\phi_-}{\Delta\phi_+} \geq \frac{r_\lambda}{3 + 2r_\lambda - 3(1 + r_\lambda)^{2/3}}. \quad (\text{B.16})$$

We then analyse the second case. Imposing the boundary conditions we get the solutions

$$\phi(r) = \begin{cases} \phi_R(r) = \phi_- & 0 < r < R_0 \\ \phi_R(r) = \phi_- - \frac{\lambda_-}{6} \left(r^2 - 3R_0^2 + 2\frac{R_0^3}{r} \right) & R_0 < r < R_P \\ \phi_L(r) = \phi_+ + \frac{\lambda_+}{6} \left(r^2 - 3R_+^2 + 2\frac{R_+^3}{r} \right) & R_P < r < R_+ \end{cases} \quad (\text{B.17})$$

By imposing matching of the fields and the derivative at $R = R_P$ we get the following equations for the unknown parameters R_0, R_P, R_+

$$R_P^3 = \frac{r_\lambda R_0^3 + R_+^3}{1 + r_\lambda} \quad (\text{B.18})$$

$$\Delta\phi_- = \frac{r_\lambda \lambda_+ (R_0 - R_P)^2 (2R_0 + R_P)}{6R_P} \quad (\text{B.19})$$

$$\Delta\phi_+ = \frac{\lambda_+ (R_+ - R_P)^2 (2R_+ + R_P)}{6R_P} \quad (\text{B.20})$$

We then compute the bounce action by inserting the solutions and integrating from r to R_+ , and after some rearrangements we get

$$\left(\frac{S_3}{T} \right)_{\text{TBA}} = \frac{8\pi}{15} \frac{1}{T} \left(R_+^3 \Delta\phi_+ - r_\lambda R_0^3 \Delta\phi_- \right) \frac{\Delta V_+}{\Delta\phi_+} \quad (\text{B.21})$$

where R_+ and R_0 are functions of parameters of the scalar potential through the implicit equations (B.20).

So we conclude that in both possible cases, the computation of the bounce action in the TBA approximation only needs to specify the *critical* points of the potential, that is the metastable vacuum, the peak of the barrier and the true vacuum. For the scenarios studied in this paper the first case (B.15) is the relevant one, and the validity condition is reported also in (3.6) (note that in the conventions in the main text we always choose the metastable vacuum to be at the origin of the field space). In this appendix we have nevertheless reviewed both cases for completeness.

In the following we will compute the TBA bounce action by both evaluating the potential numerically and approximating it analytically. These approximations can be compared with the results of the full-fledged numerical bounce action computation.

B.1.1 Optimized triangular bounce

Studying the evolution of the bubble profiles for the actions computed numerically we note that the release point ϕ_0 is typically closer to the potential barrier than to the true vacuum at ϕ_- in our setups. Therefore, we introduce here a modified version of the TBA that takes into account this feature, leading to a better agreement with the full numerics than

the analytic formulas presented above. The idea is to allow the minimum of the potential to be a free parameter rather than to fix it at the true vacuum, allowing the TBA to more closely represent the shape of the potential, where the slope is closer to linear.

The TBA bounce action is computed by replacing $\phi_- \rightarrow \phi_0$ and $V_-(\phi_-) \rightarrow V_-(\phi_0)$, where ϕ_0 is now an arbitrary point along the potential in the interval $\phi_{\text{eq}} < \phi_0 < \phi_-$ (here $\phi_{\text{eq}} > \phi_P$ is the point after the potential barrier where $V(\phi_{\text{eq}}) = V_+$). This procedure defines a function $S_3/T(\phi_0)$ that we can minimize over ϕ_0 in the allowed interval. The resulting minimum is the sought bounce action, that we have dubbed the optimal TBA.

B.1.2 Triangular bounce for the O’Raifeartaigh model with gauge interactions

In this section, we specify the discussion to the triangular barrier approximation for the model of section 4.3 and compute the inputs needed for the TBA bounce action. We denote the usual combination of parameters as $y_F \equiv \frac{\lambda F}{m^2}$ and $y_D \equiv \frac{gD}{m^2}$.

The local minimum at the origin is approximated as

$$\phi_+ = 0, \tag{B.22}$$

$$V_+(T) = F^2 + \frac{1}{2}D^2 - \frac{3T^{5/2}e^{-\frac{m}{T}}(128m^2 + 240mT)}{128\sqrt{2}\pi^{3/2}\sqrt{m}} + \frac{m^4}{32\pi^2} \left[(1 + y_F)^2 \log(1 + y_F) + (1 - y_F)^2 \log(1 - y_F) - 3y_F^2 \right], \tag{B.23}$$

The peak of the barrier is located at

$$\phi_P \simeq \frac{F}{m} \frac{\sqrt{2 - 2y_D}}{y_F \sqrt{y_D}}, \tag{B.24}$$

$$V_P(T) \simeq F^2 + \frac{1}{2}D^2 + \frac{m^4}{16\pi^2} y_F^2 \log\left(\frac{1 - y_D}{y_D}\right) - \frac{T^{5/2}e^{-\frac{m}{T}}(128m^2 + 240mT)}{32\sqrt{2}\pi^{3/2}\sqrt{m}}, \tag{B.25}$$

Finally, the true vacuum location and energy are given by

$$\phi_- \simeq \frac{F}{m} \frac{4\pi}{g} \frac{\sqrt{2y_D}}{y_F^2}, \tag{B.26}$$

$$V_- \simeq F^2 + \frac{m^4}{16\pi^2} y_F^2 \log\left(\frac{16\pi^2}{g^2} \frac{y_D}{y_F^2}\right), \tag{B.27}$$

where we set the renormalization scale $\mu = m$. Within our approximation the thermal effects only enter at the origin, and at the top of the barrier, where they act to lower the potential relative to the true vacuum, and the potential difference between the top of the barrier and origin, respectively.

In figure 13 we consider two benchmarks with very different r_λ at T_n and show the bounce action S_3/T as a function of the temperature, computed in different approximations. The black line is computed using the fully numerical thermal effective potential and the mathematica package “FindBounce” [88]. The blue line is obtained with the TBA evaluated on the full-numerical scalar potential and optimized with the procedure explained above. The red line is the TBA (as computed in appendix B.1) evaluated on the full-numerical

Figure 13. Bounce action computed using different approximations in the O’Raifeartaigh model with gauge interactions of section 4.3. The benchmarks on the left and on the right are distinguished by the size of r_λ . The *black lines* are the full numerical computation of the bounce action. In *blue* we show the TBA computed using the numerical scalar potential and optimized with the procedures explained in the text. The *red lines* are the standard TBA approximations as described in appendix B.1. The *green line* is the standard TBA evaluated on the analytic approximation of the scalar potential (as detailed in the text) and taking only the zeroth order term in the expansion for small r_λ (as in eq. (3.6)). This last approximation is the one used in section 3 to derive analytic estimates.

scalar potential. Finally, the green is the TBA evaluated on the analytical approximation of the critical points of the scalar potential as explained above, and moreover keeping only the leading order term in the small r_λ expansion in eq. (3.6). This is the approximation used to derive the analytic formulas in section 3.

First, we see that the optimal TBA reproduces almost perfectly the numerical bounce computation. The standard TBA can predict well the location of T_{\min} but the overall normalization can be off up by a factor of \sim few, and in particular it does not agree with the numerical result in the vicinity of T_c . However, the different trend in the overall shape of the bounce action in the two benchmarks (e.g. very flat around T_{\min} in the left one) is also captured in the standard TBA approximation.

Then, we note that the simplest approximation of the standard TBA reproduces very well the TBA when r_λ is small. This was not obvious a priori since, besides expanding the TBA at leading order in small r_λ , we have: i) assumed that the only temperature dependence is in the height of the potential at the origin; ii) employed the low- T approximation of the scalar potential to estimate it. The agreement between the red and green curve in the left panel of figure 13 hence confirms the fact that low- T is the correct approximation to employ, as discussed at length in section 3. When r_λ is larger (right plot) the simplest approximation (green line) clearly deviates from the standard TBA (red line), but nevertheless capture approximately the location of T_{\min} and the shape of the numerical results. It is important to observe that even if the normalization of the bounce action and its raising towards T_c are not exactly reproduced by the approximations employed, they can still track the changes of the bounce action (shape deformations and overall size) as a function of the fundamental parameters of the model. This elucidates why the analytic estimates obtained in section 3 can capture the scaling of T_n in the different models as discussed in section 4.2 and 4.3.

Figure 14. *Left:* bubble profiles for the single field and three field bounce actions as a function of the bubble radii. The release point for the single field (pseudo flat) direction is practically identical in both schemes, while the contribution coming from motion along the other field directions is generally small, but non-zero. *Right:* the bubble trajectory in field space for the single field and three field bounce action. The x-axis represents motion along the pseudo flat direction while the y-axis represents motion along the larger of the other two field directions ($\tilde{\phi}_2$). It is clear from both plots that the motion along the pseudo flat direction is mostly unaffected by the motion along the other directions, and therefore the single field path approximation is viable.

B.2 Single field approximation of the multi-field bounce action

As discussed previously, the model presented in section 4.3, contains more than one dynamical degree of freedom that actually enters into the bounce action computation. Namely, the fields X , ϕ_1 and $\tilde{\phi}_2$ vary along the minimal potential energy trajectory in field space which connects the two minima of the potential. This implies that the full bounce solution is that of a three field problem, which is in general only solvable numerically. In this appendix we explain why in the model under study the bounce action can be effectively approximated with a one field problem and what is the regime of validity of such approximation.

The bounce action involving the three fields is

$$\begin{aligned}
 S_3 &= \frac{2\pi^{3/2}}{\Gamma(3/2)} \sum_i \int_0^\infty r^2 (T_i + V(\phi_i)) \\
 &= \frac{2\pi^{3/2}}{\Gamma(3/2)} \int_0^\infty r^2 \left(\frac{1}{2} \dot{X}^2 + \frac{1}{2} \dot{\phi}_1^2 + \frac{1}{2} \dot{\tilde{\phi}}_2^2 + V(X, \phi_1, \tilde{\phi}_2) \right),
 \end{aligned}
 \tag{B.28}$$

where T_i is the kinetic energy associated with each field, which is an additive quantity. In our analysis we approximate this action by minimizing $V(X, \phi_1, \tilde{\phi}_2)$ along all three directions and by solving the bounce equation only for X . This corresponds to neglect the contribution from the kinetic energy of the other two fields ϕ_1 and $\tilde{\phi}_2$. Since the kinetic energy of these fields is related to the potential energy along the same directions by the equation

of motion, we expect that the kinetic energy contributions of ϕ_1 and $\tilde{\phi}_2$ can be consistently neglected if their VEVs along the bounce trajectory are small compared to the one of X .

This is typically what happens in this model as we show in the left panel of figure 14, where we plot the bubble profiles of the full three field problem computed using FindBounce (red, blue and green line). We also show for comparison (in dashed black) the bubble profile that we obtain for the single-field bounce solution for X , which is essentially identical to the one in the three-field solution. In the right panel of figure 14 we show a two dimensional slice of the field path along the bounce solution, in the $X, \tilde{\phi}_2$ plane (we show $\tilde{\phi}_2$ since the ϕ_1 vev is smaller and hence it has even a smaller impact on the value of the bounce action). We see that the X trajectory is almost unchanged by the addition of the second field. We hence conclude that it is typically a robust approximation in this model to neglect the kinetic contribution of the fields ϕ_1 and $\tilde{\phi}_2$ and to solve the one-field problem.

Nevertheless, we would like to estimate the range of validity of our approximation. As mentioned, we expect the difference to come from the kinetic terms of ϕ_1 and $\tilde{\phi}_2$, which will be non negligible if the size of the ϕ_1 and $\tilde{\phi}_2$ VEV's compared to the one of X is not negligible. In particular, we would like to estimate the impact of this approximation in the overall bounce action. We hence use intuition from the TBA where the size of the bounce action is proportional to the cubic power of the field displacement. We define the following ratio

$$R_{1d/3d} \stackrel{\text{def}}{=} \frac{X^3(r)}{\left(X^2(r) + \phi_1^2(r) + \tilde{\phi}_2^2(r)\right)^{3/2}} \Bigg|_{r=0}, \quad (\text{B.29})$$

where $X(0)$, $\phi_1(0)$ and $\tilde{\phi}_2(0)$ are the field distances from the origin computed at the release point $r = 0$. The ratio $R_{1d/3d}$ provides a measure of the relative error of the single-field bounce action computation against the full three-field one. Indeed, we have also cross-checked numerically in several benchmarks that the difference in the values of the bounce action is negligible when $R_{1d/3d}$ is small. In the main body of the paper, we will define the region where the 1-field approximation breaks down as when the quantity $R_{1d/3d} > 0.5$, corresponding approximately to a relative error of $\sim 50\%$ of the single field approximation compared to the full three field solution.

C Sensitivity of GW interferometers

In this section we briefly discuss the interpretation and generation of the sensitivity curves used to define detection of a GW signal. We follow standard definitions and conclusions obtained in [106–109], see also [110] and references therein. The detection sensitivity for GW background for a given experimental setup, is given by the integrated signal-to-noise ratio (SNR) over an observation time interval t_{obs} as

$$\rho = \frac{\langle S \rangle}{\langle N^{1/2} \rangle} = \left[n_{\text{det}} t_{\text{obs}} \int_{f_{\text{min}}}^{f_{\text{max}}} df \left(\frac{S_S(f)}{S_N^{\text{eff}}(f)} \right)^2 \right]^{1/2}, \quad S_N^{\text{eff}}(f) = \frac{D_N(f)}{\mathcal{R}(f)}, \quad (\text{C.1})$$

where $\langle S \rangle$ is the mean signal, $\langle N^{1/2} \rangle = \sqrt{\langle S_{IJ}^2 \rangle - \langle S_{IJ} \rangle^2}$ is the average noise, $I, J = 1, 2$ indicate coupled detectors, n_{det} distinguishes between experiments that aim at detecting

the signal by means of an auto-correlation of a single detector ($n_{det} = 1$) or a cross-correlation of a couple of detectors ($n_{det} = 2$) measurement. The effective noise strain can be written in terms of the noise strain power spectrum $D_N(f)$ and the frequency dependent detector response function $\mathcal{R}(f)$. The latter quantities are the ones typically reported by the experimental collaborations. The detector response becomes more intricate in the case of correlated detectors [109], where an overlap detection function must be computed. We perform the appropriate procedure when computing the relevant SNR. The signal/noise strains can be rewritten in terms of the signal/noise spectrum density as

$$\Omega_{S/N}(f) = \frac{2\pi^2 f^3}{3H_0^2} S_{S/N}(f), \tag{C.2}$$

so that eq. (C.1) becomes

$$\rho = \left[n_{det} t_{obs} \int_{f_{min}}^{f_{max}} df \left(\frac{\Omega_S(f)}{\Omega_N(f)} \right)^2 \right]^{1/2}, \tag{C.3}$$

where in this paper $\Omega_S(f)$ will be the energy density of a SGWB produced by the SUSY-breaking FOPT in the early universe redshifted till today (see eq. (2.26)). The frequency interval (f_{min}, f_{max}) is determined by the bandwidth of each experiment, typically related to the length scale of each detector. This integrated quantity will imply detection if it surpasses a predefined threshold value $\rho^2 \geq \rho_{thr}^2$ set by bayesian probabilistic measures [106], usually taken between 3 and 10.

By defining a frequency dependent shape function which models the expected signal one can define the sensitivity of a given experiment even though this procedure does not provide a precise statistical indication of the expected sensitivity as the signal to noise ratio in eq. (C.3). Depending on how well the signal shape is approximated, sensitivity curve based on the shape function approximation can provide an instructive visual tool for estimating detection in a frequency dependent way. In the following section we discuss the most common method of generating sensitivity curves for 1OPT GW signal detection.

C.1 PLI curves

Power Law Integrated (PLI) curves are generated by considering a power law function of the frequency f for the GW signal shape. The most common assumption, is a power law of the form

$$h^2 \Omega_S(f) = h^2 \tilde{\Omega}_{S,b}(\tilde{f}) \left(\frac{f}{\tilde{f}} \right)^b, \tag{C.4}$$

where b is known as the spectral index. Taking this assumption we obtain the integrated SNR as [111, 112]

$$h^2 \tilde{\Omega}_{S,b}(\tilde{f}) > h^2 \tilde{\Omega}_{GW,b}^{thr}(\tilde{f}) \equiv \frac{\rho_{thr}}{\sqrt{t_{obs} n_{det}}} \left[\int_{f_{min}}^{f_{max}} df \left(\frac{(f/\tilde{f})^b}{h^2 \Omega_N(f)} \right)^2 \right]^{-1/2}. \tag{C.5}$$

Finally, we can define the PLI sensitivity curve by maximizing the integrated SNR over the spectral index b , that is

$$h^2 \Omega_{PLI}(\tilde{f}) \equiv h^2 \max_b \left[\tilde{\Omega}_{S,b}^{thr}(\tilde{f}) \right], \tag{C.6}$$

Figure 15. PLI curves for the different experiments considered here with the threshold value for the signal to noise ratio is conservatively fixed to $\rho_{\text{thr}} = 10$. The required data to derive a PLI curve for every experiment are collected in table 1.

which gives the threshold value for the signal at each frequency. A curve which crosses the threshold value at a given frequency will therefore represent a detectable signal, assuming an approximate power law behavior. Given that GW signals from FOPTs have a broken power law shape, the method described here is typically appropriate to visualize the sensitivity of a given experiment. In figure 15 we summarize the PLI curves for the different GW interferometers considered here.

C.1.1 Experimental parameters

For completeness we recompute here the PLI curves as described in the previous section for ground based interferometers such as The Laser Interferometer Gravitational Wave Observatory (LIGO) [17], the Einstein Telescope (ET) [18], the Cosmic Explorer (CE) [19, 20] and the Atom Interferometer Observatory and Network (AION) [121], as well as for space based detectors such as The Laser Interferometer Space Antenna (LISA) [113], the Big Bang Observer (BBO) [116], the Deci-Hertz Interferometer Gravitational-Wave Observatory (DECIGO) [122–124] and the Atomic Experiment for Dark Matter and Gravity Exploration (AEDGE) [120]. While many more experiments are planned in the future, such as AIGSO [125, 126], AMIGO [127], Taiji [128], TianGO [129], TianQin [130, 131] and more, we focus on the ones cited above as representatives of the potential detection range in coming years.

In order to determine the reach of a given experiment, we need to know the frequency band, the response function of the detector $\mathcal{R}(f)$ within this band, the measured noise

	n_{det}	t_{obs} (months)	Δf (Hz)	$\mathcal{R}(f), \Gamma_{IJ}(f), D_{\text{noise}}(f), S_{\text{noise}}(f)$
LISA	1	48	$[10^{-5}, 1]$	[11, 80, 113]
DECIGO	2	48	$[10^{-3}, 10]$	[114, 115]
BBO	2	48	$[10^{-3}, 10]$	[112, 116]
CE	1	60	[4.98, 5000]	[19]
ET	2	60	[1.12, 7066.72]	[18]
LIGO	2	20	[4.98, 4978]	[17, 112, 117–119]
AEDGE	2	60	[0.006, 14.83]	[120]
AION	1	60	[0.1, 1.84]	[121]

Table 1. Summary of the experimental parameters used in generating PLI curves for GW detection in this work. Auto/cross-correlation measurement is indicated by $n_{\text{det}} = 1(2)$, the observation time and bandwidth for each experiment are presented above. The detector response $\mathcal{R}(f)$, multiple detector overlap function $\Gamma_{IJ}(f)$ and noise strain spectrum $D_{\text{noise}}(f), S_{\text{noise}}(f)$ are extracted from the references herein.

at every accessible frequency $D_{\text{noise}}^I(f)$, the time of observation t_{obs} and the number of coupled detectors n_{det} . We report the extracted parameters for the various experiments in the table 1.

ABSTRACT: We study the Singlet-Doublet dark matter model in the regime of feeble couplings, where the dark matter abundance is obtained via the freeze-in mechanism. As a consequence of the small couplings, the heavier particles in the model are long-lived with decay length at typical scales of collider experiments. We analyse the collider signatures of the model, characterised by displaced h and Z bosons plus missing momentum, employing current LHC searches for displaced vertices and missing energy to significantly constrain the parameter space of the model. We also take into account the cosmological bounds relevant for our light dark matter candidate arising from Lyman- α forest constraints. Our analysis emphasises the interplay between displaced signatures at the LHC and cosmology for dark matter candidates whose relic abundance is obtained through the freeze-in mechanism.

1 Introduction

Compelling observational evidence supports the existence of dark matter (DM), the most abundant form of matter in the Universe [1]. Yet, at present, the nature of the dark sector, possibly including dark matter particle(s) and new mediators driving the interactions between dark matter and the Standard Model (SM), is still unknown. In the last decades most of the attention has been devoted to the weakly interacting massive particle (WIMP) paradigm, in which dark matter is a new type of elementary particle with weak-type interactions with the SM. In WIMP models the abundance of the dark matter is obtained through the freeze-out mechanism. The weak couplings involved typically imply a viable — i.e. giving rise to the observed relic abundance — dark matter particle with mass of the order of the electroweak (EW) scale. This remarkable coincidence — the so-called *WIMP miracle* — has motivated a large effort in the study of WIMP dark matter scenarios both

in top-down approaches, triggered by supersymmetry, and bottom-up approaches focusing on effective theories and simplified models. In the latter framework, an important effort has been deployed in the last years to characterise dark matter simplified model parameter space, to search for the dark matter particle and the associated mediators at colliders, and to explore the complementarity between the LHC, the direct and indirect detection experiments, see e.g. [2–4]. The recurrent null results in the search for WIMPs (both at the LHC and in direct/indirect detection experiments) provide good motivations though to take a step back and to investigate alternative dark matter paradigms and to study thoroughly their phenomenology.

Here we focus on the so-called *freeze-in* mechanism for producing a *feebly* coupled dark matter candidate, i.e. particles that were not in thermal equilibrium with the SM in the early universe, see e.g. [5–7]. Because of the very small coupling involved, these models can give rise to displaced signatures at the LHC in terms of long-lived mediators decaying into dark matter plus SM fields, as it has already been underlined in a number of works [5, 8–11]. Long-lived particles and displaced signatures at colliders in relation to dark matter simplified models have been discussed also in [12–18]. The requirement of a viable frozen-in dark matter scenario giving rise to displacement at colliders of detector size points directly towards light dark matter candidates, with a mass of the order of the keV [5]. This is typically the mass scale currently tested by cosmology and astrophysics probes in the framework of warm dark matter scenarios, see e.g. [19–21], that lead to the suppression of the small scale structure formation and, by the same token, can help to alleviate the small scale crisis [22–27] in the Λ CDM (the Standard Cosmological scenario) see e.g. the discussion in [28–35]. On the other hand, due to the feeble coupling involved, direct and indirect detection dark matter searches are challenging, see however e.g. [36–39].

In this paper we will study how the combination of collider and cosmological constraints can probe a significant portion of the parameter space of frozen-in dark matter models. First, note that the long-lived mediators typically possess sizeable couplings with the SM particles that keep them in thermal equilibrium with the SM bath, and thus they can copiously be produced at the LHC. Second, the reach of displaced vertex signatures at the LHC can actually extend beyond the regime where the mean decay length of the heavy mediator, $c\tau$, is within the tracking detector with typical radius $\simeq 1$ m. This is because of the background-free nature of displaced signatures and because of the exponential decay distribution.¹ In general, the study of displaced signatures with missing energy at the LHC is thus a powerful probe of frozen-in dark matter in the small mass regime (keV to a few MeV), complementing the existing constraints from astro-physics and cosmology on light free-streaming DM candidates.

For concreteness, we focus here on the Singlet-Doublet dark matter model [41–52]. In the Singlet-Doublet model, the SM is augmented with a pair of electroweak doublet Weyl fermions and one Majorana singlet, interacting with the SM Higgs via Yukawa couplings. The dark sector contains thus a charged fermion and three neutral fermions, whose lightest

¹The latter is indeed such that a substantial fraction of the mediators produced at LHC would decay within the detector even for $c\tau > 1$ m, see e.g. [40].

state constitutes a stable dark matter candidate. Within the freeze-in regime of such model, the Yukawa couplings are feeble and thus the dark matter particle is mostly singlet while the role of the long-lived mediators is played by the components of the electroweak doublets. Two of them are neutral and hence a smoking-gun signature of this scenario at the LHC consists of displaced Higgs bosons or Z -bosons plus missing momentum. We analyse the LHC sensitivity on such interesting final states by recasting an existing ATLAS search for displaced vertices and missing energy [53]. Making use of the large statistics already collected, we show that the proper decay length that can be (will be) tested is actually significantly larger than the detector size, reaching more than 10 (100) meters. In the corresponding parts of the parameter space with the correct dark matter abundance, this currently constrains the dark matter mass to be as large as 500 keV and could reach a few MeV with 300 fb^{-1} , hence well beyond the warm dark matter regime.

The rest of the paper is organised as follows. In section 2, we discuss the model in the feeble-coupling regime and analyse the decay modes of the dark sector particles. Section 3 is devoted to the calculation of the abundance of dark matter produced through the freeze-in mechanism. We then study the constraints on light dark matter from cosmology in section 4. In section 5, we analyse in detail the main collider signatures — disappearing charged tracks, as well as displaced Higgs or Z plus missing transverse momentum (\cancel{E}_T) — of our scenario and we present the recasting of the ATLAS search [53]. In section 6, we combine the results of the previous sections and show the interplay between collider and cosmological signatures in probing our model of freeze-in dark matter. We summarise and conclude in section 7, while we present some technical details in the appendices.

2 The feebly-coupled Singlet-Doublet DM model

We perform our analysis within the Singlet-Doublet dark matter model [41], which consists in adding to the SM a pair of Weyl doublet fermions, ψ_u and ψ_d , with opposite hypercharges and one fermionic singlet, ψ_s :

$$(\psi_u)_{2, \frac{1}{2}} = \begin{pmatrix} \psi^+ \\ \psi_u^0 \end{pmatrix}, \quad (\psi_d)_{2, -\frac{1}{2}} = \begin{pmatrix} \psi_d^0 \\ \psi^- \end{pmatrix}, \quad (\psi_s)_{1, 0}. \quad (2.1)$$

The subscripts indicate the $SU(2)_L \times U(1)_Y$ quantum numbers and these new fields are assumed to be odd under an unbroken Z_2 symmetry, under which the SM fields are even, so as to guarantee the stability of dark matter.

The mass terms and Yukawa interactions of the model read

$$-\mathcal{L} \supset \mu \psi_d \cdot \psi_u + y_d \psi_d \cdot H \psi_s + y_u H^\dagger \psi_u \psi_s + \frac{1}{2} m_s \psi_s \psi_s + h.c., \quad (2.2)$$

where H is the Higgs doublet (with hypercharge 1/2) and \cdot indicates a contraction of the $SU(2)_L$ indices through the antisymmetric tensor ϵ_{ab} , see appendix A for more details. For later convenience, we also define the following alternative parameterisation of the two Yukawa couplings:

$$y_u \equiv y \sin \theta, \quad y_d \equiv y \cos \theta. \quad (2.3)$$

As is apparent from the field content, the model is a generalisation of the “Bino-Higgsino” system of supersymmetric models with free couplings y_u and y_d (whereas supersymmetry would relate them to the SM gauge couplings).

2.1 The spectrum

Upon EW-symmetry breaking, the Lagrangian in eq. (2.2) leads to mixing among the neutral components $(\psi_s, \psi_d^0, \psi_u^0)$ of the Z_2 -odd fermions. The resulting mass matrix reads

$$\mathcal{M} = \begin{pmatrix} m_s & \frac{y_d v}{\sqrt{2}} & \frac{y_u v}{\sqrt{2}} \\ \frac{y_d v}{\sqrt{2}} & 0 & \mu \\ \frac{y_u v}{\sqrt{2}} & \mu & 0 \end{pmatrix}, \quad (2.4)$$

where $v \simeq 246$ GeV is the vev of the Higgs field. The above matrix is diagonalised by a rotation matrix U , $UMU^T = \hat{\mathcal{M}}$. The mass eigenstates are then given by

$$(\chi_1, \chi_2, \chi_3)^T = U (\psi_s, \psi_d^0, \psi_u^0)^T. \quad (2.5)$$

We employ the convention $|m_{\chi_1}| < |m_{\chi_2}| < |m_{\chi_3}|$, thus our dark matter candidate is χ_1 .

The model has already been extensively investigated within the framework of the freeze-out mechanism of dark matter production [41–52]. The latter requires the couplings y_u and y_d to be of the order of $10^{-2} - 1$ for the Yukawa interactions to drive the relic abundance to the observed one. In that case the model is constrained by direct and indirect detection experiments and also features interesting collider signatures, typically resembling the Bino-Higgsino system of supersymmetric models (but with arbitrary Yukawa couplings). In contrast, in this work, we focus on the freeze-in mechanism of dark matter production associated to very feeble Singlet-Doublet interactions. As it will become clear from the discussion in section 3, the typical Yukawa couplings of interest for our analysis range from 10^{-9} to 10^{-6} and a large mass difference between the singlet and the doublet mass-scales will have to be considered: $|m_s| \ll |\mu|$. As a result, the model features suppressed mixing between the singlet and doublet and the singlet fermion $\psi_s \simeq \chi_1$ is the lightest of the neutral fermions.

In the limit

$$|y_u|, |y_d| \ll 1, \quad |m_s| \ll |\mu|, \quad (2.6)$$

we can expand the mass eigenvalues at the first order in $y_{u,d}^2$ and get²

$$\begin{aligned} m_{\chi_1} &= m_s + \frac{v^2 (y_u - y_d)^2}{4 (\mu + m_s)} - \frac{v^2 (y_u + y_d)^2}{4 (\mu - m_s)}, \\ m_{\chi_2} &= -\mu - \frac{v^2 (y_u - y_d)^2}{4 (\mu + m_s)}, \\ m_{\chi_3} &= \mu + \frac{v^2 (y_u + y_d)^2}{4 (\mu - m_s)}. \end{aligned} \quad (2.7)$$

From these expressions, we see that, in the feebly-coupled regime, there is one neutral state of mass approximately m_s (corresponding to $\chi_1 \sim \psi_s$), two neutral fermions $\chi_{2,3}$

²An approximate expression of the corresponding rotation matrix U is given in appendix A.

Figure 1. Mass spectrum of the Singlet-Doublet model considered here and possible decay modes.

with mass approximately μ (equal mixture of ψ_u^0 and ψ_d^0), and one charged fermion with mass $m_\psi = \mu$, that we denote with ψ^\pm .

The set of states with tree-level mass μ is further split by quantum corrections at one loop, which increases the mass of the charged state. Using the results of [54], one finds that the splitting between the charged and the neutral states is

$$\Delta M = |m_\psi| - |m_{\chi_{2,3}}| = \frac{\alpha_2 \mu}{4\pi} \sin^2 \theta_W f\left(\frac{m_Z}{\mu}\right), \quad (2.8)$$

$$f(x) = \frac{x}{2} \left(2x^3 \log x - 2x + \sqrt{x^2 - 4}(x^2 + 2) \log \left[\frac{1}{2}(x^2 - 2 - x\sqrt{x^2 - 4}) \right] \right),$$

where $\alpha_2 = g^2/(4\pi)$ (with g being the $SU(2)_L$ gauge coupling) and θ_W is the weak mixing angle. Considering $|\mu| > 100$ GeV, ΔM spans the following range

$$250 \text{ MeV} \lesssim \Delta M \lesssim 350 \text{ MeV}. \quad (2.9)$$

A sketch of the spectrum of the model and the possible decay modes, described in the next section, is shown in figure 1.

2.2 Decay modes and decay lengths

In this subsection we study the decay modes of the fermion mass eigenstates in the feeble coupling regime that control the phenomenology of the model. General expressions for the decay widths through the model’s Yukawa interactions can be found in the appendix of ref. [47], while here we specialise to the regime of (2.6) making use of the expression for the mixing matrix reported in appendix A.

Throughout this work, we consider $|\mu| > m_W$ as a doublet mass lower than about 90 GeV is excluded by searches for charged fermions performed at LEP (see [55], for a recent reassessment). In this regime, the heavy charged states ψ^\pm can decay directly into the lightest mass eigenstate, $\psi^\pm \rightarrow W^\pm \chi_1$, via the suppressed Singlet-Doublet mixing, or to the heavier neutral states (\sim neutral components of the doublet) and a soft pion, $\psi^\pm \rightarrow \pi^\pm \chi_{2,3}$, via gauge interactions. The latter decay mode occurs via an off-shell W and, for the range of charged-neutral state mass splitting reported in eq. (2.9), it dominates over possible leptonic modes involving $\ell^\pm \nu$ instead of π^\pm . Half of the decays into pions

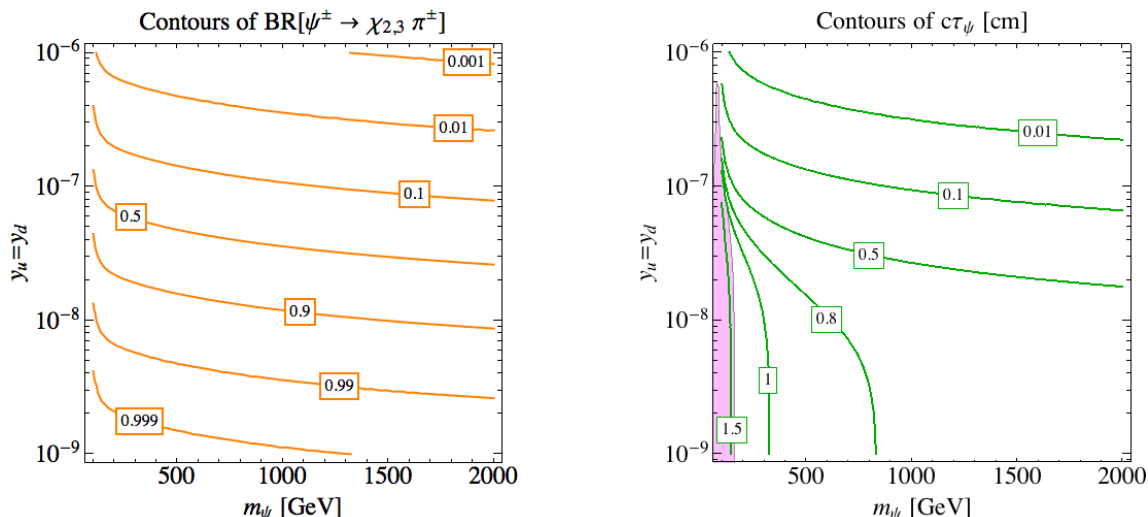

Figure 2. Left: branching ratios of the decay of the charged fermion into $\chi_{2,3}$ plus a pion. Right: decay length (in cm) of the charged fermion; the shaded region is excluded by the ATLAS search for disappearing tracks [57, 58]. The mass of the lightest neutral fermion is fixed to $m_{\chi_1} = 10$ keV.

plus neutral states go to $\pi^\pm \chi_2$ and the other half to $\pi^\pm \chi_3$, with the partial decay widths given by [56]:

$$\Gamma[\psi^\pm \rightarrow \pi^\pm \chi_{2,3}] = \frac{G_F^2}{2\pi} \cos^2 \theta_c f_\pi^2 \Delta M^3 \sqrt{1 - \left(\frac{m_\pi}{\Delta M}\right)^2}, \quad (2.10)$$

where $f_\pi \simeq 130$ MeV, G_F is the Fermi constant and θ_c the Cabibbo angle. As mentioned above, this decay mode competes with the decay into the lightest fermion eigenstate $W^\pm \chi_1$ induced by the small Singlet-Doublet mixing. At leading order in the Yukawa couplings, taking $\tan \theta = 1$ (i.e. $y_u = y_d = \frac{y}{\sqrt{2}}$), the decay width reads (for $\mu \geq 0$):

$$\Gamma[\psi^\pm \rightarrow W^\pm \chi_1] = \frac{\alpha y^2 v^2}{32 s_W^2} \sqrt{\lambda(m_\psi^2, m_{\chi_1}^2, m_W^2)} \times \frac{((m_\psi \pm m_{\chi_1})^2 + 2m_W^2) ((m_\psi \mp m_{\chi_1})^2 - m_W^2)}{m_\psi^3 m_W^2 (\mu - m_s)^2}, \quad (2.11)$$

where

$$\lambda(a, b, c) = a^2 + b^2 + c^2 - 2ab - 2ac - 2bc,$$

α is the electromagnetic constant, and $s_W \equiv \sin \theta_W$. It can be shown that $\Gamma[\psi^\pm \rightarrow W^\pm \chi_1]$ has a negligible dependence on $\tan \theta$ in the limit (2.6), and hence the formula (2.11) will suffice to our purposes.

Making use of eqs. (2.10) and (2.11), we show in figure 2 the branching ratios for the decay process $\psi^\pm \rightarrow \pi^\pm \chi_{2,3}$ (left panel) and the contours for fixed values of the charged fermion decay length $c\tau_\psi$ (right panel) on the (m_ψ, y) plane in the custodial symmetry limit $y_u = y_d$ for $m_{\chi_1} = 10$ keV. We can see that for $y \leq 10^{-8}$ the decay mode into $\pi^\pm \chi_{2,3}$ is the dominant one. Moreover, comparing the two panels of figure 2, we can see that, when ψ^\pm decays preferably into pions plus heavy neutral state, the decay length is about 1 cm

that is approximately the minimal length, to which LHC searches for disappearing charged tracks have sensitivity. For illustrative purposes, we thus also show, in the right panel of figure 2, a purple region excluded by a recent ATLAS analysis [57, 58]. We will address the collider constraints in more details in section 5. Let us mention that the overall picture depends neither on m_{χ_1} nor on $\tan\theta$ in the limit (2.6) that we are interested in here.

The two neutral states χ_2 and χ_3 can decay either into $Z\chi_1$ or into $h\chi_1$ through the Yukawa interactions. At leading order in y_u and y_d , the decay widths read (for $\mu \gtrsim 0$):

$$\Gamma[\chi_2 \rightarrow Z\chi_1] = \frac{\alpha(y_u + y_d)^2}{64s_W^2 c_W^2} \sqrt{\lambda(m_{\chi_2}^2, m_{\chi_1}^2, m_Z^2)} \times \frac{v^2((m_{\chi_2} \pm m_{\chi_1})^2 + 2m_Z^2)((m_{\chi_2} \mp m_{\chi_1})^2 - m_Z^2)}{m_{\chi_2}^3 m_Z^2 (\mu - m_s)^2}, \quad (2.12)$$

$$\Gamma[\chi_3 \rightarrow Z\chi_1] = \frac{\alpha(y_u - y_d)^2}{64s_W^2 c_W^2} \sqrt{\lambda(m_{\chi_3}^2, m_{\chi_1}^2, m_Z^2)} \times \frac{v^2((m_{\chi_3} \mp m_{\chi_1})^2 + 2m_Z^2)((m_{\chi_3} \pm m_{\chi_1})^2 - m_Z^2)}{m_{\chi_3}^3 m_Z^2 (\mu + m_s)^2}, \quad (2.13)$$

$$\Gamma[\chi_2 \rightarrow h\chi_1] = \frac{(y_u - y_d)^2}{64\pi} \frac{(m_{\chi_2} \mp m_{\chi_1})^2 - m_h^2}{m_{\chi_2}^3} \sqrt{\lambda(m_{\chi_2}^2, m_{\chi_1}^2, m_h^2)}, \quad (2.14)$$

$$\Gamma[\chi_3 \rightarrow h\chi_1] = \frac{(y_u + y_d)^2}{64\pi} \frac{(m_{\chi_3} \pm m_{\chi_1})^2 - m_h^2}{m_{\chi_3}^3} \sqrt{\lambda(m_{\chi_3}^2, m_{\chi_1}^2, m_h^2)}, \quad (2.15)$$

after having redefined the fermionic fields in order for m_{χ_i} to be positive. Notice that, in practice, in the regime of (2.6), the above decay widths are not affected by the sign of μ . The typical decay lengths of χ_2 (solid line) and χ_3 (dashed line) are shown as a function of their mass in figure 3 for two values of $\tan\theta$ and $m_s = 10$ keV. As can be seen, for a y coupling of the order 10^{-7} , the decay length is around 1 cm, while it exceeds 10 m for $y \sim 10^{-9}$. In addition, the decay lengths of χ_2 and χ_3 appear to be essentially equal for $m_{\chi_{1,2}} \gtrsim 300$ GeV or for $\tan\theta \gg 1$. Let us also emphasize that, in the limit of eq. (2.6), the decays $\chi_3 \rightarrow \chi_2$ are not allowed due to the tiny mass splittings, as it can be verified by inspecting the expressions in eq. (2.7).

3 Dark matter abundance from Freeze-in

In the feeble Yukawa coupling regime that we are considering, the dark matter candidate $\chi_1 \sim \psi_s$ has strongly suppressed interactions with the SM particles. Hence it is not in thermal equilibrium with the SM bath at the time of production. In contrast, the components of the electroweak doublet are in thermal equilibrium because of their unsuppressed gauge interactions. Assuming zero initial abundance of χ_1 , the dominant production mechanism for the dark matter particle is through the decay of the heavy mediators (ψ^\pm and $\chi_{2,3}$) along the cosmological evolution.³ This production “freezes-in” when the abundance of

³In our model, the scattering processes with χ_1 in the final state give definitely subdominant contributions with respect to mediators’ decays, such as in e.g. [5]. Moreover, decays of SM particles into DM, such as $Z \rightarrow \chi_1\chi_1$ and $h \rightarrow \chi_1\chi_1$, also give negligible contributions, because doubly suppressed by the tiny Singlet-Doublet mixing.

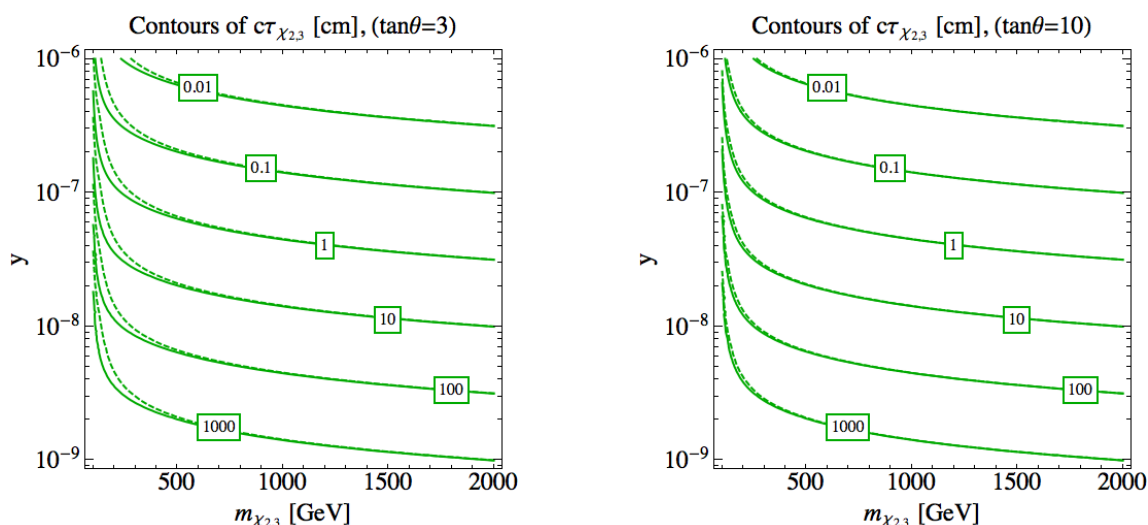

Figure 3. Decay length of the two heavy neutral fermions, χ_2 (solid lines) and χ_3 (dashed lines) for two different choices of $\tan \theta = y_u/y_d$. The mass of the lightest neutral fermion is set to $m_{\chi_1} = 10$ keV.

the heavy mediators is Boltzmann suppressed, that is approximately when the temperature drops below their mass. This is the framework in which we carry out our analysis; see e.g. [5–9, 11, 59, 60] for some previous examples. The DM comoving number density induced through the decay of $A \rightarrow B \chi_{\text{DM}}$ simply reduces to [5]

$$Y_{\chi_{\text{DM}}} = \frac{135g_A}{(1.66)8\pi^3g_*^{3/2}} \frac{M_{\text{Pl}}\Gamma_A}{m_A^2}, \tag{3.1}$$

where g_A counts the spin degrees of freedom of the mother particle A , g_* is the number of degrees of freedom at the freeze-in temperature $T \sim m_A$, and $M_{\text{Pl}} = 1.22 \times 10^{19}$ GeV is the Planck mass. This result is obtained making the following simplifying assumptions: (i) the mother particle A and the daughter particle B are in thermal equilibrium with the SM thermal bath; (ii) A follows a Maxwell-Boltzmann distribution function; (iii) we can neglect the Pauli-blocking/stimulated emission effects associated to B . See also the discussion in [61].

Let us notice that the freeze-in mechanism considered here — taking place through the decay of a mediator that is in thermal equilibrium with the Standard Model sector in the early universe — shares some similarities with the so-called superWIMP mechanism [62]. In the latter case, the late decay of the WIMP mother particle — occurring considerably after its freeze-out — give rise to the dark matter abundance. The main difference between the two mechanisms is the life-time of the mother particle in thermal contact with the Standard Model. In the superWIMP case, the life-time is typically much longer ($\tau \sim 10^5 - 10^8$ s) and the scenario is subject to constraints from big bang nucleosynthesis [62, 63].

3.1 Freeze-in: collider and cosmology interplay

In the context of the Singlet-Doublet model, three mass degenerate heavy states can decay into dark matter, namely the charged fermion ψ^\pm and the two neutral fermions $\chi_{2,3}$, giving rise to the DM yield:

$$Y_{\chi_1} = \frac{270M_{\text{Pl}}}{(1.66)8\pi^3 g_*^{3/2}} \left(\sum_{B=Z,h} \frac{\Gamma[\chi_3 \rightarrow B\chi_1]}{m_{\chi_3}^2} + \sum_{B=Z,h} \frac{\Gamma[\chi_2 \rightarrow B\chi_1]}{m_{\chi_2}^2} + g_\psi \frac{\Gamma[\psi^+ \rightarrow W^+\chi_1]}{m_\psi^2} \right), \quad (3.2)$$

where $g_\psi = 2$ takes into account the number of degrees of freedom of the charged fermion. Notice that the contributions of the heavy neutral fermions $\chi_{2,3}$ directly depend on the total decay widths of $\chi_{2,3}$, which we will denote $\Gamma_{\chi_{2,3}}$ in the following, as the decays into χ_1 are the only available decay modes. On the other hand, for the charged fermion, only the partial decay width into the $W^+\chi_1$ final state appears since the ψ^\pm decays into $\chi_{2,3}$ are already accounted for by the two first contributions associated to the thermal equilibrium abundances of $\chi_{2,3}$. We can now compute the DM relic density in terms of Y_{χ_1} :

$$\Omega_{\chi_1} h^2 = m_{\chi_1} \frac{s_0 h^2}{\rho_c} Y_{\chi_1}, \quad (3.3)$$

where the present entropy density and critical density are respectively $s_0 = 2.8912 \times 10^9 \text{ m}^{-3}$ and $\rho_c = 10.537 h^2 \text{ GeV}/\text{m}^3$. Considering that, in our scenario, we have $m_{\chi_{2,3}} \simeq m_\psi \simeq \mu$, we obtain as a result

$$\Omega_{\chi_1} h^2 = 0.1 \left(\frac{105}{g_*} \right)^{3/2} \left(\frac{m_{\chi_1}}{10 \text{ keV}} \right) \left(\frac{1 \text{ TeV}}{\mu} \right)^2 \left(\frac{\sum_{ij} g_{A_i} \Gamma_{ij}}{5 \times 10^{-15} \text{ GeV}} \right), \quad (3.4)$$

where g_{A_i} is the number of degrees of freedom of the mother particle A_i , Γ_{ij} denotes the decay width $\Gamma[A_i \rightarrow B_j \chi_1]$, with $A_i = \chi_{2,3}^0$ or ψ^\pm decaying into χ_1 plus a SM boson, $B_j = Z, h$ or W^\pm .

Obtaining the dark matter yield on more general grounds, starting from Maxwell-Boltzmann statistics, requires a fully numerical treatment of the evolution equations, which makes the computation and the interpretation of the freeze-in mechanism less straightforward. The authors of ref. [61] have however recently delivered the public code `micrOMEGAs5.0` that allows to easily handle such computations. We have explicitly checked that the analytical results presented here are in excellent agreement with the ones obtained with `micrOMEGAs5.0` (employing the Singlet-Doublet model files from our implementation in `FeynRules` [64]) in the Maxwell-Boltzmann limit.⁴ Beyond this simplifying assumption, the full numerical treatment of the evolution equations gives rise to a moderate positive correction to $\Omega_{\chi_1} h^2$ with respect to our analytical result (about 25%). In this paper, we choose to discuss the results of our analysis with the Maxwell-Boltzmann approximation, thus neglecting the above small correction, in order to have a fully analytical understanding of the parameter space of the model yielding the observed DM abundance.

⁴See ref. [61] for a discussion on the relevance of the statistics in different dark matter scenarios.

The result of eq. (3.4) is rather generic for the freeze-in scenarios, independently of the underlying dark matter model, and indicates the typical order of magnitude of the physical quantities involved, that is the dark matter mass, the mediator(s) mass, and the mediator(s) widths. Note that the decay length of a particle is related to the total decay width through

$$c\tau_A = \frac{10^{-15} \text{ GeV}}{\Gamma_A} \times 19 \text{ cm}. \quad (3.5)$$

Hence mother particles or equivalently mediators, A , with a total decay width allowing for the dark matter density to be in agreement with the observed abundance $\Omega h^2 \simeq 0.12$, are in the right ballpark to give rise to macroscopically long displacements at colliders. In order for the mediators to be produced at the LHC, their mass cannot typically exceed the TeV scale. For such mass scale, a DM mass in the heavy range $1 \text{ MeV} \lesssim m_{\chi_1} \lesssim 1 \text{ GeV}$ corresponds to mediators escaping the detectors, while for light dark matter, $1 \text{ keV} \lesssim m_{\chi_1} \lesssim 1 \text{ MeV}$, the signature will be characterised by displaced vertices visible inside the detectors. This highlights the natural interplay among LHC long-lived or displaced signatures, the freeze-in mechanism, and cosmological or astrophysical probes of light ($\simeq \text{keV}$) dark matter. An important remark is that these considerations and correlations are strictly correct for mediators that can decay into dark matter only, which is the case of $\chi_{2,3}$ here. We study this complementarity in further detail in sections 5 and 6.

3.2 The viable dark matter parameter space

We can now employ the decay widths that we computed in section 2.2 to derive the predicted value of the dark matter relic abundance on the parameter space of the Singlet-Doublet model. Expanding the expressions of the decay widths in the limit of small m_{χ_1} one finds at leading order:

$$\sum_{i=2,3} \Gamma[\chi_i \rightarrow Z\chi_1] = \frac{y^2}{32\pi} \frac{(m_Z^2 - \mu^2)^2 (2m_Z^2 + \mu^2)}{\mu^5} \quad (3.6)$$

$$\sum_{i=2,3} \Gamma[\chi_i \rightarrow h\chi_1] = \frac{y^2}{32\pi} \frac{(m_h^2 - \mu^2)^2}{\mu^3} \quad (3.7)$$

$$\Gamma[\psi^\pm \rightarrow W^\pm\chi_1] = \frac{y^2}{32\pi} \frac{(m_W^2 - \mu^2)^2 (2m_W^2 + \mu^2)}{\mu^5}. \quad (3.8)$$

These expressions show that the combinations of the decay widths entering in the computation of the relic abundance do not depend on $\tan\theta$ at zeroth order in m_{χ_1} . Plugging these expressions into eq. (3.3), we find the following approximate expression

$$\Omega_{\chi_1} h^2 \simeq 0.11 \left(\frac{105}{g_*}\right)^{3/2} \left(\frac{y}{10^{-8}}\right)^2 \left(\frac{m_{\chi_1}}{10 \text{ keV}}\right) \left(\frac{700 \text{ GeV}}{\mu}\right), \quad (3.9)$$

which accounts for the correct relic abundance up to a few percent level error when $\mu \gtrsim 400 \text{ GeV}$. Eq. (3.9) shows how the dark matter relic abundance via freeze-in scales with the different parameters of the model. The results of the dark matter calculations presented in what follows always make use of the full expressions of eqs. (3.2), (3.3) with $g_* = 105$.

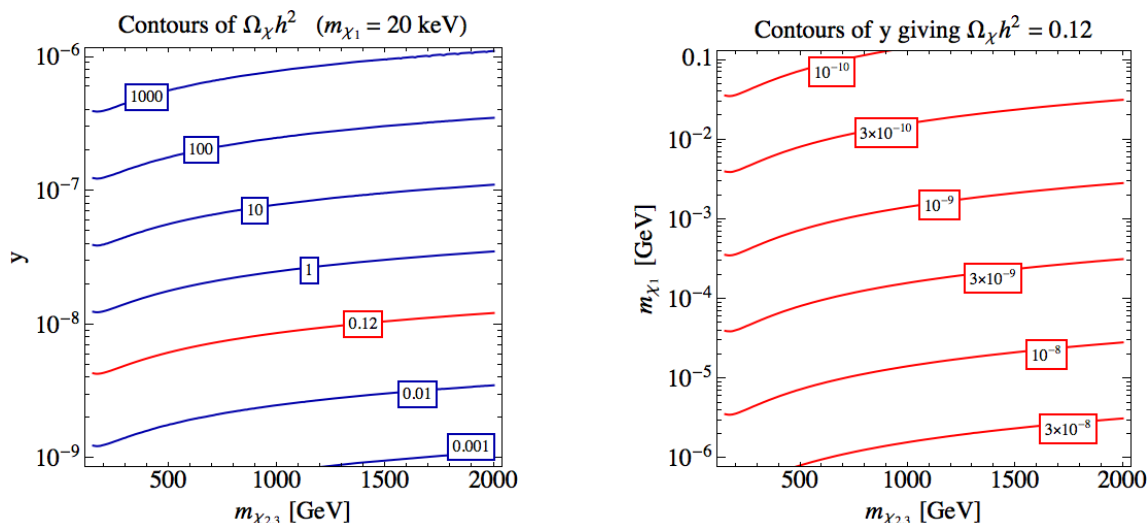

Figure 4. Left: contours of Ωh^2 for $m_{\chi_1} = m_s = 20$ keV. Right: contours of the values of y on the $(m_{\chi_{2,3}}, m_{\chi_1})$ plane required to get the observed DM relic abundance.

In the left panel of figure 4, we show the dependence of the dark matter abundance through the freeze-in mechanism on the parameters of the model for a fixed DM mass $m_{\chi_1} = 20$ keV on the $(m_{\chi_{2,3}}, y)$ plane, or equivalently (μ, y) plane. It appears that, for $m_{\chi_1} \sim$ few tens of keV, the coupling should be $y = \mathcal{O}(10^{-8})$ in order to reproduce the observed dark matter density. In the right panel of figure 4 instead, we show on the $(m_{\chi_{2,3}}, m_{\chi_1})$ plane contours of the values of the coupling y that yield $\Omega_{\chi_1} h^2 = 0.12$. We can see that, for m_{χ_1} in the [100 MeV, 1 keV] mass range and a μ scale of relevance for colliders, the required size of the Yukawa coupling is in the range

$$10^{-8} \lesssim y \lesssim 10^{-10}. \quad (3.10)$$

The largest values of the coupling $y \sim 10^{-8}$ allow for very light dark matter candidates (few keV) to account for all the dark matter while heavier particles of hundreds of MeV requires even more suppressed Yukawa interactions with $y \sim 10^{-10}$. This observation will be relevant when comparing the reach of collider experiments to the one of cosmology probes on the frozen-in Singlet-Doublet dark matter parameter space.

4 Cosmology probe of light dark matter

Dark matter candidates with non negligible velocity dispersion deep in the radiation dominated era can leave a distinctive imprint in cosmology and astrophysics observations due to their free-streaming that delays the structure growth. Overdensities are suppressed below the comoving free-streaming horizon given by

$$\lambda_{fs} = \int_0^1 \frac{\langle v \rangle}{a^2 H} da \quad (4.1)$$

where a is the scale factor and H is the Hubble rate and $\langle v \rangle$ is the velocity dispersion of the dark matter ($\langle v \rangle$ is given by the velocity of light for relativistic dark matter). For example,

thermal warm dark matter (WDM), which was in thermal equilibrium and relativistic until decoupling at temperature T_D , has a free-streaming length of $\lambda_{fs} \simeq \text{Mpc} (\text{keV}/m_X) T_D/T_\nu$ where T_ν is the temperature of active neutrinos and m_X is the WDM mass.⁵ Such a WDM scenario has served as a benchmark for non-cold dark matter cosmology. In this work we exploit the results of Lyman- α forest studies that have been used to set a lower bound on the thermal WDM mass of

$$m_{\text{WDM}} > 4.65 \text{ keV} \quad [\text{thermal WDM}] \quad (4.2)$$

at 95% confidence level (CL) [20]. Notice that the above constraint can e.g. relax to $m_{\text{WDM}} > 3.2 \text{ keV}$ at 95% CL when the WDM makes only part ($> 80\%$) of the total DM content [65]. It has also been argued that considering a different thermal history in the treatment of the Lyman- α forest data (especially the ones associated to high redshift quasars), a few keV DM candidate could even provide a good fit to the data, see [19, 65, 66], a possibility that is strongly challenged by X-ray constraints in the context of sterile neutrinos [65].

Thermal warm dark matter is not the only relic that would suppress small scale structure formation. Other DM candidates with non negligible velocity at the time of production will give rise to similar effect.⁶ Among them, one finds (non-)resonantly produced sterile neutrinos [78–82], sterile neutrinos from frozen-in scalars [83, 84], mixed dark matter scenarios [85] and — of interest for this paper — other frozen-in particles [5, 86–89]. The different mechanisms of production involved can typically give rise to distribution functions that can differ from the (thermal) Fermi-Dirac distribution. As a result, the imprint on the linear matter power spectrum should a priori be recomputed making use of the relevant Boltzmann codes. Dedicated hydrodynamical simulations should then be performed so as to extract the non-linear evolution of a baryon+DM population and properly compute the observables relevant to estimate the Lyman- α flux power spectra within a given DM scenario and compare with data. All this procedure is however beyond the scope of this paper.

Here we use the constraints that have been derived in refs. [86, 88] on keV dark matter produced through the freeze-in from the decay(s) of some thermalised mother particle A into the DM and another daughter particle B . In ref. [88], the suppression of the linear matter power spectrum in the freeze-in scenario has been computed and compared to the one of thermal WDM with a mass of 4.65 keV.⁷ This provided a constraint on the mass of

⁵The thermal abundance of WDM is given by $\Omega_X h^2 \simeq (T_D/T_\nu)^3 m_X / 94 \text{ eV}$ where $T_D/T_\nu = (g_*(T_\nu)/g_*(T_D))^{1/3}$ for entropy conservation with $g_*(T)$ the effective number of relativistic degrees of freedom and $g_*(T_\nu) = 10.75$. All together, an injection of large number of relativistic degrees ($> 10^4$) of freedom is needed, compared to the available ones in the SM $g_*(T > T_{EW}) = 106.75$, so as to be able to get a thermal WDM of a still allowed few keV WDM [19–21].

⁶Notice that collisional or Silk damping (in contrast with free streaming \equiv collision-less damping) can also give rise to a similar imprint in small scale structures. This would be typically the case of dark matter interacting with relativistic species, see e.g. [67–77].

⁷In ref. [88], the transfer function of DM (associated to the ratio of cold DM and freeze-in DM linear matter power spectra) produced through freeze-in from the decays of some thermalised mother particle $A \rightarrow B + \text{DM}$ always appear to have the very same spectral form as the one of thermal WDM. For other references, estimating the range of viable non-cold dark matter candidates based on the derivation of the linear matter power spectrum, see e.g. [71, 85, 87, 90–92].

Figure 5. Bound on the DM mass from Lyman- α ; the area below the curve is excluded.

the frozen-in dark matter particle that shows a dependence on the mass splitting between A and B for compressed spectra. Within our framework, the resulting constraint on the dark matter mass reads:

$$m_{\text{DM}} > 12 \text{ keV} \left(\frac{\sum_{ij} g_{A_i} \Gamma_{ij} \Delta_{ij}^\eta}{\sum_{ij} g_{A_i} \Gamma_{ij}} \right)^{1/\eta}. \quad (4.3)$$

where $\eta = 1.9$ (as obtained in ref. [88] from a numerical fit), and Γ_{ij} is the decay width $\Gamma(A_i \rightarrow B_j \chi_1)$, $\Delta_{ij} = (m_{A_i}^2 - m_{B_j}^2)/m_{A_i}^2$ with $A_i = \chi_{2,3}^0$ and ψ^\pm denoting the mediators that decay into the dark matter fermion χ_1 and another SM final state $B_j = Z, h$ or W^\pm . The results of ref. [88] imply thus that, in general, frozen-in DM, resulting from the decay of a thermalised mother particle with $m_{\text{DM}} > 12 \text{ keV}$, evades the constraints from the Lyman- α forest data derived in [20]. Lower DM masses can become allowed when Δ_{ij} is small, i.e. for small mass splittings between A_i and B_j (as pointed out in [86]). Our bound is shown in figure 5 as a function of the doublet mass μ . As we can see, the lower bound on the DM mass becomes weaker than $m_{\chi_1} > 12 \text{ keV}$ only for values of the doublet mass μ approaching the mass of the decay products $B_j = Z, h, W^\pm$.

Notice that astrophysics and cosmology already provide other complementary probes of dark matter scenarios suppressing structure formation on small scales. Among them one finds CMB fluctuations, galaxy clustering, galaxy satellite number count, etc., see e.g. refs. [35, 71, 73, 76, 77, 93–97]; and also e.g. refs. [76, 77, 98–100] for future probes. Currently, most (combinations of) probes tend to exclude a few keV thermal warm dark matter scenarios, on a par with the results of the Lyman- α forest analysis considered here.

5 Signatures at the LHC

In the feebly-coupled regime of the Singlet-Doublet dark matter model, the mediators ψ^\pm and $\chi_{2,3}$ are essentially the charged and neutral components of the extra $\text{SU}(2)_L$ doublets. As a result, they can be produced at the LHC through electroweak processes. These

Figure 6. NLO production cross section of the states belonging to the fermion doublet pair at the LHC with $\sqrt{s}=13$ TeV as computed by `Prospino2` [101]. The solid red line indicates the sum over all possible production modes, while the dashed blue line shows the production cross section of the neutral states $\chi_2\chi_3$ only.

production processes are induced by gauge couplings only and thus the cross sections are independent of the couplings y_u and y_d . They are actually equal to those of a pure Higgsino in supersymmetry (SUSY) that can be computed using public tools such as `Prospino2` [101]. Referring to the SUSY nomenclature, the relevant production modes include neutralino pair production, chargino pair production, and associated production of neutralino and chargino:

$$pp \rightarrow \chi_2\chi_3 + X, \quad pp \rightarrow \psi^+\psi^- + X, \quad pp \rightarrow \chi_{2,3}\psi^\pm + X. \quad (5.1)$$

Being substantially decoupled from the SM sector, the singlet dark matter χ_1 can only be produced at the last step of the decay chain, with the possible decay modes as illustrated in figure 1. We report in figure 6 the total production cross section (obtained by summing over all mediator pair and associated production modes) with a continuous red line, and the production cross section of a $\chi_2\chi_3$ pair with a dashed blue line, as a function of the doublet mass scale μ . The cross sections were computed by means of `Prospino2` for pp collisions with $\sqrt{s} = 13$ TeV at next-to-leading order (NLO).

In order to obtain the collider constraints, we first have to compute the typical decay length of the heavy mediators in the viable dark matter parameter space, i.e. where $\Omega_{\chi_1} h^2 = 0.12$. In figure 7, we present the decay length of the mediators for the model parameters accounting for the whole observed dark matter abundance. In the left panel, we show contours for the decay length of the heavy neutral fermions, $c\tau_{\chi_{2,3}}$. On general grounds, the results depend on $\tan\theta$ but, as already noticed in figure 3, the $\tan\theta$ dependence is negligible as long as $\mu \gtrsim 300$ GeV or $\tan\theta \gg 1$. Also, as expected from the discussion in section 3, the figure shows that decay lengths leading to displaced signatures within the volume of LHC detectors correspond to the light dark matter regime, $m_{\chi_1} \lesssim 1$ MeV. On the right panel of figure 7, the dashed orange contours indicate the branching fraction of the ψ^\pm decay into pions and $\chi_{2,3}$. We see that this decay mode is dominant except in a small corner of the parameter space where $m_{\chi_1} = \mathcal{O}(1)$ keV and $m_\psi = \mu$ is larger

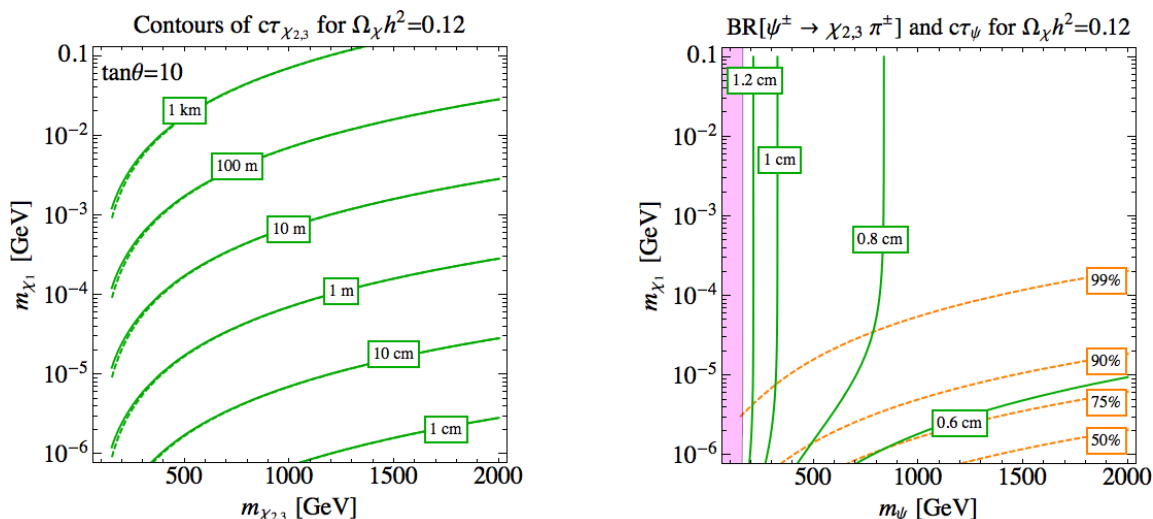

Figure 7. Left: decay length of the neutral fermions χ_2 (solid lines) and χ_3 (dashed lines). Right: branching ratio (orange dashed lines) and decay length (green solid lines) of $\psi^\pm \rightarrow \chi_{2,3} \pi^\pm$; the shaded region is excluded by searches for disappearing tracks [57, 58]. The coupling y is set in both plots by requiring $\Omega h^2 = 0.12$.

than about 1 TeV. The ψ^\pm decay mode into $W^\pm \chi_1$, driven by the Yukawa interactions and contributing to the dark matter relic abundance, is typically subdominant, due to the feeble couplings involved. As a consequence, the decay length of ψ^\pm is always of the order of 1 cm in the parameter region relevant for the freeze-in mechanism as shown by the green solid lines in the right panel of figure 7.

We can now discuss the LHC signatures of our freeze-in Singlet-Doublet model.

- Disappearing tracks:** independently of the final steps of the decay chain, the charged fermions ψ^\pm decay with a small displacement (of the order 1 cm at most, cf. figure 7) leading to ‘disappearing’ charged tracks that can be searched for at the LHC. In fact, a recent ATLAS analysis [57] (see also the similar search [102] from the CMS Collaboration), reinterpreted in [58] in terms of pure Higgsino production (which is exactly our case), excludes the regions shaded in purple in the right panels of figures 2 and 7. This search constrains the mass of the charged fermions to be larger than about 150 GeV in the regime in which $\psi^\pm \rightarrow \pi^\pm \chi_{2,3}$ dominates. For future prospects of searches for disappearing tracks and possible strategies to increase their sensitivity, see [103, 104], where Higgsino masses up to approximately 400 – 500 GeV are foreseen to be accessible at the future high-luminosity run of the LHC (HL-LHC).

- Displaced h and/or $Z + \cancel{E}_T$:** most of the mediator production modes will eventually produce a pair of heavy neutral fermions ($\chi_2 \chi_2$, $\chi_2 \chi_3$ or $\chi_3 \chi_3$), possibly with extra soft objects that will go undetected. Indeed, as shown above, the relic abundance requirement implies that the charged fermions decay dominantly into the heavy neutral ones, $\chi_{2,3}$, plus soft pions. Given the possible decay modes of $\chi_{2,3}$, our key collider signature is thus characterised by a final state with displaced ZZ , hh or Zh , plus missing momentum,

Figure 8. Schematic representation of one of the processes leading to displaced Z or h bosons plus missing energy at the LHC. The red lines denote long-lived particles. Similar final states arise from χ_2 or χ_3 pair production. Note that we do not specify the production mechanism of the pair of neutral heavy fermions since it could be produced directly through electroweak processes or through the decay of the charged fermion.

as illustrated in figure 8. By summing all the possible production modes, the process is symmetric in the $\chi_2 \leftrightarrow \chi_3$ exchange, since ψ^\pm decays democratically into $\chi_{2,3}$, cf. eq. (2.10). Hence, the precise signal yield in each of the three channels ZZ , hh and hZ is determined by the branching fractions of the two neutral fermions $\chi_{2,3}$. In figure 9, we show the branching fractions of the $\chi_{2,3}$ decays into $h\chi_1$ (dashed line) and $Z\chi_1$ (continuous line) as a function of $\tan\theta$ and for several benchmark masses. As we can see, for $\tan\theta \approx 1$, i.e. $y_u \approx y_d$, one of the two heavy fermions decays predominantly into $Z + \chi_1$ and the other one into $h + \chi_1$, independently of their mass. This leads to final states with a balanced sample of hh (25%), ZZ (25%) and hZ (50%). The same is true for $\tan\theta \gg 1$ or $\tan\theta \ll 1$ and when the mass of the neutral fermions is much larger than the Higgs mass (where effectively one has $\text{BR}[\chi_{2,3} \rightarrow Z\chi_1] = \text{BR}[\chi_{2,3} \rightarrow h\chi_1] = 50\%$). The only configuration where there is not a balance in h and Z is when the mass of the neutral fermions is close to the Higgs mass. In this latter case, kinematics favor the decays into $Z + \chi_1$, and hence final states with $ZZ + \cancel{E}_T$ are more probable.

In the next subsection, we will estimate the constraints on the three final states with displaced $ZZ + \cancel{E}_T$, $hh + \cancel{E}_T$ or $hZ + \cancel{E}_T$ that can be obtained from existing LHC searches at 13 TeV for displaced signatures, and we will subsequently study the impact on the parameter space of our model. Notice that searches performed at the LHC with $\sqrt{s} = 8$ TeV can also be sensitive to the main signatures of our model, $ZZ + \cancel{E}_T$, $hh + \cancel{E}_T$ or $hZ + \cancel{E}_T$. A number of such searches have been considered in ref. [105] and reinterpreted in terms of supersymmetric models. In particular, our scenario is similar to the case of Higgsinos decaying into gravitino in gauge-mediated SUSY models considered in [105], which is constrained mainly by a search for displaced dileptons [106] and a search for displaced jet pairs [107, 108], both performed by CMS. In the next subsection, we show a comparison of the sensitivity of these searches with the 13 TeV analysis we are going to recast. Note that our model and the Higgsino-gravitino scenario considered in [105]

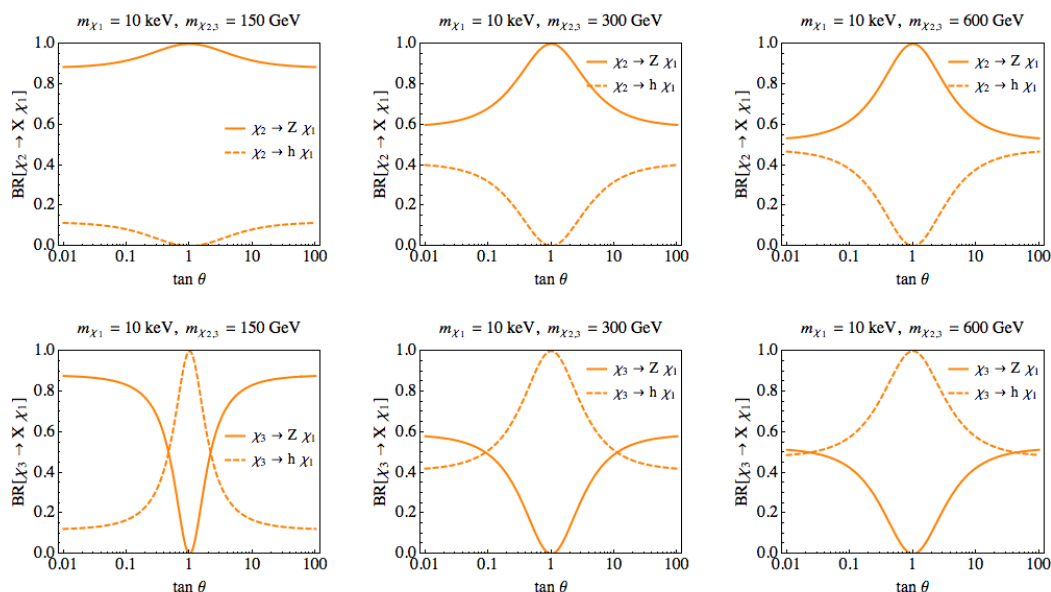

Figure 9. Branching ratios of χ_2 (first row) and χ_3 (second row) as a function of $\tan \theta \equiv y_u/y_d$, for different choices of their mass. If $\tan \theta < 0$, χ_2 and χ_3 simply exchange role.

differ in an important aspect. The main difference is that the mass splitting between the neutral components of the Higgsino multiplets in SUSY scenarios is typically sizeable ($\gtrsim \mathcal{O}(1)$ GeV) due to mixing with gauginos, even if such particles are substantially heavier than the Higgsino (up to $\mathcal{O}(10)$ TeV). As a consequence, the heaviest neutral component of the Higgsino decays mostly in the lightest component plus soft SM particles and the balance among the hh , hZ , and ZZ final states only depends on the branching ratios of the lightest neutral component of the Higgsino into the gravitino plus h or Z . In contrast, in the Singlet-Doublet freeze-in model, the mass splitting between the heavy neutral components is so small — as shown by the expressions in eq. (2.7) — that the two neutral fermions always decay directly to $\chi_1 Z$ or $\chi_1 h$ with branching ratios as illustrated in figure 9.

• **Searches for prompt decays:** for small values of the decay length of the mediators (corresponding to moderate/large values of y), we expect that limits from standard prompt searches can be effective. A combination of recent searches at the LHC with $\sqrt{s} = 13$ TeV for production of supersymmetric charginos and neutralinos can be found in ref. [109]. Possible final states are $hh + \cancel{E}_T$, $ZZ + \cancel{E}_T$ and $hZ + \cancel{E}_T$, which are typical signatures of searches targeting Higgsino-like neutralinos in gauge mediated supersymmetry breaking [110], or Higgsinos decaying into light Bino, see e.g. [111]. In these final states, limits to the Higgsino mass up to 600–700 GeV were obtained.⁸ A second type of relevant final states are $WZ + \cancel{E}_T$ and $Wh + \cancel{E}_T$, which are possible in our model for moderate/large values of y , such that the charged fermions ψ^\pm decay promptly into $W^\pm \chi_1$, cf. figure 2.

⁸Searches performed with the dataset of the 8 TeV run of the LHC are comparatively much less sensitive, constraining Higgsino masses up to around 250 GeV [111], so that we are not going to consider them here.

Experiment	Final state	\mathcal{L}, \sqrt{s}	Ref.
ATLAS	DV+ \cancel{E}_T	32.8 fb ⁻¹ , 13 TeV	[53]
ATLAS	lepton-jets	3.4 fb ⁻¹ , 13 TeV	[118]
ATLAS	jets	3.2 fb ⁻¹ , 13 TeV	[119]
CMS	jets	2.6 fb ⁻¹ , 13 TeV	[120]
CMS	μ, e	2.6 fb ⁻¹ , 13 TeV	[121]

Table 1. Summary of 13 TeV ATLAS and CMS searches for displaced signatures possibly relevant for the final state under study.

Note that the configurations of the model giving rise to the observed relic abundance through freeze-in considered in section 3 never give rise to prompt decays, i.e. the decay length is always larger than about 1 mm. We discuss thus these prompt decay searches briefly. For more detailed discussions of the prompt signatures of the Singlet-Doublet model, see refs. [43, 47].

- **Mono-X searches:** in the region with very large decay length, where the neutral fermions escape the detectors, mono-X searches could be the only strategy to look for this model at the LHC (besides the disappearing charged tracks associated to the charged fermion). In this regime the collider signature of our model is very similar to an Higgsino dark matter scenario in which the mass splitting among the Higgsino components is tiny, as already mentioned. There have been several investigations on this scenario and the corresponding mono-X signatures, e.g. in [112–117]. Some of these investigations have exploited the soft leptons that would be present for a mass splitting of the order of few GeV, which is however not the case of our model. Instead, the case of a pure mono-jet signal has been shown to be not promising, with an estimated reach on the Higgsino mass of order 200 GeV at HL-LHC with 3000 fb⁻¹ [115]. Hence we decide not to include these signatures in our analysis.

5.1 Recasting strategy for displaced h and $Z + \cancel{E}_T$

The aim of this subsection is to estimate the current LHC limit on displaced ZZ , Zh and $hh + \cancel{E}_T$ using public information from ATLAS and CMS searches. In table 1, we report on the relevant ATLAS and CMS searches for displaced signatures, focussing on the most recent analyses at 13 TeV. Among these searches, we identify the recent ATLAS analysis on displaced vertices (DV) with jets and \cancel{E}_T [53] as the most promising for our scenario. The motivation is manifold: (i) this analysis exploits the largest available dataset among those listed in table 1; (ii) the large hadronic branching fractions of h and Z imply that our model yields a sizeable production cross section in this channel; (iii) our final states contain a relevant source of \cancel{E}_T , and the analysis of ref. [53] is the only one targeting it with a dedicated selection; (iv) and finally, detailed auxiliary material is provided with the information needed for a recasting [122].

The ATLAS DV+ \cancel{E}_T analysis [53] targets final states with at least one displaced vertex with jets and large missing transverse momentum. The results are interpreted in a model with long-lived gluinos decaying into jets and the lightest neutralino. In the auxiliary material [122], the efficiencies for the missing momentum and the displaced vertex reconstruction are provided. In particular, the efficiencies of the displaced vertex reconstruction are given prior to detector simulation, as a function of the invariant mass of the vertex, of the number of tracks and of the displacement.

In order to estimate the sensitivity of this search on our final states, we have first implemented the model in `FeynRules` [64], and then simulated the relevant samples with `MadGraph5` [123], combined with `Pythia8` [124] for the parton showering and the underlying pp collision, and `Delphes3` [125] (with the standard ATLAS card) for the detector simulation. The displacement is applied to the simulated events a posteriori, taking into account the four momenta of the long-lived particle in order to properly compute the displacement,⁹ which is obtained by sampling an exponential distribution with mean decay length $c\tau_{\chi_{2,3}}$. In appendix B, we discuss the details of the selection and the validation of our implementation. The latter was performed by reproducing the exclusion limits set by the ATLAS search on the simplified model they considered with long-lived gluino.

After this validation, we can now estimate the efficiency of the ATLAS DV+ \cancel{E}_T analysis in the final states we are interested in, which are $ZZ + \cancel{E}_T$, $hh + \cancel{E}_T$ or $hZ + \cancel{E}_T$.¹⁰ We do this as a function of the lifetime $\tau_{\chi_{2,3}}$ and of the mass of the long-lived particles, which are simply the two neutral fermions χ_2 and χ_3 produced in pairs (cf. appendix B for plots displaying the resulting efficiencies). The mass is important in order to determine the boost factor in the displacement, as well as to get the correct p_T distribution of the displaced tracks. We can now use the obtained selection efficiencies to evaluate the reach of the ATLAS analysis in three simplified models with fixed branching fractions, that serve for illustrative purposes:

- i) $\text{BR}[\chi_{2,3} \rightarrow h\chi_1] = 100\%$;
- ii) $\text{BR}[\chi_{2,3} \rightarrow Z\chi_1] = \text{BR}[\chi_{2,3} \rightarrow h\chi_1] = 50\%$;
- iii) $\text{BR}[\chi_{2,3} \rightarrow Z\chi_1] = 100\%$.

In order to constrain the above simplified models, we consider the total production cross section of the doublet fermions states, computed at NLO by `Prospino2` [101], summing all production modes shown in (5.1), corresponding to the solid red line in figure 6. With no background in the signal region, the parameter configuration of a model is excluded at 95% confidence level (CL) or more if it yields a number of selected events ≥ 3.0 . The resulting estimated exclusion is depicted in figure 10 by the three solid lines. As we can see, the difference in the efficiencies among the three simplified models results in only a

⁹In this approach we neglected distortions of the kinematic distributions of the final state charged tracks due to the displacement.

¹⁰If Z or h decay into $b\bar{b}$, (some of) the resulting tracks may have an additional displacement, which makes the reconstruction of the DV more involved, as discussed in more detail in appendix B. In the following, we neglect possible issues related to this for the reasons discussed in the appendix.

Figure 10. Estimated exclusion curves from collider searches in the plane of the decay length versus the mass of the heavy neutral fermions. Our recasting of the ATLAS DV+ \cancel{E}_T search, associated to the final states of $hh + \cancel{E}_T$, $hZ + \cancel{E}_T$ or $ZZ + \cancel{E}_T$, for the simplified models i), ii) and iii) (see the text for details) are shown with red, blue and green solid lines respectively. The orange dashed line is the exclusion of displaced searches at 8 TeV LHC, as estimated in [105]. The purple dashed-dotted line is our estimate of the impact of the prompt searches at 13 TeV performed by CMS [109].

small impact on the sensitivity. Moreover, the largest doublet mass (about 1.3 TeV) is probed for a decay length around $c\tau \approx 5$ cm. Also, the exclusion curves are not symmetric in $c\tau$ with respect to this maximal reach. This is due to the fact that the exponential distribution determining the displacement is falling very rapidly for a displacement larger than a given $c\tau$, while it goes to zero less steeply for displacement smaller than $c\tau$. This also explains why the reach of the analysis extends to regions with very large decay lengths, up to $c\tau \approx 50$ m.

In figure 10, we also show for comparison the exclusion from the 8 TeV searches, as reported by ref. [105]. This is depicted as a dashed orange line and includes both searches targeting displaced leptons [106] and displaced di-jets [107, 108]. The displayed 8 TeV limit has been obtained in ref. [105] in a simplified model with an Higgsino-like neutralino undergoing displaced decays into gravitino plus Z or h in the large $\tan\beta$ regime, which roughly corresponds to our simplified model ii).¹¹ As we can see, in the region of low doublet mass, the sensitivity of the ATLAS DV+ \cancel{E}_T analysis is diminished because the spectrum is compressed and jet/ \cancel{E}_T cuts become more severe. This is where the 8 TeV searches, in particular the one targeting displaced dileptons, become instead more efficient,

¹¹The other simplified models considered in ref. [105], corresponding to our cases i) and iii), give very similar exclusion power.

despite the small leptonic branching fractions of the bosons.¹² Finally, we also display on the same plot an estimate of the reach of the prompt searches (as a purple dot-dashed line), considering the $\text{BR}[\chi_{2,3} \rightarrow Z\chi_1] = \text{BR}[\chi_{2,3} \rightarrow h\chi_1] = 50\%$ case reported in [109]. We stress that this limit will never be relevant in the parameter region leading to the correct freeze-in dark matter abundance, but we report it here for illustrative purposes. In order to draw this line, we have compared the cross section limits reported in ref. [109] to the total production cross section of the doublets multiplied by the probability that both produced particles decay promptly given a certain mean decay length $c\tau_{\chi_{2,3}}$.¹³

5.2 DV + \cancel{E}_T constraints on the Singlet-Doublet model

We can now use the recasting presented above to provide estimates for the ATLAS exclusion on the parameter space of the Singlet-Doublet freeze-in model. For this purpose, at each point of the parameter space, we sum the production cross sections over the production channels weighted by the appropriate branching fraction in order to determine the signal strength for each of the possible final states. For instance, the signal cross section in $hh + \cancel{E}_T$ is given by

$$\begin{aligned} \sigma(pp \rightarrow hh\chi_1\chi_1) &= \sigma(pp \rightarrow \psi^+\psi^-) \times \text{BR}[\psi^\pm \rightarrow \pi^\pm\chi_{2,3}]^2 \times \text{BR}[\chi_{2,3} \rightarrow h\chi_1]^2 + \\ &\quad \sigma(pp \rightarrow \psi^\pm\chi_{2,3}) \times \text{BR}[\psi^\pm \rightarrow \pi^\pm\chi_{2,3}] \times \text{BR}[\chi_{2,3} \rightarrow h\chi_1]^2 + \\ &\quad \sigma(pp \rightarrow \chi_2\chi_3) \times \text{BR}[\chi_2 \rightarrow h\chi_1] \times \text{BR}[\chi_3 \rightarrow h\chi_1], \end{aligned} \quad (5.2)$$

and analogous expressions can be written for the $hZ + \cancel{E}_T$ and $ZZ + \cancel{E}_T$. The production cross section in each channel is hence a function of the parameter space of the model through the branching fraction dependence on (y_u, y_d, μ, m_s) . We multiply these three type of signal cross sections with the corresponding efficiencies (derived in appendix B) to obtain the final estimate on the number of expected events. Each efficiency is also a function of the parameters (y_u, y_d, μ, m_s) , since it depends on the mass of the long-lived particle, which is simply μ , and on the decay lengths that follow from eqs. (2.12)–(2.15). For simplicity, we take the average of the decay length of χ_2 and χ_3 as the mean decay length setting the displacement. As we have discussed above, this is an excellent approximation as long as $\tan\theta \gg 1$ or $\mu \gtrsim 300$ GeV (see figure 3). We neglect the extra displacement induced by the decay of the charged fermion. Note that this is indeed typically a small fraction of the overall displacement in the relevant portion of the parameter space, as illustrated by the green contours in the right panel of figure 7. In our estimate we also consider the same efficiency in the case in which the neutral heavy fermions are directly pair produced as in the case in which the neutral fermions are produced through the decay of the charged fermion. We checked this hypothesis on a few benchmark points and it induces an effect of at most 20%, which is largely negligible for the purpose of our recasting. As for the

¹²We also remark that, as discussed in detail in the appendix B, our implementation of the ATLAS DV+ \cancel{E}_T analysis tends to overestimate the exclusion in the compressed region (for mass splittings $\lesssim 100$ GeV). The complementarity with the 8 TeV searches is thus welcome.

¹³As a rough estimate, we consider to be prompt the events with a total displacement ≤ 0.5 mm that we compute based on $c\tau$ only, without taking into account the boost factor.

Figure 11. Exclusion capability of the 13 TeV ATLAS search for displaced jets + \cancel{E}_T for the Singlet-Doublet freeze-in model (cyan region labelled as “DV+MET”) on the plane (μ, y) with $m_{\chi_{2,3}} = m_{\psi} = \mu$. The dashed cyan line represents the prospected bound with 300 fb^{-1} . The dot-dashed purple line is our estimate of the limit set by LHC searches for the prompt signature $WZ + \cancel{E}_T$ (see the text for details). The green contours indicate the average decay length of χ_2 and χ_3 . The red line corresponds to the correct relic abundance for $m_{\chi_1} = 12 \text{ keV}$.

case of the simplified models considered in section 5.1, we employ the NLO cross sections computed by Prospino2 [101] and we calculate 95% CL cross section upper exclusion limits assuming no background.

Under the above assumptions, we can assess the current limits on the Singlet-Doublet parameter space from the ATLAS DV+ \cancel{E}_T search. The region excluded according to our recasting is shown with filled cyan colour in figure 11. Its shape follows from combining the excluded regions for the simplified models reported in figure 10 with the iso-contours of the average $c\tau_{\chi_{2,3}}$ (denoted as $c\tau$). The latter are shown with green continuous lines in figure 11 while the dashed cyan curve gives the estimated reach of an analogous DV+ \cancel{E}_T search with a dataset of 300 fb^{-1} .¹⁴ The red continuous curve shows the (y, μ) combinations that account for all the DM for a 12 keV DM candidate. Going above the red line, i.e. to larger values of the coupling y , induces an overabundant dark matter population, while below the red line it is underabundant; see eq. (3.9). Finally, the dot-dashed line delimits the region excluded by LHC searches for the prompt signature $WZ + \cancel{E}_T$.

¹⁴The estimated curve for the DV+ \cancel{E}_T search with a dataset of 300 fb^{-1} results from simply rescaling the luminosity and assuming the signal to remain background free. While this is an optimistic assumption, it may not be unthinkable that backgrounds can continue to be suppressed at the cost of only a small signal inefficiency.

It is remarkable that the sensitivity of the ATLAS DV+ \cancel{E}_T search extends to heavy electroweak states and to quite large values of the decay lengths. This is related to the almost background-free nature of displaced vertices signatures which renders the search very efficient even for small signal cross section. Note that the largest excluded mediator mass is about 1.2 TeV, somewhat smaller than for the simplified model analysis of figure 10. The reason is as follows. In the high mass region, when the lifetime, or equivalently the coupling y , maximises the experimental sensitivity ($y \approx 10^{-8}$) the branching fraction of the process $\psi^\pm \rightarrow \chi_1 W^\pm$ is not completely negligible (up to about 10%, see figure 2 left), and hence the signal yield into long-lived neutral fermion pairs is slightly diminished. In the case of the DV+ \cancel{E}_T analysis extrapolation to 300 fb^{-1} , we expect to probe masses of the neutral fermions up to 1.7 TeV and decay lengths as large as 100 m.

Let us add here a remark on the uncertainties on our recasting and their effects on the estimated limits in figure 11. Given the steep fall of the production cross section as a function of the mediators' mass (see figure 6), we expect that even $\mathcal{O}(1)$ modifications of our estimated efficiencies would have a small impact on the mass reach (for instance a 50% change in the efficiency would only correspond to a change of around 10% in the mediators' mass limits).¹⁵

Let us stress that the collider bounds presented in figure 11 are expected to be independent of the dark matter mass for m_{χ_1} below the GeV scale. The only curve that is affected by the m_{χ_1} parameter is the relic abundance continuous red contour. Considering larger values of the dark matter mass the red line would be shifted to lower values of y . As a result, the dark matter candidates with $m_\chi > 12 \text{ keV}$ (i.e. compatible with the Lyman- α bound discussed in section 4) are concerned with the excluded region below the red curve of figure 11. For instance, from the right panel of figure 4, one can deduce that for e.g. $m_{\chi_1} \approx 1 \text{ MeV}$ the $\Omega h^2 = 0.12$ contour should appear at $y \approx 10^{-9}$ in figure 11. This corresponds to larger values of $c\tau$ where the DV+ \cancel{E}_T search loses sensitivity in such a way that no constraint can be set at present.

For completeness, let us briefly discuss the prompt decay constraints. In the upper part of figure 11, the size of the coupling y is such that the mediators decays are prompt. In particular, the charged fermion ψ^\pm predominantly decays into $W^\pm \chi_1$.¹⁶ In order to estimate the corresponding constraint, we have computed the $WZ + \cancel{E}_T$ production cross section in the Singlet-Doublet model multiplied by the probability that both heavy particles decay promptly, using the same approximations as for the prompt exclusion in figure 10. Comparing the latter results with the limits on the cross section given in ref. [109] we exclude the region delimited by the dot dashed purple line of figure 11. As discussed above, such constraint lies however in a zone of the parameter space where the frozen-in dark matter scenarios with masses above the Lyman- α bound give an overabundant dark matter relic density.

¹⁵Note in particular that this applies to the possible issues associated with b -jets, discussed at the end of appendix B, that would at most reduce the signal strength by $\approx 25\%$.

¹⁶The other prompt signatures discussed above are less sensitive as the production cross section is sensibly lower for χ_2, χ_3 production only. The latter is indeed almost one order of magnitude smaller than the total doublet production as seen in figure 6.

Figure 12. Combined constraints on the mediator mass vs DM mass plane ($m_{\chi_{2,3}} = m_\psi = \mu$). Our estimate of the ATLAS DV + \cancel{E}_T exclusion is shaded in cyan (“DV+MET”), the magenta region is excluded by disappearing tracks (“DT”), the Lyman- α bound is shown in gray (“Ly- α ”). Green contours correspond to the average $\chi_{2,3}$ decay length. The cyan dashed line is the estimated exclusion of LHC with 300 fb^{-1} . The coupling y is fixed such that $\Omega_{\chi_1} h^2 = 0.12$ everywhere.

6 Displaced vertices vs cosmology for freeze-in DM

We can now combine the LHC limits and the cosmological bound derived in the previous sections, in order to characterise the experimental sensitivity on the viable parameter space of the freeze-in Singlet-Doublet model. As at the end of section 3, we present our results in the DM mass vs mediator mass plane fixing in each point the coupling y to the value that accounts for the observed relic abundance through the freeze-in mechanism. On the same two dimensional plane, we can show the combination of the existing (and future) constraints on the model. Our summary plot is shown in figure 12. As before, the green lines indicate contours of fixed average decay length of the neutral fermions, which controls the phenomenology at colliders. The magenta shading at low mediator masses represents the region excluded by searches for disappearing charged tracks (DT) [57, 58]. It does not depend on the DM mass (or equivalently on the value of the y coupling) since, in this region, the decay length of the charged fermion is independent of m_{χ_1} , as can be seen in the right panel of figure 7. The cyan region and the dashed cyan line are the estimated exclusion and future prospect of the ATLAS DV+ \cancel{E}_T search, discussed in section 5. The gray region, finally, is excluded by the Lyman- α forest data, as discussed in section 4.

Figure 12 summarises the findings of this paper, as it nicely shows the interplay between collider searches for displaced signatures and cosmological constraints in our freeze-in dark matter model. On the one side, the observed DM abundance implies a relation among the parameters of the theory, leaving only two free parameters (plus a third one, $\tan\theta$, that affects the phenomenology of the model very mildly in our limit, as we discussed in

the previous sections). On the other side, for the range of decay lengths that are a priori optimal for studying displaced signatures at the LHC ($\mathcal{O}(10)$ cm) and μ scales within the reach of the collider ($\mu \lesssim \mathcal{O}(1)$ TeV), our dark matter model can leave a testable imprint on small scale structures. In such a region, we have a complementary constraint from the Lyman- α forest observations, which is essentially independent of the mediator mass. In contrast, the reach of LHC searches is intrinsically limited by the production cross section of the mediators, hence by their mass, and by the size of the detector. Due to the very low background of the recast search and the large dataset available, the current LHC limit actually extends to rather large values of the mediators' lifetime and, likewise, it can probe DM masses larger than those tested by cosmology, reaching up to $m_{\chi_1} = \mathcal{O}(1)$ MeV.

7 Summary and conclusions

Despite many experimental and theoretical efforts, the nature of dark matter remains a mystery. It is thus timely to look for DM beyond the most popular paradigms. In this work, we considered the case of a dark matter candidate with such a tiny coupling that it never reaches thermal equilibrium with the SM in the early universe. It is well known that, despite such suppressed interactions, the observed dark matter density can be accounted for by the freeze-in mechanism, with the dark matter being produced, for instance, via the decay of thermalised mediators. Within this context, we studied the case of the Singlet-Doublet dark matter model that consists in extending the SM with a pair of Weyl electroweak doublet fermions and a singlet Majorana fermion. The new fermions interact with the SM through gauge interactions and/or the Higgs portal induced by Yukawa interaction terms that couple the doublet and the singlet fermions to the Higgs particle. The Singlet-Doublet model rests thus on 4 free parameters only: 2 new mass scales (the doublet mass scale μ and the singlet mass scale m_s), and two Yukawa couplings (y_u and y_d). We have shown that, considering these couplings in the range $[10^{-8}, 10^{-10}]$ together with a doublet mass scale μ larger than the Higgs mass, the lightest neutral fermion, which is essentially the singlet Majorana fermion, can account for the whole dark matter abundance via the freeze-in mechanism. In this regime, the DM is light with a mass between a few keV up to hundreds of MeV.

Such a dark matter scenario could seem hopelessly beyond the reach of any dark matter experimental search. We show instead that the range of model parameters required for a successful freeze-in naturally gives rise to long-lived/displaced collider signatures that are already strongly bounded by the present LHC data. In addition, it is well known that thermal warm dark matter candidates of a few keV are also constrained by cosmology due to their free-streaming suppressing the growth of small scale structure. Even though frozen-in dark matter was never in thermal equilibrium in the early universe, Lyman- α bounds turn out to constrain the dark matter to be always heavier than 12 keV. In the low dark matter mass region, the model features thus both exotic LHC signals and a testable imprint on cosmology providing two complementary handles to probe the same scenario.

Concerning the collider searches, the relevant signatures of this model consist of disappearing charged tracks, related to the production of the charged component of the doublet

ψ^\pm , and displaced h and/or $Z + \cancel{E}_T$, associated to the decay of the two neutral fermions $\chi_{2,3}$. In the first case, ψ^\pm decays with a small displacement (about 1 cm) and our scenario is essentially the case of pure Higgsino DM in supersymmetric models. Current searches for disappearing tracks thus constrain the doublet mass scale μ to be larger than 150 GeV. In the second case, the $\chi_{2,3}$ fermions decay with displacements in a wide range, from centimetres to kilometres, depending on the point of the viable parameter space of interest (i.e. for y_u, y_d giving rise to the right relic abundance through freeze-in). We have argued that, at present, the most constraining search was provided by ATLAS in ref. [53] and we have reinterpreted its results in the framework of the Singlet-Doublet dark matter model. According to our recasting, this analysis can exclude scenarios with a decay length of the heavy neutral mediators as large as ~ 50 m, mediator masses as large as 1.2 TeV, and dark matter candidates with masses as large as 500 keV.

In figure 12, we have brought together all the experimental signatures which can probe the viable parameter space where the freeze-in production mechanism gives rise to the correct dark matter abundance. This nicely illustrates the interplay between collider searches and cosmology for frozen-in dark matter.

An interesting extension of our work is to enlarge the experimental reach on the parameter space of the model. The LHC sensitivity, shown in figure 12, could be improved towards large mediator masses, or towards small or large decay lengths. This is possible on all these three fronts by exploiting the presence of a displaced Z or h resonance, both in hadronic and leptonic decay channels, such that some of the event selection requirements that currently limit selection efficiencies can be relaxed, while keeping backgrounds to a negligible level. Also, at higher luminosities a dedicated event selection would help to suppress the increasing backgrounds. As a result of our study, we thus advocate dedicated experimental searches for displaced $Z + \cancel{E}_T$ or $h + \cancel{E}_T$ signatures, potentially in association with an extra identified Z or h boson. On the other hand, it would be interesting to also probe the case with large/moderate dark matter mass and very long-lived mediators (upper part of figure 12). For this purpose, one could for instance estimate the reach of the proposed detector MATHUSLA [126] on this scenario.

Finally, we stress again that interplay between exotic collider signatures and cosmology constraints go beyond the Singlet-Doublet model and apply to a large class of simplified models of freeze-in dark matter where the production occurs through decays of heavy mediators in thermal equilibrium with the SM bath. From the model building perspective, it would be interesting to investigate such complementarity in other models, also including those where the freeze-in is not realised through the decays of heavy mediators, but via scattering processes and/or via non-renormalisable interactions [127]. We leave these interesting possibilities for future works.

A Yukawa interactions and mixing matrix

A.1 Yukawa interactions

For the contraction of the indices in the Lagrangian of eq. (2.2), we follow the conventions of refs. [47, 50]. In particular, the Yukawa interactions

$$- y_d \psi_d \cdot H \psi_s - y_u H^\dagger \psi_u \psi_s + h.c. \tag{A.1}$$

can be explicitly written as

$$- y_d \psi_{di} H_j \epsilon^{ij} \psi_s - y_u \psi_{ui} H^{*i} \psi_s + h.c., \tag{A.2}$$

where i and j are $SU(2)_L$ indices.

A.2 Approximate expression of the rotation matrix

In the limit (2.6), the mass eigenvalues at the first order in the couplings $y_{u,d}^2$ result as shown in eq. (2.7). We report here the rotation matrix, defined as in eq. (2.5), at leading order in y_u and y_d :

$$U = \begin{pmatrix} 1 & -\frac{v}{2\sqrt{2}} \left(\frac{y_u - y_d}{\mu + m_s} + \frac{y_u + y_d}{\mu - m_s} \right) & \frac{v}{2\sqrt{2}} \left(\frac{y_u - y_d}{\mu + m_s} - \frac{y_u + y_d}{\mu - m_s} \right) \\ \frac{v}{2} \frac{y_u - y_d}{\mu + m_s} & -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ -\frac{v}{2} \frac{y_u + y_d}{\mu - m_s} & -\frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{pmatrix}. \tag{A.3}$$

We omit the $\mathcal{O}(y_{u,d}^2)$ terms that are needed in order to diagonalise correctly the mass matrix \mathcal{M} obtaining the eigenvalues shown in eq. (2.7). In fact, in our parameter regime, the above expression suffices to reproduce the rotations resulting from numerical diagonalisation to high accuracy. Hence, we employ it to derive the expressions for the decay widths of the heavy particles reported in section 2.2.

B Recasting of the ATLAS search

In this appendix, we provide details about the recasting of the ATLAS search of ref. [53] that we employed in order to set limits on the Singlet-Doublet model and in particular on displaced neutral bosons + \cancel{E}_T final states.

The signature that we consider both in the validation (gluino-neutralino simplified model) and in the Singlet-Doublet model is constituted by a pair of heavy long-lived particles decaying into charged tracks plus missing energy. For the case of two neutral heavy fermions, the process is depicted in figure 8, with the long-lived particle highlighted in red.

We first review the selection cuts of the search, we then validate our simulation with the simplified model studied in the ATLAS analysis, and then we apply the same recasting to our dark matter model.

Selection criteria of the ATLAS DV+ \cancel{E}_T search [53]. The ATLAS analysis [53] is explained in detail in the auxiliary material in [122]. The search targets displaced vertices and missing transverse momentum.

The displaced vertices are identified by analysing the associated displaced tracks. First, a selected displaced track should satisfy the following requirements:

- The track is associated to a stable particle;
- The particle has a transverse momenta $p_T > 1$ GeV;
- The transverse impact parameter $d_0 \equiv R_{\text{decay}} \sin \Delta\phi > 2$ mm, where R_{decay} is the transverse decay length and $\Delta\phi$ is the azimuthal angle between the heavy decaying particle momentum and the track momentum.

With the following selected tracks, one can construct a candidate displaced vertex which should satisfy the following criteria:

- The transverse displacement R_{decay} should be within 4 and 300 mm;
- The longitudinal displacement should be smaller than $|z_{\text{decay}}| < 300$ mm;
- The number of associated charged tracks should be $n_{\text{tracks}} \geq 5$;
- The invariant mass of the vertex should be larger than 10 GeV (a pion mass for the tracks is assumed).

Given the previous strategy to select displaced tracks and displaced vertices, events are hence required to satisfy the following conditions.

1. $\cancel{E}_T^{\text{truth}} > 200$ GeV where $\cancel{E}_T^{\text{truth}}$ is the missing energy at truth level, here interpreted as the magnitude of the transverse component of the vector sum of the dark matter momenta.
2. On 3/4 of the events, the ATLAS analysis also demands the presence of either
 - One jet with $p_T > 70$ GeV
 - Two jets with $p_T > 25$ GeV

These jets should satisfy the requirement that the scalar sum of the p_T of the charged particles that are not displaced (according to the previous selection) should not exceed 5 GeV.

3. The events must contain at least one displaced vertex which has passed the selection.

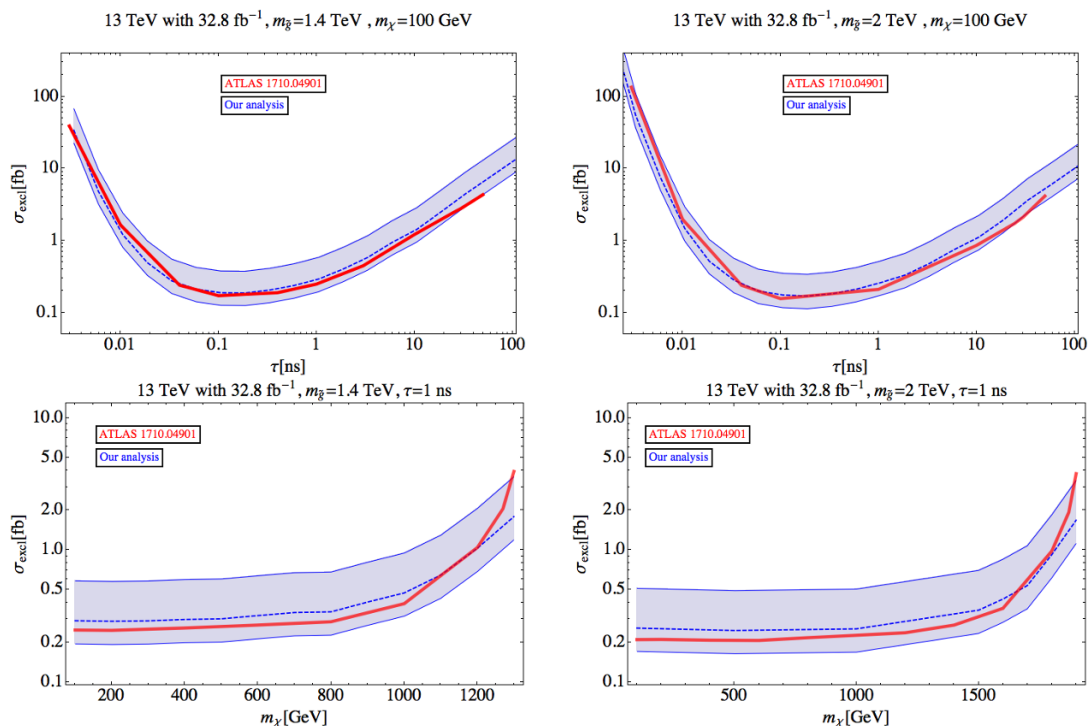

Figure 13. Comparison between the result of our simulation and the excluded cross section reported in the ATLAS paper [53] for a long-lived gluino simplified model. The ATLAS results are shown as red lines, while our analysis corresponds to the blue bands. In order to draw our bands, we considered variation of the efficiency of $\pm 50\%$. The upper plots show the excluded cross section as a function of $c\tau$ for a fixed neutralino mass $m_\chi = 100$ GeV and two benchmark values for the gluino mass, $m_{\tilde{g}} = 1400, 2000$ GeV. The lower plots show the excluded cross section as a function of m_χ fixing $\tau = 1$ ns and the same two benchmarks for $m_{\tilde{g}}$.

Recasting and validation. On the selected events, one can then apply the efficiency as reported in the auxiliary material. Indeed, the ATLAS collaboration provides the efficiency for reconstructing the displaced vertices as a function of the number of displaced tracks and of their invariant mass. They also provides the efficiency tables as a function of the missing energy at truth level.

In order to recast this analysis, we have simulated LO events of the new physics process with `MadGraph5 + Pythia8 + Delphes3` with standard minimal cuts, default parameters for MC and detector simulator (we used the default ATLAS card), assuming prompt decays of the heavy pair-produced particles. We employed generator level information in order to extract the momenta of the two heavy particles and of their associated tracks and in order to introduce the displacement by hand, including the boost factor of the heavy decaying particle. The decay time was generated through an exponential distribution with a mean lifetime τ . With this information we derived the impact parameter of each track and the other relevant geometrical properties. Then we processed the output following the ATLAS selection cuts strategy, including the reconstruction efficiencies. We first applied this procedure to a simplified model analogous to the one considered in the ATLAS paper, by considering gluino pair production followed by displaced decays into $q\bar{q}$ plus neutralino.

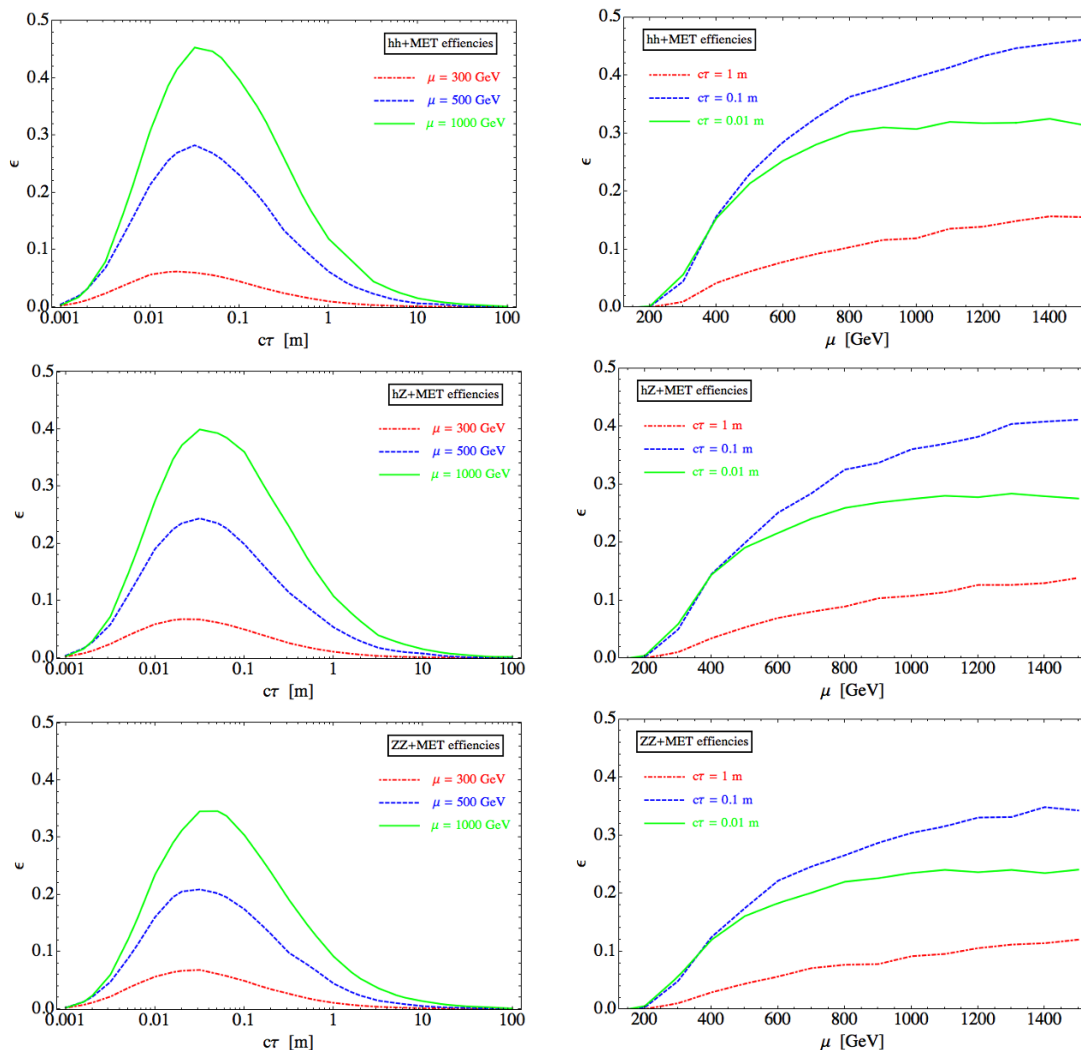

Figure 14. Efficiencies for the simplified final states with $hh + \cancel{E}_T$, $hZ + \cancel{E}_T$, $ZZ + \cancel{E}_T$. Left: efficiencies as a function of $c\tau$ for $m_{\chi_2} = m_{\chi_3} = 300, 500, 1000$ GeV. Right: efficiencies as a function of the mass $m_{\chi_2} = m_{\chi_3}$ for $c\tau = 1, 10, 100$ cm.

In figure 13 we show our estimated cross section exclusion compared to the ATLAS results. We find a good agreement in the region of un-compressed spectrum, while our simulation overestimate the exclusion power in the compressed spectrum case. We argue that this is due to our implementation of the jet cut (number 2. in the list above), for which we have only a limited amount of information provided by the ATLAS documentation. The plots of figure 13 shows that, on the other hand, our simulation consistently reproduces the ATLAS analysis for a mass difference between the heavy particle and its decay products larger than ≈ 100 GeV, taking into account an uncertainty of $\pm 50\%$ on the efficiency.

In figure 14 we display the result of our recasting: the efficiency curves for the final states characterising the Singlet-Doublet model. The samples have been generated at LO with MadGraph5 + Pythia3 + Delphes3 after implementing the model in FeynRules. We

simulated the following three cases

$$pp \rightarrow \chi_2\chi_3 \rightarrow ZZ\chi_1\chi_1, \quad pp \rightarrow \chi_2\chi_3 \rightarrow hh\chi_1\chi_1, \quad pp \rightarrow \chi_2\chi_3 \rightarrow hZ\chi_1\chi_1,$$

where the decay of the bosons is performed in `Pythia`. We then processed the output with the selection procedures explained above to extract the efficiencies as a function of the mean lifetime $c\tau$ and the mass of the decaying heavy particles $m_{\chi_2} = m_{\chi_3}$.

As a final remark, let us notice that the efficiencies displayed in figure 14 have been obtained by treating displaced heavy flavour jets like light-flavour ones. However, the case of Z or h decaying into $b\bar{b}$ pairs requires in principle additional care, since the recast DV+ \cancel{E}_T search associates tracks to a displaced vertex based on track-vertex compatibility requirements, and merges displaced vertices if within 1 mm. For displaced b jets, these requirements are difficult to recast. As we mentioned, we choose to neglect this possible issue (an interesting discussion of which can be found in ref. [128]). We argue that this simplification has a limited impact on our estimated exclusions (shown in figures 11 and 12) for the following reasons: (i) Only one DV is enough to satisfy the analysis' requirements, thus there is no loss of sensitivity if at least one of the pair-produced heavy particles decays into a Z decaying into light flavours (and the DV is reconstructed); (ii) Due to the gluons radiated by the b quarks, a DV can still be formed on the tracks not coming from the b -decay vertex; (iii) Part of the b decays will still happen within the required 1 mm.

 (Received 13 May 2020; accepted 17 July 2020; published 6 August 2020)

We report on a search for elementary particles with charges much smaller than the electron charge using a data sample of proton-proton collisions provided by the CERN Large Hadron Collider in 2018, corresponding to an integrated luminosity of 37.5 fb^{-1} at a center-of-mass energy of 13 TeV. A prototype scintillator-based detector is deployed to conduct the first search at a hadron collider sensitive to particles with charges $\leq 0.1e$. The existence of new particles with masses between 20 and 4700 MeV is excluded at 95% confidence level for charges between $0.006e$ and $0.3e$, depending on their mass. New sensitivity is achieved for masses larger than 700 MeV.

I. INTRODUCTION

Over a quarter of the mass energy of the Universe is widely thought to be some kind of nonluminous “dark” matter (DM), however, all experiments to date have failed to confirm its existence as a particle, much less its properties. The possibility that DM is not a single particle, but rather a diverse set of particles with as complex a structure in their sector as normal matter, has grown in prominence in the past decade, beginning with attempts to explain observations in high-energy astrophysics experiments [1,2].

Many experimental efforts have been launched to look for signs of a dark sector, including searches at high-energy colliders, explorations at low-energy colliders, precision tests, and effects in DM direct detection experiments (for recent reviews see Refs. [3–5]). Most of these experiments target the dark sector via a massive dark photon, in what we refer to as the “Okun phase” [6,7]. An alternative assumption, which we call the “Holdom phase” [7,8], results in massless dark photons. In these models the principal physical effect is that new dark sector particles that couple to the dark photon will have a small effective electric charge. These are generically called millicharged particles since a natural value for their electric charge of $Q \sim \alpha e / \pi$ arises from one-loop effects [9]. In this paper we use the symbol χ to denote a millicharged particle. For a given mass and charge, the pair production of millicharged particles at the CERN Large Hadron Collider (LHC) is almost model independent. Every standard model (SM) process that results in dilepton pairs through a virtual photon would, if kinematically allowed, also produce $\chi^+ \chi^-$ pairs with a cross section reduced by a factor of $(Q/e)^2$ and by mass-dependent factors that are well understood.

Millicharged particles can also be produced through Z boson couplings that depend on their hypercharge [7].

Previous experiments have searched for millicharged particles [10–17]. The parameter space spanned by the mass and charge of χ is also constrained by indirect observations from astrophysical systems [9,15,18–24], terrestrial matter [25], the cosmic microwave background (CMB) [26], big-bang nucleosynthesis [27], and universe overclosure bounds [18]. While direct searches robustly constrain the parameter space of millicharged particles, indirect observations can be evaded by adding extra degrees of freedom, which can readily occur in minimally extended dark sector models [7]. In particular, the parameter space $1 < m_\chi < 100$ GeV, an ideal mass range for production at the LHC, is largely unexplored by direct (or indirect) searches. Such a signature would not be detectable by the CMS and ATLAS experiments at the LHC [28,29], as all detector elements rely on the electromagnetic (EM) interaction of the millicharged particle with ordinary matter. For a millicharged particle the interaction strength is reduced by a factor of $(Q/e)^2$ with respect to that of a particle of the same mass that has charge e . The detector signal is also reduced by the same factor, and is typically too small to be recorded by detectors designed for particles of charge e . The production of millicharged particles in collider experiments would result in events with missing transverse momentum, however, SM processes with neutrinos as well as instrumental effects tend to overwhelm their signatures. No searches for particles with $Q \lesssim 0.1e$ have been performed at hadron colliders.

It is then clear that dedicated detectors are needed to search for millicharged particles at a hadron collider. In 2016, we discussed the possibility to build such a detector at the LHC, which we called milliQan [30], at the CMS experimental site and aligned with the CMS interaction

point (IP). Since then we have installed and operated a small fraction of such a detector (“milliQan demonstrator”) to measure backgrounds and provide a proof of principle and feedback for the full detector design. In 2018, the demonstrator collected a dataset of proton-proton (pp) interactions corresponding to an integrated luminosity of 37.5 fb^{-1} , at a center-of-mass energy of 13 TeV. This corresponds to 86% of the total luminosity delivered by the LHC in the period the demonstrator was operational. While the demonstrator is only $\sim 1\%$ of the full milliQan, the data collected already provides competitive constraints on the existence of millicharged particles of mass $20\text{--}4700 \text{ MeV}/c^2$ and $Q/e \sim 0.01\text{--}0.3$.

II. DETECTOR

A thick sensitive volume is required to be capable of observing the small energy deposition of a particle with $Q \lesssim 0.1e$. The milliQan demonstrator is, therefore, composed of three layers of $80 \times 5 \times 5$ cm scintillator bar arrays pointing to the CMS IP, with each array consisting of three pairs of bars, stacked on a 3.6 m long rectangular aluminum tube, for a total of 18 bars. We label the closest, middle and furthest layer from the CMS IP as layer 1, layer 2 and layer 3, respectively.

The milliQan demonstrator is located in an underground tunnel at a distance of 33 m from the CMS IP, with 17 m of rock between the CMS IP and the demonstrator that provides shielding from most particles produced in LHC collisions. In the CMS coordinate system [29], the detector is positioned at an azimuthal angle (ϕ) of 43° and pseudorapidity (η) of 0.1. Diagrams of the detector’s position are shown in Fig. 1. Located 70 m underground, the muon flux from cosmic rays is reduced by a factor of ~ 100 compared to the surface. The detector is aligned

FIG. 2. A diagram of the detector components. The PMTs are not shown for the slabs or panels. All components are installed on an aluminum tube.

using standard laser-based survey techniques such that the center of the scintillator array projects a line to within 1 cm of the CMS IP. This alignment is validated using muons produced at the CMS IP, as discussed in Sec. IV C.

In addition to the scintillator bars, additional components were installed to reduce or characterize certain types of backgrounds. Lead bricks are placed between the layers to prevent low-energy secondary particles from one layer from entering another layer. Four scintillator slabs are located along the length of the detector to tag throughgoing particles, provide time information, and shield the bars from neutron radiation. Thin scintillator panels cover the top and sides, providing the ability to reject cosmic muons. Lastly, hodoscopes consisting of $2 \times 2 \times 45$ cm scintillator volumes are used to identify the tracks of beam and cosmic muons. A diagram of the detector components is shown in Fig. 2, and a photograph of the installed detector is shown in Fig. 3. All scintillator volumes are comprised of Eljen EJ-200 [31].

Scintillator light in the bars, panels, and slabs is detected by photomultiplier tubes (PMTs) coupled to the scintillator volumes. Three types of PMTs are used in order to test different manufacturers and gains: the Hamamatsu R878, Hamamatsu R7725 [32], and Electron Tube 9814B [33]. Analog signals from each PMT are sent to two 16-channel CAEN V1743 digitizers [34], operating at 1.6×10^9 samples per second with 12-bit resolution, providing 1024 samples within a 640 ns acquisition window. Each scintillator volume with a PMT attached is referred to as a

FIG. 3. A photograph of the detector, with the panels removed from layer 1 so that the bars may be seen.

“channel.” Since millicharged particles produced at the CMS IP would traverse the full length of the detector in $\mathcal{O}(10)$ ns, tight timing requirements allow for a significant reduction in combinatoric backgrounds by requiring the coincidence of in time signals in all layers, as described in Sec. V. The PMTs are powered by a CAEN SY5527 power supply system [35]. The hodoscopes are readout with silicon photomultipliers. Their data are triggered and stored independently from the main data stream.

The dataset analyzed for this search was collected during 2018, including periods with the LHC beam providing pp collisions (the “beam-on” dataset) and periods with no collisions (the “beam-off” dataset). The beam-off dataset provides a statistically independent sample to study background processes. The detector is located in an area in the far fringe field of the CMS superconducting magnet, and both beam-on and beam-off datasets were recorded with the magnet at its nominal strength of 3.8 T. The actual magnetic field in the milliQan cavern is measured by magnetic field sensors installed in various positions around the detector. We find this magnetic field to be under 2 mT when the CMS

magnet is at 3.8 T. Additional data samples were recorded with the field at 0 T for PMT calibration.

Data is collected by triggering on the coincidence of at least three channels (triple coincidence) within a window of 100 ns. A bar contributes to this coincidence if it has a rising edge consistent with a single photoelectron threshold, and the panels and slabs contribute to the coincidence with more stringent thresholds appropriate for identification of muons from cosmic rays (“cosmic muons”) and muons from pp interactions (“beam muons”). The total trigger live times were 1106 and 1042 hours for the beam-on and beam-off datasets, respectively. The average trigger rate was 14.4 Hz. Outside of the beam time, additional specialized runs were taken using single-channel and double-coincidence triggers, with different thresholds and operating voltage settings, in order to collect data samples for calibrations and validation studies.

III. CALIBRATION

We first calibrate the size of the generated pulses in each channel, which requires a measurement of the average size of a pulse from a single photoelectron (SPE) in each PMT, as well as the mean number of photoelectrons $\langle N_{\text{PE}} \rangle$ generated in each channel by a throughgoing muon. The former is strictly a property of each PMT, while the latter depends on each scintillator, its wrapping, its coupling to the PMT, and the PMT quantum efficiency.

The SPE calibration is performed *in situ* by isolating pulses from late-arriving scintillation photons, which largely produce SPEs in the PMTs. The mean SPE area is then found by locating the peak of the resulting pulse area distribution. These measurements are cross-checked by bench measurements of SPE waveforms generated by a flashing LED, following the method outlined in Ref. [36]. In the following, the n_{pe} of a given pulse is defined as the pulse area divided by this per-channel SPE calibration, and represents an estimate of the true number of photoelectrons that generated the pulse.

For panels and slabs, the $\langle N_{\text{PE}} \rangle$ calibration is performed directly based on throughgoing beam muons (slabs) and cosmic muons (panels). The measured average pulse area is scaled by the per-channel SPE measurement to calculate the mean number of photoelectrons generated by a beam or cosmic muon.

For the bars, we use cosmic ray muons for calibration. Direct calibration with radioactive sources was not possible because the detector could not be accessed during LHC running. Since cosmic ray muons saturate the readout, we take an indirect approach, using the fact that the PMT response scales as a power law over a wide range of operating voltages. First, the mean areas of cosmic muon pulses are measured at 5–6 operating voltages, which are low enough to ensure that the PMT signals do not saturate. A power law function is then fit to these points, and extrapolated to the nominal operating voltage. Finally, this

number is scaled by the per-channel SPE measurement to arrive at an estimate of the number of photoelectrons generated by a cosmic muon. The validity of the power law assumption is confirmed by separately fitting a power law function to the mean areas of SPE pulses over a range of voltages near the nominal operating voltage. The fitted exponent is found to be consistent with that from the fit to the cosmic muon pulse areas for all bars. The calibrated value of $\langle N_{\text{PE}} \rangle$ for a beam muon traversing the full 80 cm length of a bar varies from 22 000 to 82 000; this means that $\langle N_{\text{PE}} \rangle = 1$ is expected in the bars for particles of charge $Q/e \sim 0.004\text{--}0.007$.

The dominant source of uncertainty in each bar’s $\langle N_{\text{PE}} \rangle$ measurement is the statistical uncertainty from the power law fit and extrapolation, which is 10%–20% depending on the channel, and is uncorrelated between channels. Smaller uncertainties, generally on the order of a few percent, come from differences in the residual magnetic field between calibration runs and data-taking runs; the effect of a low-pass filter applied to the waveforms; and differences between the *in situ* and lab-based SPE measurements. These are correlated between bars with PMTs of the same type. Time dependent drifts in the response, inferred from variations in the dark count rate, are subdominant.

The timing of the PMTs must also be calibrated. The calibration procedure is designed such that a particle traveling near the speed of light through the detector from the CMS IP should have the same time value in every bar, panel and slab. This calibration is performed using both beam and cosmic muons. Figure 4 shows the time difference between a muon pulse in layer 3 compared to a muon pulse in layer 1, where the events have been categorized as either beam or cosmic muons based on the timing of the pulses in the slabs. The resolution in the time difference between layers is approximately 4 ns for beam muons which travel through the detector from the CMS IP. An additional correction is applied to account for the dependence of the timing of the pulses on their size. This correction is derived using secondary particles that result from the interactions of beam muons with the detector as they traverse it. The timing resolution degrades as the size of the pulses gets smaller; the resolution of the lowest n_{pe} pulses passing the selection outlined in Sec. V is ~ 15 ns. The modeling of the timing of these secondaries is used to derive a systematic uncertainty in the timing in simulation.

The trigger efficiency is measured as a function of n_{pe} for each channel by comparing the rate between dedicated triple-coincidence runs and double-coincidence runs. For the triple-coincidence runs, the trigger decision is based on coincident signals in two “tag-channels” and one “probe channel,” whose trigger efficiency is to be measured. For the double coincidence runs, the trigger decision involves only the two tag channels. The trigger efficiency for each channel is given by the ratio of the pulse rate when the

FIG. 4. Time difference, measured in a combination of the beam-on and beam-off datasets, between layer 3 and layer 1 for beam (red) and cosmic (blue) muons that travel through the detector.

probe channel is required in the trigger over the pulse rate when the probe channel is not required in the trigger. This efficiency is used to reweight the simulated samples of signals from millicharged particles described in Sec. IV B. The trigger efficiency is measured to reach 100% for $n_{pe} \gtrsim 2$ for all channels.

IV. SIMULATION

A. Event generation

We generate pair production of millicharged particles in 13 TeV pp collisions through the Drell-Yan process, as well as from Υ , J/ψ , $\psi(2S)$, ϕ , ρ , and ω decays into $\chi^+\chi^-$, and from Dalitz decays of π^0 , η , η' , and ω .

Drell-Yan events are generated assuming that χ s are isospin singlet fermions, using the Lagrangian of Ref. [37] implemented in the MADGRAPH5_aMC@NLO [38] event generator, with a minimum invariant mass requirement on the millicharged pair of $2 \text{ GeV}/c^2$. Because of the limited integrated luminosity and the small size of the demonstrator, there is essentially no sensitivity to Drell-Yan production of millicharged particles in the dataset discussed in this paper.

The production cross section and transverse momentum p_T distribution of J/ψ and $\psi(2S)$ in the central rapidity y region is taken from calculations of charmonium production from direct processes [39–41] and from bottom hadron decays [42–44], including theoretical uncertainties. Theoretical calculations of bottomonium production [45] are not reliable at low transverse momentum ($p_T < 15 \text{ GeV}$) [46], where most of the cross section lies. As a result, for $p_T > 20 \text{ GeV}$ we use the cross sections and p_T spectra measured at a center-of-mass energy of 13 TeV [47]; at lower p_T we use measurements from 7 TeV data

[48,49], rescaled using the measured ratio of 13 to 7 TeV cross sections at slightly higher rapidity ($2 < y < 2.5$) [50].

All relevant light flavor mesons except ϕ mesons are generated with the minimum bias PYTHIA8 generator [51] with the Monash 2013 tune [52]. This is the tune that gives the best agreement with several measurements of light meson rates and p_T spectra at the LHC, albeit in most cases at center-of-mass energies lower than 13 TeV [53–56]. The Monte Carlo spectra for $\eta(\rho, \omega)$ with $p_T < 3$ (1) GeV are scaled down by factors as large as 2, based on the experimental results cited above. On the other hand, the production of ϕ mesons is modeled with the minimum bias PYTHIA6 generator [57] with the DW tune [58], since this Monte Carlo setup best reproduces ϕ meson data [59]. All PYTHIA Monte Carlo generations are normalized to a minimum bias cross section of $80 \pm 10 \text{ mb}$ based on a measurement by ATLAS [60], with an uncertainty taken to cover the difference with respect to a similar CMS measurement [61]. We assess an additional 30% uncertainty in the overall rate of each process to account for remaining differences between experimental measurements and PYTHIA predictions of the rates of light mesons per minimum bias event, based on the references cited above.

The branching fractions for all vector meson decays, $V \rightarrow \chi^+\chi^-$, as a function of the χ mass are calculated using the Van Royen-Weisskopf formula [62], normalized to the PDG value of the branching fraction for $V \rightarrow e^+e^-$ [63], and rescaled appropriately for the assumed charge of the χ . The branching fractions for meson Dalitz decays, e.g., $\eta' \rightarrow \chi^+\chi^-\gamma$ or $\omega \rightarrow \chi^+\chi^-\pi^0$, as well as the $\chi^+\chi^-$ invariant mass distributions in these decays are modeled as a function of the χ mass and charge using the partial width for decays into photons, e.g., $\eta' \rightarrow \gamma\gamma$ or $\omega \rightarrow \pi^0\gamma$ [64], assuming a vector dominance model for the form factors.

Production cross sections of millicharged particles from different processes are summarized in Fig. 5. The possible contribution from millicharged particle production in EM showers in the CMS calorimeters generated by particles from pp collisions is not considered in this analysis.

We also generate inclusive muon events ($pp \rightarrow X \rightarrow \mu$) that are used for calibration and background studies. The same theoretical calculation used to obtain the differential cross sections of J/ψ and $\psi(2S)$ from bottom hadron decays is also used to generate muons from bottom and charm hadron decays, while muons from decays in flight of pions and kaons are generated with PYTHIA8 using the Monash 2013 tune. Muons from W and Z decays are taken from MADGRAPH5, though these electroweak processes contribute only $\sim 3\%$ of the total muon flux. Finally, muons are generated using an appropriate angular distribution to simulate cosmic ray events. This angular distribution is derived by assuming a $\cos^2(\theta_{\text{zenith}})$ distribution at the surface and propagating the muons to the demonstrator using the method described in Sec. IV B.

FIG. 5. Cross section times branching ratios for production of different particles with $|\eta| < 2$ decaying into $\chi^+\chi^-$ pairs, as a function of χ mass. For Drell-Yan the plotted cross section requires at least one of the χ s to have $|\eta| < 1$.

B. Detector response

Generated particles are propagated through a simplified model of the material in the CMS detector, including the magnetic field, and the 17 m of rock between the CMS cavern and the demonstrator.

Propagation is performed with fourth-order Runge-Kutta integration, incorporating the effects of the magnetic field, multiple scattering, and energy loss. Particles are propagated until 2 m before the face of the demonstrator, after which they are fed into a full GEANT4 [65] simulation of the remaining rock, the drainage gallery where the demonstrator is located, and the demonstrator itself. Similarly, muons from cosmic ray showers are propagated from the surface of the earth to a plane 1 m above the top of the cavern. Muon interactions in the cavern walls generate showers of gamma rays and electrons that significantly contribute to the cosmic ray background. A simulated cosmic ray shower event is shown in Fig. 6.

The simulation parameters are nominally configured to be consistent with EJ-200 scintillator and existing measurements for Tyvek reflectivity and each PMT species' quantum efficiency [66]. Overall photon propagation is handled using GEANT4's UNIFIED optical model [67]. Photon propagation is further calibrated by measuring the effects of scintillator roughness and wrapping quality on light attenuation in the scintillator bars and matching the effect in simulation. These measurements indicated a wrapping reflectivity $R = 0.97$ and scintillator roughness $\sigma = 1\%$, typical values for Tyvek and EJ-200 [68]. A per-channel calibration is applied to each PMT quantum efficiency so that the measured $\langle N_{PE} \rangle$ values agree between data and simulation.

The electronic response is simulated using SPE waveform templates measured on a test bench with an LED. SPE templates for each GEANT4 photoelectron are added

FIG. 6. Simulation of the milliQan demonstrator response to a simulated cosmic ray shower event. The incident muon (red) interacts with the cavern walls to produce a shower. Electrons (black) and gamma rays (green) generated in the rock are a significant background source. The interactions of muons and shower particles with detector material produce scintillation photons (cyan).

together, with appropriate arrival times, and including the individual PMT calibration described in Sec. III. The resulting waveform is then added to a randomly selected zero-bias data waveform to properly account for electronic noise.

C. Validation

The simulation is validated by studying beam muons as well as cosmic ray events. The absolute rate of beam muons passing through all four slabs is compared with the rate predicted from a simulated sample of muon production from heavy-flavor and electroweak decays, as well as meson decays in flight, as described in Sec. IV B. We measure a rate of 0.20 ± 0.01 muons/pb $^{-1}$, based on a sample of 7363 muons, in agreement with the prediction of 0.25 ± 0.08 muons/pb $^{-1}$. The dominant uncertainties in this prediction arise from the uncertainty in the $b\bar{b}$ cross section (21%) and from the modeling of the material between the CMS IP and milliQan (25%). This last uncertainty is derived from a 7% variation in the total amount of intervening material, which is in turn due primarily to uncertainties in both the thickness and density of the rock layer. This 7% variation corresponds to a 25% uncertainty in the muon rate because of the steeply falling muon momentum distribution. This same variation is used to derive a systematic uncertainty in the predicted signal yields, though in that case the effect is much smaller because of the smaller charge of the χ .

We additionally perform a comparison of the angular distribution of beam muon trajectories, in order to probe the scattering and magnetic field modeling in simulation and

FIG. 7. Comparison of data and simulation n_{pe} distributions in events with a tagged throughgoing beam muon, for bars that do not contain a pulse consistent with originating from a muon, and are not neighboring any such bars. Note that only 783 out of 7363 tagged muons produced detectable showers entering this figure. Simulation events are categorized based on the material in which the particle(s) that produced the pulse originated.

validate the alignment of the detector. We compare rates of muons passing through various subsets of bars that trace a range of angles through the detector. The rates of these paths in both the horizontal and vertical directions are measured to be consistent within statistical uncertainties between data and simulation.

Finally, the GEANT4 modeling is validated by comparing distributions of photoelectron counts in bars near either beam or cosmic muon trajectories. Hits are expected from electrons and gamma rays produced as the muon travels through the rock or nearby detector material. An example comparison is shown in Fig. 7. Here we show n_{pe} distributions in data and simulation in events with a tagged beam muon, for bars that do not contain a pulse consistent with originating from a muon ($n_{pe} < 750$), and are not neighboring any such bars. Contributions come primarily from electrons and gamma rays produced in scintillator material, rock, or the lead bricks. Good agreement is seen across a wide range of n_{pe} levels.

V. SEARCH FOR MILLICHARGED PARTICLES

The search for millicharged particles looks for a signal with the signature of a pulse in each of the three layers of the demonstrator. A number of sources can produce such a signature:

- (i) Each PMT has a dark current arising from effects such as the thermal emission of electrons from the cathode. The simplest background source comes from random overlap of three such dark rate pulses.

In addition, dark rate counts may overlap with two correlated pulses from another source.

- (ii) Cosmic muon showers may generate a large number of gamma rays and electrons from an interaction of one or more cosmic ray muons with the rock in the milliQan cavern. This may cause a pulse in each layer of the demonstrator. Such a background could also be expected from a beam muon that travels close to the demonstrator.
- (iii) Radiation in the cavern, scintillator bars or surrounding material can cause correlated deposits in several bars. The lead blocks placed between layers should reduce the probability of deposit in multiple layers arising from photons or electrons while the slabs provide shielding of neutrons.
- (iv) Afterpulses, which are small pulses caused by positive ions generated by the ionization of residual gases in the PMT, can appear several hundred nanoseconds to over a few microseconds after the initial pulse. The afterpulses from correlated deposits in several PMTs may overlap and produce a signal-like signature in the demonstrator. For this to occur, the interaction event that gives rise to the afterpulses must not be triggered because, in this case, the afterpulses will fall in the $125 \mu s$ readout deadtime that follows each triggered event, and will not be recorded.

Selections are applied in order to reject contributions from these background sources. If there is a pulse within the acquisition time window in any panel, or in more than one bar in each layer, the event is rejected. These requirements reject backgrounds due to cosmic muon showers, which are expected to cause deposits across the detector. In addition, if there is a pulse in any slab within the acquisition time window consistent with originating from a muon ($n_{pe} > 250$) the event is vetoed. This requirement rejects deposits due to beam and cosmic muons passing close to the bars. The bars with reconstructed pulses are required to be pointing to the CMS IP. This reduces the backgrounds from neutrons, cosmic muon showers and random overlap, while being efficient for signal, which typically has a small angular spread. To mitigate backgrounds from afterpulses, in each channel a requirement is made to reject the event if a pulse occurs before the window in which the pulse may be involved in the trigger decision. In addition, the first pulse in each channel must have the largest n_{pe} value. Events that contain initial pulses in the bars with a large spread in n_{pe} (maximum $n_{pe}/\text{minimum } n_{pe} > 10$) are vetoed to reject events containing contributions from different sources, such as dark rate overlap with shower deposits or deposits from two or more shower particles traveling through the demonstrator. Finally, the maximum calibrated time difference between the first bar pulse in each layer (Δt_{max}) is required to be less than 15 ns, which is efficient for signals traveling through the detector from the CMS IP and forms a

TABLE I. Sequential impact of each requirement on the number of events passing the selection criteria.

Selection	Data	Data	Signal	Signal	Signal	
	beam-on $t = 1106$ h	beam-off $t = 1042$ h	$m_\chi = 0.05$ GeV $Q/e = 0.007$	$m_\chi = 1.0$ GeV $Q/e = 0.02$	$m_\chi = 3.0$ GeV $Q/e = 0.1$

SR 3	$N_{\text{slab}} = 1$ and $\min n_{pe} \in [5, 30]$	8	9	1.1	0.5	0.0
SR 4	$N_{\text{slab}} = 1$ and $\min n_{pe} > 30$	4	4	0.0	8.7	0.0
SR 5	$N_{\text{slab}} \geq 2$	1	1	0.0	2.0	4.2

powerful rejection of backgrounds that have different paths through the detector, such as cosmic muon showers, or that have deposits in each layer that are uncorrelated in their timing, such as dark rate overlap.

Selected events are subsequently categorized into five signal regions (SRs) through requirements on both the number of slabs that contain a pulse and the minimum n_{pe} of the pulses in the three bars. This categorization allows for sensitivity to a wide range of charge values in the signal parameter space. The definitions of the five SRs are summarized in Table I. For events with a pulse in each of the three layers the selection criteria provide high efficiency for the targeted models while rejecting the background by more than 5 orders of magnitude.

Residual background passing selection is estimated for each signal region by measuring the pass/fail ratio of the timing requirement in events with a hit in each layer, consistent with signal requirements except that the bars do not form a pointing path towards the CMS IP, and then multiplying it by the number of events failing the timing selection that form a pointing path towards the CMS IP. This prediction method relies on the independence of the dominant backgrounds on the pointing path requirement. This method is used rather than taking the prediction from the beam-off dataset as it is robust against time dependent drifts in the background rate. However, the beam-off dataset provides a statistically independent sample to validate the prediction without contamination from signal. The results of the beam-off prediction for the SR are summarized in Table II. The uncertainty in the prediction

reflects the limited statistics in the regions used to make the prediction. The prediction is shown to be in agreement with the observation for all validation regions. The level of agreement between prediction and observation in each validation region is used to derive a systematic uncertainty in the prediction.

Given the validation of the background prediction method with the beam-off dataset, the SR prediction is made using the beam-on dataset. The background contribution from beam processes is estimated from simulation to be less than 2% for all regions. Results are given in Table III. The predictions are seen to be consistent with those from the beam-off dataset (taking the 6% difference in collection time into account), which provides additional confidence that the beam-based backgrounds are negligible. The uncertainty in the prediction reflects both the limited statistical power of the regions used for the

TABLE II. Summary of the results of the validation using the beam-off dataset. The systematic values are derived from the level of agreement between the prediction and observation.

Region	N_{slab}	$\min n_{pe}$	Prediction	Observation	Systematic
1	0	[2,20]	$121.2^{+6.0}_{-5.9}$	131	8%
2	0	>20	$47.4^{+5.2}_{-4.8}$	45	5%

4	1	>30	$2.7^{+2.1}_{-1.1}$	4	48%
5	≥ 2	...	$0.8^{+1.4}_{-0.4}$	1	25%

TABLE III. Summary of the results of the signal region prediction.

Region	N_{slab}	min n_{pe}	Prediction	Observation
1	0	[2,20]	124^{+11}_{-11}	129
2	0	> 20	$49.9^{+6.0}_{-5.4}$	52
3	1	[5,30]	$10.7^{+3.6}_{-2.6}$	8
4	1	>30	$2.4^{+2.1}_{-1.1}$	4
5	≥ 2	...	$0.0^{+0.9}_{-0.0}$	1

prediction as well as the systematic uncertainty derived from the validation using the beam-off dataset. The predictions are found to be consistent with the observations in all SRs.

VI. INTERPRETATION

The search is interpreted using the signal model described in Sec. IV. The full set of selection criteria described in Sec. V is applied to each event. The efficiency to pass these criteria for three benchmark χ masses and charges is shown in Table I.

There are several sources of systematic uncertainty in the number of signal events entering the SRs. These are evaluated independently for each model point and are summarized below:

- (i) Signal cross section (described in Sec. IV A): typically 15%–30% depending on the mass of the χ .
- (ii) Material interactions (described in Sec. IV C): typically 1%–5% depending on the charge and mass of the χ .
- (iii) Pulse timing (described in Sec. III): typically 1%–40% depending on the charge of the χ .
- (iv) $\langle N_{\text{PE}} \rangle$ calibration (described in Sec. III): 1%–50% depending on the SR populated by the χ .
- (v) Limited simulated sample size: up to 30%.

Under the signal plus background hypothesis, a modified frequentist approach is used to determine observed upper limits at 95% confidence level on the cross section (σ) to produce a pair of χ s, as a function of mass and charge. The approach uses the LHC-style profile likelihood ratio as the test statistic [69] and the criterion of the C.L. [70,71]. The observed upper limits are evaluated through the use of asymptotic formulas [72]. Figure 8 shows the exclusion at 95% confidence level in mass and charge of the χ . The exclusion is compared to existing constraints, showing new sensitivity for χ masses above 700 MeV.

VII. FUTURE PLANS

In Refs. [30,37] we assumed the largest irreducible background to the signal would come from dark-current pulses in the PMTs. From experience gained by operating the demonstrator, we now know that an equally important background comes from correlated effects caused by

FIG. 8. Exclusion at 95% confidence level compared to existing constraints from colliders, CMS, ArgoNeuT and SLAC MilliQ [10–16,27] as well as the indirect constraint from the CMB relativistic degrees of freedom [26].

activity in the scintillator (from effects such as environmental radiation or cosmic muon showers). This realization prompted us to revisit the milliQan design, adding a fourth layer in order to mitigate the contribution from these correlated backgrounds.

We have studied the effect of adding a fourth layer with the demonstrator. The demonstrator has three rather than four layers so backgrounds are determined for threefold coincidence and then extended to fourfold using an additional pulse in a slab. The results of this study indicate that the contribution from pure dark-current overlap drops to a negligible level for the case of fourfold coincidence, even with the somewhat high-noise PMTs that are used in the demonstrator. The calculations presented in Refs. [30,37] remain a conservative estimate of the milliQan discovery potential since the background with four layers as measured with the demonstrator is significantly smaller than the estimate used in those simulations.

Given the experience obtained from the demonstrator, we are confident that the proposed full-scale detector will perform as expected provided sufficient funding becomes available.

VIII. CONCLUSIONS

We have deployed a prototype dedicated detector at the LHC to conduct the first search for elementary particles with charges much smaller than the electron charge at a hadron collider. We analyzed a data sample of proton-proton collisions collected at $\sqrt{s} = 13$ TeV provided by the LHC, corresponding to an integrated luminosity of 37.5 fb^{-1} . The existence of new particles with masses between 20 and 4700 MeV is excluded at 95% confidence level for charges varying between $0.006e$ and $0.3e$,

depending on mass. New sensitivity is achieved for masses larger than 700 MeV. The successful operation of the milliQan demonstrator and search carried out have shown the feasibility of a dedicated detector for millicharged particles at the LHC and provided important lessons for the design of the full detector.

ACKNOWLEDGMENTS

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN.

In addition, we gratefully acknowledge the CMS collaboration for supporting this endeavor by providing invaluable logistical and technical assistance. We also thank Eder Izaguirre and Itay Yavin for their enduring contributions to this idea. Finally, we acknowledge the following funding agencies who support the investigators that carried out this research in various capacities: FWO (Belgium) under the Excellence of Science EOS be.h Project No. 30820817; DFG and HGF (Germany); Swiss Funding Agencies (Switzerland); STFC (United Kingdom); DOE and NSF (USA); Lebanese University (Lebanon).

Search for a Narrow Resonance Lighter than 200 GeV Decaying to a Pair of Muons in Proton-Proton Collisions at $\sqrt{s} = 13$ TeV

A. M. Sirunyan *et al.**
(CMS Collaboration)

 (Received 10 December 2019; accepted 24 February 2020; published 3 April 2020)

A search is presented for a narrow resonance decaying to a pair of oppositely charged muons using $\sqrt{s} = 13$ TeV proton-proton collision data recorded at the LHC. In the 45–75 and 110–200 GeV resonance mass ranges, the search is based on conventional triggering and event reconstruction techniques. In the 11.5–45 GeV mass range, the search uses data collected with dimuon triggers with low transverse momentum thresholds, recorded at high rate by storing a reduced amount of trigger-level information. The data correspond to integrated luminosities of 137 and 96.6 fb⁻¹ for conventional and high-rate triggering, respectively. No significant resonant peaks are observed in the probed mass ranges. The search sets the most stringent constraints to date on a dark photon in the ~ 30 –75 and 110–200 GeV mass ranges.

DOI: [10.1103/PhysRevLett.124.131802](https://doi.org/10.1103/PhysRevLett.124.131802)

A large body of cosmological evidence points to the existence of dark matter [1–4]. Unraveling its origin remains one of the outstanding problems of particle physics and cosmology. Dark matter is expected to interact very weakly, if at all, with standard model (SM) particles. This raises the possibility of a hidden, dark sector of particles whose interaction with SM particles may be mediated by a hypothetical dark photon (Z_D) [5].

We present a search for a narrow resonance decaying to a pair of oppositely charged muons using $\sqrt{s} = 13$ TeV proton-proton (pp) collision data recorded by the CMS experiment at the CERN LHC. The search looks for a narrow resonance in the 11.5–200 GeV mass range, omitting the 75–110 GeV range where Z boson production dominates. The results of this search are interpreted in the context of a Z_D that interacts with SM particles through the kinetic mixing of its $U(1)_D$ gauge field with the $U(1)_Y$ hypercharge field of the SM [6–8]. The degree of mixing and the strength of the coupling of Z_D to SM particles is determined by the kinetic mixing coefficient ϵ . A discussion of the theory of kinetic mixing and its impact on electroweak symmetry breaking and on the electroweak precision variables can be found in Ref. [9]. Constraints have been placed on visible Z_D decays in direct searches by beam dump [10], fixed-target [11], rare meson decay [12], and collider [13–16] experiments.

The central feature of the CMS apparatus is a superconducting solenoid of 6 m internal diameter, providing a magnetic field of 3.8 T. Within the solenoid volume are a silicon pixel and strip tracker, a lead tungstate crystal electromagnetic calorimeter, and a brass and scintillator hadron calorimeter, each composed of a barrel and two end cap sections. Forward calorimeters extend the pseudorapidity (η) coverage provided by the barrel and end cap detectors. Muons are detected in gas-ionization chambers embedded in the steel flux-return yoke outside the solenoid. A detailed description of the CMS detector, together with a definition of the coordinate system used and the relevant kinematic variables, can be found in Ref. [17].

Events of interest are selected using a two-tiered trigger system [18]. The first level (L1), composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events at a rate of around 100 kHz within a time interval of 4 μ s. The second level, known as the high-level trigger (HLT), consists of a farm of processors running a version of the full event reconstruction software optimized for fast processing. A set of triggers in the HLT system reduces the event rate to around 1 kHz, allowing data containing all the information necessary for complete event reconstruction, ~ 1 MB/event, to be transferred to storage. These triggers are termed “standard triggers” in this Letter. The standard dimuon triggers have transverse momentum (p_T) requirements of 12–15 GeV on the highest p_T muon, and 5–7 GeV on the second-highest p_T muon reconstructed at L1. Requirements of $p_T > 17$ and 8 GeV are imposed at the HLT on the highest and second-highest p_T muons, respectively. The standard dimuon triggers collect data at a rate of around 30 Hz at the peak instantaneous luminosity of 2×10^{34} cm⁻² s⁻¹. These data are then fully reconstructed and used in the

search for dimuon resonance masses greater than 45 GeV. Dimuon events that do not pass the standard dimuon triggers, but are selected by certain single-muon triggers are also included. These required $p_T > 24$ GeV in the 2016 and 2018 data taking periods, and $p_T > 27$ GeV in 2017. The data collected during the years 2016–2018 correspond to an integrated luminosity of 137 fb^{-1} .

For dimuon resonance masses below ~ 40 GeV, the p_T thresholds in the standard dimuon triggers significantly reduce the signal acceptance, thereby adversely affecting the search sensitivity. Therefore, a dedicated set of triggers with significantly lower muon p_T thresholds were implemented. Events selected with these triggers contain a very limited amount of information about muons reconstructed at the HLT. This includes the muon four momenta, the number of hits left by each muon track in the tracking system, the normalized χ^2 of the muon track, and the isolation around the muon computed as the scalar sum of the p_T of all additional tracks in a $R = \sqrt{(\eta)^2 + (\phi)^2} = 0.3$ cone around the muon. The resulting event size is $\sim 4(8)$ kB for data taken in 2017 (2018). Consequently, these triggers can operate at significantly higher rates compared to the standard triggers. We refer to this approach as “data scouting” [19], and the high-rate triggers are termed “scouting triggers.”

The scouting triggers include an L1 trigger requiring two muons with opposite charge and $p_T > 4(4.5)$ GeV for data collected in 2017 (2018). An additional requirement of

$R < 1.2$ is imposed on the two muons to reduce the trigger rate. Furthermore, an L1 trigger requiring a pair of oppositely charged muons with $p_T > 4.5$ GeV and $|\eta| < 2.0$, forming an invariant mass between 7 and 18 GeV, is added. These two L1 triggers collect most of the events of interest in the dimuon mass range below ~ 20 GeV. Events passing the standard L1 dimuon triggers are also included, and collect a large fraction of events in the dimuon mass range above ~ 20 GeV. The two muons are required to have $p_T > 3$ GeV at the HLT. Lower muon thresholds are used for the HLT to maximize efficiency for events accepted by the L1 Trigger. The scouting dimuon triggers were fully commissioned for 2017 and recorded events at a rate of ~ 2 kHz at the peak instantaneous luminosity of $2 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$. Data corresponding to an integrated luminosity of 96.6 fb^{-1} were collected with these triggers in 2017 and 2018.

The Z_D signal is simulated at leading order (LO) using the hidden Abelian Higgs model (HAHM v3) [9,20] implemented with the MadGraph5_aMC@NLO2.2.2 (2.4.2) generator [21] for the 2016 (2017, 2018) data period. The width and cross section of the signal process are directly proportional to e^2 . The analysis does not rely on simulation for background estimation. However, simulations of certain SM processes are used to evaluate data-to-simulation corrections and corresponding uncertainties in the signal prediction. The process involving the production of the

$\Upsilon(1S)$ resonance and its decay to a pair of muons is simulated at LO with PYTHIA8.230 [22]. The Drell-Yan (DY) background is simulated at LO and next-to-LO (NLO) using MadGraph5_aMC@NLO, with up to four and two additional partons in the matrix element calculations, respectively.

Events simulated at the matrix element level for the signal and background processes are then interfaced with PYTHIA in order to simulate the fragmentation, parton shower, and hadronization of partons in the initial and final states, along with the underlying event. This is done using the CUETP8M1 (CP5) tune [23,24] in the simulation for the 2016 (2017, 2018) data period. Jets from LO (NLO) simulations obtained with MadGraph5_aMC@NLO are matched to the parton shower produced by PYTHIA following the MLM [25] (FxFx [26]) prescription. The 2016 (2017, 2018) era simulations use the NNPDF 3.0 (3.1) parton distribution functions (PDFs) [27,28]. The interactions of all final-state particles with the CMS detector are simulated using GEANT4 [29]. Simulated events include the contribution of particles from additional pp interactions within the same or nearby bunch crossings (pileup), with the multiplicity of reconstructed primary vertices adjusted to match that in data.

Events selected with the standard muon triggers are reconstructed using a particle-flow (PF) algorithm [30] that aims to reconstruct and identify individual particles in an event, with an optimized combination of information from the various elements of the CMS detector. Muons are reconstructed by associating a track reconstructed in the tracking detectors with a track in the muon system. The muon momentum is obtained from the curvature of the corresponding track. The candidate vertex with the largest value of summed physics-object p_T^2 is taken to be the primary pp interaction vertex (PV). The physics objects in this case are the jets, clustered using the jet finding algorithm [31,32] with a distance parameter of 0.4, with the tracks assigned to the candidate vertices as inputs, and the associated missing transverse momentum, taken as the negative vector sum of the p_T of those jets. Jets arising from b quark hadronization and decay (b jets) are identified using a deep neural network algorithm termed “deepCSV,” which takes as input tracks that are displaced from the PV, secondary vertices, and jet kinematic variables [33]. A working point on the output of the deepCSV algorithm is chosen such that the efficiency of identifying a b jet is ~ 65 – 75% and the probability of misidentifying a light-flavor jet as a b jet is about 1%.

In the search performed using the standard triggers, events are required to contain at least one well-reconstructed PV and two oppositely charged muons that are geometrically matched to the HLT muon candidates within a cone of $R = 0.1$. The highest and second-highest p_T muons are required to have $p_T > 20$ and 10 GeV, respectively, and $|\eta| < 1.9$. The restriction on η is imposed

to ensure optimal dimuon mass resolution without incurring a significant loss in acceptance. In events selected with the single-muon triggers, the muon p_T threshold is set to 26 (29) GeV for data collected in 2016 (2017, 2018). The muons are required to pass certain selection requirements based on the quality of their reconstructed tracks. The absolute values of the transverse and longitudinal impact parameters of the muon tracks are required to be less than 0.2 and 0.5 cm, respectively. The muon isolation, computed as the scalar sum of the p_T of PF candidates (photons, charged hadrons, neutral hadrons) within a cone $R = 0.4$ around the direction of the muon momentum, is required to be less than 15% of the muon p_T . Charged PF hadrons not associated with the PV are ignored in this sum. The contribution of neutral particles from pileup, estimated to be one half of the scalar sum of the p_T of charged PF hadrons from pileup in the cone, is subtracted from this sum. Events containing one or more b jets with $p_T > 30$ GeV and $|\eta| < 2.4$ are rejected to suppress most of the background from single and pair-produced top quarks.

In the search performed using the scouting triggers, events are required to contain two muons of opposite charge, with $p_T > 4$ GeV and $|\eta| < 1.9$, that are consistent with originating from the same vertex. The muons are required to pass selection requirements based on the track quality information available in the event. The muon isolation is required to be less than 15% of the muon p_T . In order to suppress the background involving muons from heavy flavor decays that typically have low p_T , the (second-) highest p_T muon is required to have $p_T > m_{\mu\mu}/(4) \cdot 3$, where $m_{\mu\mu}$ is the dimuon invariant mass.

Figure 1 shows the $m_{\mu\mu}$ distributions obtained with data collected using the standard and scouting triggers. The $m_{\mu\mu}$ distribution of fully reconstructed events collected using the standard triggers suffers from a significant acceptance loss resulting in the structure visible for $m_{\mu\mu} \lesssim 40$ GeV. The loss of acceptance is due to the p_T thresholds of 20 and 10 GeV on the two muons. The $m_{\mu\mu}$ distribution of events collected using the scouting triggers, however, continues to rise steadily for masses lower than 40 GeV. For masses lower than 20 GeV, an even steeper rise is observed. This is the region where the L1 trigger with a requirement for $m_{\mu\mu}$ to be in the range 7–18 GeV contributes significantly.

The $m_{\mu\mu}$ resolution depends strongly on the $|\eta|$ of the two muons. The p_T resolution of muons with $p_T < 50$ GeV is $\sim 1\%$ in the central barrel region of the detector ($|\eta| < 0.9$), and $\sim 3\%$ in the end caps of the muon system ($|\eta| > 1.2$) [34]. Therefore, events are divided in two categories. The barrel category consists of events in which both muons have $|\eta| < 0.9$, and the forward category contains events in which at least one of the two muons has $0.9 < |\eta| < 1.9$.

The intrinsic width of the signal resonance considered in this search is assumed to be much narrower than the detector resolution. The signal line shape is modeled using a parametric shape called the double-sided crystal ball

FIG. 1. The $m_{\mu\mu}$ distributions of events selected with the standard muon triggers (maroon, darker), and the scouting dimuon triggers (green, lighter). Events are required to pass all the selection requirements. The inset is restricted to events in the barrel category in the mass range 23.9–26.1 GeV. A function describing the background is fit to these data, and a 25 GeV Z_D signal corresponding to $\epsilon^2 = 2 \times 10^{-5}$ is added. The bottom panel of the inset shows the bin-by-bin difference between the number of events in data and the prediction from the background fit, divided by the statistical uncertainty.

(DCB) function [35]. The core of this function consists of a Gaussian distribution of mean s and standard deviation σ . The s and σ parameters represent the peak position and resolution of the resonance, and are allowed to vary using constrained nuisance parameters corresponding to the muon momentum scale and resolution uncertainties. The uncertainty in the $m_{\mu\mu}$ resolution is estimated to be 10% of σ . The uncertainty in the mass scale is 0.1% of the resonance mass in the search performed using data from standard triggers, while it varies in the range 0.06–0.1% for the search performed using data from the scouting triggers.

There are several experimental sources of systematic uncertainty in the estimation of the signal yield. The measured integrated luminosity has an uncertainty of 2.3 (2.5)% for data collected in 2017 (2016, 2018) [36–38]. In the search performed using the standard muon triggers, uncertainties of 0.2 and 1.5–3.0% are ascribed to the measurement of the trigger and muon selection efficiencies, respectively. The uncertainty in the inefficiency caused by the b jet rejection is 1%. In the search performed using scouting data, the uncertainty in the muon selection efficiency varies in the range 3–10%. The efficiency of the scouting triggers is measured with respect to fully reconstructed muons using events selected with independent standard triggers. The average uncertainty in the trigger efficiency is of order 5%, a value that takes into account a small uncertainty associated with the requirement that the muons be fully reconstructed, and a potential effect arising from background contamination.

FIG. 2. Expected and observed upper limits at 95% C.L. on the product of the signal cross section (σ) for a narrow resonance, branching fraction to a pair of muons (B), and acceptance (A) as a function of the mass of a narrow resonance. Results obtained using the scouting (standard) triggers are to the left (right) of the vertical purple line.

In order to extract the signal from data, a simultaneous binned maximum likelihood fit is performed to the $m_{\mu\mu}$ distributions in the barrel and forward event categories. A parametric function is used to model the shape of the background. The parameters of this function and the background yield are allowed to float freely in the fit, and are uncorrelated between the two event categories. In the search using the standard triggers, the fit is performed in a range of $\pm 7\sigma$ around the probed resonance mass, where σ is the mass resolution parameter of the DCB function used to model the signal. The background, which is dominated by DY events, is modeled in both event categories using the product of a modified form of the Breit-Wigner function [39] and a second-order Bernstein polynomial. In the search using the scouting triggers, the fit is performed in a range of $\pm 5\sigma$ around the probed resonance mass. The background mass distribution is modeled using a fourth-order Bernstein polynomial. The chosen background functions, and the sizes of the mass windows maximize the expected sensitivity while introducing only a small bias in the measured signal yield. Figure 1 (inset) shows, as an example, the $m_{\mu\mu}$ distribution of events in the barrel category in the 23.9–26.1 GeV window that is used to search for a 25 GeV resonance. A fit performed to these data assuming no signal is also shown along with the expected signal contribution for a 25 GeV Z_D with $\epsilon^2 = 2 \times 10^{-5}$.

In order to assess the possible bias in the measurement of a signal due to the choice of the function used to model the background distribution, we consider several alternative functions to model the shape of the background. An alternative test function is fit to the data in each event category, and is then used to generate 2000 sets of pseudodata. A certain amount of signal is injected in each of the pseudodata sets. A signal-plus-background fit is

FIG. 3. Expected and observed upper limits at 90% C.L. on ϵ^2 , the square of the kinetic mixing coefficient, as a function of the Z_D mass. Results obtained using the scouting (standard) triggers are to the left (right) of the vertical purple line. Limits at 90% C.L. from the search performed by the LHCb Collaboration [16] are shown in red, and constraints at 95% C.L. from the measurements of the electroweak observables are shown in light blue [9].

performed using the chosen background function to each of the pseudodata sets with the signal yield allowed to float freely. The bias is quantified as the ratio of the difference between the measured and injected signals, and the statistical uncertainty in the measured signal yield. The bias is found to be less than 10% of the statistical uncertainty in the measured signal yield for resonance masses greater than 20 GeV, in both event categories. For masses below 20 GeV, the bias is estimated to be less than 20(30)% of the statistical uncertainty for the barrel (forward) category. In order to account for this uncertainty, we introduce an additional background in the fit. The shape of the background is taken to be the same as that of the signal, and its normalization is treated as a nuisance parameter with mean value zero, whose variations are constrained by a Gaussian distribution with standard deviation equal to the bias found in the tests.

The statistical analysis is performed using a profile likelihood ratio test statistic in which systematic uncertainties are modeled as constrained nuisance parameters. The nuisance parameters for the $m_{\mu\mu}$ scale and resolution uncertainties, and the bias due to the choice of the background fit function are modeled using the Gaussian probability density function. All other sources of systematic uncertainty affect the signal yield, and are modeled with nuisance parameters that are constrained using the log-normal probability density function.

The data are found to be consistent with the background expectation. Figure 2 shows the upper limits at 95% confidence level (C.L.) on the product of the signal cross section, branching fraction to a pair of muons, and the kinematic and geometrical acceptance for a narrow resonance using an asymptotic CL_s criterion [40–42].

The results of this search are interpreted in the context of a dark photon model. The signal is kinematically similar to the SM DY process. Therefore, an NLO K factor has been computed for the LO signal simulation by comparing the NLO and LO DY cross sections, and is found to be 1.09 over the entire mass range under consideration. Uncertainties due to the choice of the renormalization and factorization scales (4.5%), and the modeling of the PDFs (1%) are ascribed to the signal cross section. We set upper limits at 90% C.L. on ϵ^2 as a function of the Z_D mass, as shown in Fig. 3. These are compared with recent results from the LHCb Collaboration [16,43] and indirect constraints at 95% C.L. from measurements of the electroweak observables [9]. This search sets the most stringent limits to date in the $\sim 30\text{--}75$ and $110\text{--}200$ GeV mass ranges. Furthermore, limits from this search are competitive with those obtained in Ref. [16] at lower masses.

In summary, a search has been presented for a narrow resonance decaying to a pair of muons using proton-proton collision data recorded by the CMS experiment at $\sqrt{s} = 13$ TeV. The search in the $45\text{--}75$ and $110\text{--}200$ GeV resonance mass ranges uses fully reconstructed data containing a pair of muons with transverse momenta greater than 20 and 10 GeV, corresponding to an integrated luminosity of 137 fb^{-1} . The search in the resonance mass range of $11.5\text{--}45.0$ GeV is performed using data collected with high-rate dimuon triggers, corresponding to an integrated luminosity of 96.6 fb^{-1} . This is the first search that uses data with reduced trigger-level muon information, collected with dimuon triggers that have transverse momentum thresholds of 3 GeV. The data are found to be consistent with the background prediction. The search sets the lowest upper limits to date on the kinetic mixing coefficient of a dark photon in the $\sim 30\text{--}75$ and $110\text{--}200$ GeV mass ranges.

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC and the CMS detector provided by the following funding agencies: BMBWF and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, FAPERGS, and FAPESP (Brazil); MES (Bulgaria); CERN; CAS, MoST, and NSFC (China); COLCIENCIAS (Colombia); MSES and CSF (Croatia); RPF (Cyprus); SENESCYT (Ecuador); MoER, ERC IUT, PUT and ERDF (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); NKFI

(Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); MSIP and NRF (Republic of Korea); MES (Latvia); LAS (Lithuania); MOE and UM (Malaysia); BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI (Mexico); MOS (Montenegro); MBIE (New Zealand); PAEC (Pakistan); MSHE and NSC (Poland); FCT (Portugal); JINR (Dubna); MON, RosAtom, RAS, RFBR, and NRC KI (Russia); MESTD (Serbia); SEIDI, CPAN, PCTI, and FEDER (Spain); MOSTR (Sri Lanka); Swiss Funding Agencies (Switzerland); MST (Taipei); ThEPCenter, IPST, STAR, and NSTDA (Thailand); TUBITAK and TAEK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF (USA).

^aDeceased.

^bAlso at Vienna University of Technology, Vienna, Austria.

^cAlso at IRFU, CEA, Université Paris-Saclay, Gif-sur-Yvette, France.

^dAlso at Universidade Estadual de Campinas, Campinas, Brazil.

^eAlso at Federal University of Rio Grande do Sul, Porto Alegre, Brazil.

^fAlso at UFMS.

^gAlso at Universidade Federal de Pelotas, Pelotas, Brazil.

^hAlso at Université Libre de Bruxelles, Bruxelles, Belgium.

ⁱAlso at University of Chinese Academy of Sciences.

^jAlso at Institute for Theoretical and Experimental Physics named by A.I. Alikhanov of NRC ‘Kurchatov Institute’, Moscow, Russia.

^kAlso at Joint Institute for Nuclear Research, Dubna, Russia.

^lAlso at British University in Egypt, Cairo, Egypt.

^mAlso at Suez University, Suez, Egypt.

ⁿAlso at Purdue University, West Lafayette, Indiana, USA.

^oAlso at Université de Haute Alsace, Mulhouse, France.

^pAlso at Erzincan Binali Yildirim University, Erzincan, Turkey.

^qAlso at CERN, European Organization for Nuclear Research, Geneva, Switzerland.

^rAlso at RWTH Aachen University, III. Physikalisches Institut A, Aachen, Germany.

- ^s Also at University of Hamburg, Hamburg, Germany.
- ^t Also at Brandenburg University of Technology, Cottbus, Germany.
- ^u Also at Institute of Physics, University of Debrecen, Debrecen, Hungary.
- ^v Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary.
- ^w Also at MTA-ELTE Lendület CMS Particle and Nuclear Physics Group, Eötvös Loránd University, Budapest, Hungary.
- ^x Also at IIT Bhubaneswar, Bhubaneswar, India.
- ^y Also at Institute of Physics, Bhubaneswar, India.
- ^z Also at Shoolini University, Solan, India.
- ^{aa} Also at University of Hyderabad, Hyderabad, India.
- ^{bb} Also at University of Visva-Bharati, Santiniketan, India.
- ^{cc} Also at Isfahan University of Technology.
- ^{dd} Also at INFN Sezione di Bari, Università di Bari, Politecnico di Bari, Bari, Italy.
- ^{ee} Also at Italian National Agency for New Technologies, Energy and Sustainable Economic Development.
- ^{ff} Also at Centro Siciliano di Fisica Nucleare e di Struttura Della Materia.
- ^{gg} Also at Scuola Normale e Sezione dell'INFN, Pisa, Italy.
- ^{hh} Also at Riga Technical University, Riga, Latvia.
- ⁱⁱ Also at Malaysian Nuclear Agency, MOSTI, Kajang, Malaysia.
- ^{jj} Also at Consejo Nacional de Ciencia y Tecnología, Mexico City, Mexico.
- ^{kk} Also at Warsaw University of Technology, Institute of Electronic Systems, Warsaw, Poland.
- ^{ll} Also at Institute for Nuclear Research, Moscow, Russia.
- ^{mmm} Also at National Research Nuclear University 'Moscow Engineering Physics Institute' (MEPhI), Moscow, Russia.
- ⁿⁿ Also at St. Petersburg State Polytechnical University, St. Petersburg, Russia.
- ^{oo} Also at University of Florida, Gainesville, Florida, USA.
- ^{pp} Also at Imperial College, London, United Kingdom.
- ^{qq} Also at P.N. Lebedev Physical Institute, Moscow, Russia.
- ^{rr} Also at California Institute of Technology, Pasadena, California, USA.
- ^{ss} Also at Budker Institute of Nuclear Physics, Novosibirsk, Russia.
- ^{tt} Also at Faculty of Physics, University of Belgrade, Belgrade, Serbia.
- ^{uu} Also at Università degli Studi di Siena, Siena, Italy.
- ^{vv} Also at INFN Sezione di Pavia, Università di Pavia, Pavia, Italy.
- ^{ww} Also at National and Kapodistrian University of Athens, Athens, Greece.
- ^{xx} Also at Universität Zürich, Zurich, Switzerland.
- ^{yy} Also at Stefan Meyer Institute for Subatomic Physics, Vienna, Austria.
- ^{zz} Also at Burdur Mehmet Akif Ersoy University.
- ^{aaa} Also at Şırnak University.
- ^{bbb} Also at Department of Physics, Tsinghua University, Beijing, China.
- ^{ccc} Also at Beykent University, Istanbul, Turkey.
- ^{ddd} Also at Istanbul Aydin University, Application and Research Center for Advanced Studies (App. & Res. Cent. for Advanced Studies).
- ^{eee} Also at Mersin University, Mersin, Turkey.
- ^{fff} Also at Piri Reis University, Istanbul, Turkey.
- ^{ggg} Also at Gaziosmanpasa University, Tokat, Turkey.
- ^{hhh} Also at Adiyaman University, Adiyaman, Turkey.
- ⁱⁱⁱ Also at Ozyegin University, Istanbul, Turkey.
- ^{jjj} Also at Izmir Institute of Technology, Izmir, Turkey.
- ^{kkk} Also at Marmara University, Istanbul, Turkey.
- ^{lll} Also at Kafkas University, Kars, Turkey.
- ^{mmm} Also at Istanbul Bilgi University, Istanbul, Turkey.
- ⁿⁿⁿ Also at Hacettepe University, Ankara, Turkey.
- ^{ooo} Also at Vrije Universiteit Brussel, Brussel, Belgium.
- ^{ppp} Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom.
- ^{qqq} Also at IPPP Durham University.
- ^{rrr} Also at Monash University, Faculty of Science, Clayton, Australia.
- ^{sss} Also at Bethel University, St. Paul, Minneapolis, USA.
- ^{ttt} Also at Karamanoğlu Mehmetbey University, Karaman, Turkey.
- ^{uuu} Also at Bingol University, Bingol, Turkey.
- ^{vvv} Also at Georgian Technical University, Tbilisi, Georgia.
- ^{www} Also at Sinop University, Sinop, Turkey.
- ^{xxx} Also at Mimar Sinan University, Istanbul, Istanbul, Turkey.
- ^{yyy} Also at Texas A&M University at Qatar, Doha, Qatar.
- ^{zzz} Also at Kyungpook National University, Daegu, Korea.

Abstract

Particles beyond the Standard Model (SM) can generically have lifetimes that are long compared to SM particles at the weak scale. When produced at experiments such as the Large Hadron Collider (LHC) at CERN, these long-lived particles (LLPs) can decay far from the interaction vertex of the primary proton–proton collision. Such LLP signatures are distinct from those of promptly decaying particles that are targeted by the majority of searches for new physics at the LHC, often requiring customized techniques to identify, for example, significantly displaced decay vertices, tracks with atypical properties, and short track segments. Given their non-standard nature, a comprehensive overview of LLP signatures at the LHC is beneficial to ensure that possible avenues of the discovery of new physics are not overlooked. Here we report on the joint work of a community of theorists and experimentalists with the ATLAS, CMS, and LHCb experiments—as well as those working on dedicated experiments such as MoEDAL, milliQan, MATHUSLA, CODEX-b, and FASER—to survey the current state of LLP searches at the LHC, and to chart a path for the development of LLP searches into the future, both in the upcoming Run 3 and at the high-luminosity LHC. The work is organized around the current and future potential capabilities of LHC experiments to generally discover new LLPs, and takes a signature-based approach to surveying classes of models that give rise to LLPs rather than emphasizing any particular theory motivation. We develop a set of simplified models; assess the coverage of current searches; document known, often unexpected backgrounds; explore the capabilities of proposed detector upgrades; provide recommendations for the presentation of search results; and look towards the newest frontiers, namely high-multiplicity ‘dark showers’, highlighting opportunities for expanding the LHC reach for these signals.

Keywords: beyond the Standard Model, long-lived particles, Large Hadron Collider, high-luminosity LHC, collider phenomenology, high-energy collider experiments

1. Introduction

Document editors: James Beacham, Brian Shuve

Particles in the Standard Model (SM) have lifetimes spanning an enormous range of magnitudes, from the Z boson ($\tau \sim 2 \times 10^{-25}$ s) through to the proton ($\tau \sim 10^{34}$ years) and electron (stable), as shown in figure 1.

Similarly, models beyond the SM (BSM) typically predict new particles with a variety of lifetimes. In particular, new weak-scale particles can easily have long lifetimes for several reasons, including approximate symmetries that stabilize the long-lived particle (LLP), small couplings between the LLP and lighter states, and suppressed phase space available for decays. For particles moving close to the speed of light, this can lead to macroscopic,

Figure 1. Particle lifetime $c\tau$, expressed in meters, as a function of particle mass, expressed in GeV, for a variety of particles in the Standard Model [1].

detectable displacements between the production and decay points of an unstable particle for $c\tau \sim 10 \mu\text{m}$ ¹²⁹.

The experimental signatures of LLPs at the Large Hadron Collider (LHC) are varied and, by nature, are often very different from signals of SM processes. For example, LLP signatures can include tracks with unusual ionization and propagation properties; small, localized deposits of energy inside of the calorimeters without associated tracks; stopped particles (SPs) that decay out of time with collisions; displaced vertices (DV) in the inner detector (ID) or muon spectrometer (MS); and disappearing, appearing, and kinked tracks. A schematic of a sampling of the variety of LLP signatures that are different from both SM signatures and the majority of BSM searches at the LHC is shown in figure 2.

Because the LLPs of the SM have masses $< 5 \text{ GeV}$ and have well-understood experimental signatures, the unusual signatures of BSM LLPs offer excellent prospects for the discovery of new physics at particle colliders. At the same time, standard reconstruction algorithms may reject events or objects containing LLPs precisely because of their unusual nature, and dedicated searches are needed to uncover LLP signals. These atypical signatures can also resemble noise, pile-up (PU), or mis-reconstructed objects in the detector; due to the rarity of such mis-reconstructions, Monte Carlo (MC) simulations may not accurately model backgrounds for LLP searches, and dedicated methods are needed to do so.

Although small compared to the large number of searches for prompt decays of new particles, many searches for LLPs at the ATLAS, CMS, and LHCb experiments at the LHC have already been performed; we refer the reader to chapter 3 for descriptions of and references to these searches. Existing LLP searches have necessitated the development of novel methods for identifying signals of LLPs, and measuring and suppressing the relevant backgrounds. Indeed, in several scenarios searches for LLPs have sensitivities that greatly

¹²⁹ Recently, a comprehensive collection of the vast array of theoretical frameworks within which LLPs naturally arise has been assembled as part of the physics case document for the proposed MATHUSLA experiment [2]. Because the focus of the current document is on the experimental signatures of LLPs and explicitly not the theories that predict them, the combination of the MATHUSLA physics case document (and the large number of references therein) and the present document can be considered, together, a comprehensive view of the present status of theoretical motivation and experimental possibilities for the potential discovery of LLPs produced at the interaction points (IPs) of the LHC.

Figure 2. Schematic of the variety of challenging, atypical experimental signatures that can result from BSM LLPs in the detectors at the LHC. Shown is a cross-sectional plane in azimuthal angle, ϕ , of a general purpose detector such as ATLAS or CMS. From [3].

exceed the search for similar, promptly decaying new particles (as is true, for example, for directly produced staus in supersymmetry [4]). The excellent sensitivity of these searches, together with the lack of a definitive signal in any prompt channels at the LHC, have focused attention on other types of LLP signatures that are not currently covered. These include low-mass LLPs that do not pass trigger or selection thresholds of current searches, high multiplicities of LLPs produced in dark-sector showers, or unusual LLP production and decay modes that are not covered by current methods. Given the excellent sensitivity of LHC detectors to LLPs, along with the potentially large production cross sections of LLPs and the enormous amount of data expected to be collected when the LHC switches to high-luminosity running in the 2020s, it is imperative that the space of LLP signatures be explored as thoroughly as possible to ensure that no signals are missed. This is particularly important now, with the recent conclusion of LHC Run 2, as new triggering strategies for LLP signatures in the upcoming Run 3 can be investigated with urgency. Moreover, decisions are currently being made about detector upgrades for Phase 2 of the LHC, and design choices should be made to ensure that sensitivity to LLPs is retained or possibly improved through high-luminosity running, as may indeed be the case for many of the plans under consideration by the main experiments.

The increased interest in LLP signatures at the LHC is naturally complementary to the recognition that there are several BSM scenarios that give rise to particles difficult to optimally detect at the LHC—either promptly decaying particles or those with naturally long lifetimes—and that are searched for or planned to be searched for in fixed-target experiments, B-factories, and beam dump experiments [5–7].

The growing theoretical and experimental interest in LLPs has been mirrored by an increased activity in proposals for searches for LLPs produced at the main LHC IPs—either within the existing ATLAS, CMS, and LHCb collaborations or with new, dedicated detectors—new experimental analyses, and meetings to communicate results and discuss new ideas.

Workshops focused on LLPs at the University of Massachusetts, Amherst¹³⁰, in November of 2015; Fermilab; and KITP (UCSB)¹³¹ in May of 2016, among others, highlighted the need for a community-wide effort to map the current space of both theoretical models for LLPs and the atypical experimental signatures that could be evidence of LLPs, assess the coverage of current experimental methods to these models, and identify areas where new searches are required. Additionally, the work presented in these meetings underscored the importance of presenting the results of experimental searches in a manner that allows for their application to different models, and generated new ideas for designing analyses with the goal of minimizing model dependence. Such largely model-independent presentation makes current searches more powerful by increasing their applicability to new scenarios, while reducing redundancies in searches and ensuring that gaps in coverage are identified and addressed. This task extends beyond the purview of any particular theoretical model or experiment, and requires an effort across collaborations to address the needs of the LLP community and illuminate a path forward.

This flurry of activity eventually coalesced in the establishment of a more central and regular platform—the LHC LLP Community—for experimentalists at the LHC and those in the theoretical and phenomenological communities to exchange ideas about LLP searches to ensure the full discovery potential of the LHC. This began with a mini-workshop at CERN in May of 2016¹³² and has continued with workshops in April of 2017 at CERN¹³³, October of 2017 at ICTP Trieste¹³⁴, May of 2018 again at CERN¹³⁵, at Nikhef, in Amsterdam, in October of 2018¹³⁶, May of 2019 at CERN¹³⁷ and November of 2019 at Ghent University¹³⁸

This is the work undertaken by the LHC LLP Community and presented in this document. Based on the most pressing needs identified by the community, we organize the work of this initiative into a few key realms:

- *Simplified models:* We seek to identify a minimal (but expandable) set of simplified models that capture, with a very limited number of free parameters, the most important LLP signatures motivated by theory and accessible at the LHC. The simplified models approach has been successfully applied to models such as supersymmetry (SUSY) and dark matter (DM), and proposals exist for LLP simplified models in particular contexts. We aim to provide a basis of models that serves as a focal point for the other studies performed by the community, as well as a library that can be used in simulating LLP signal events, to allow for a common grammar to better understand how current and future searches cover LLP signature space.

¹³⁸ ‘Searching for LLPs at the LHC: Sixth Workshop of the LHC LLP Community’, https://indico.cern.ch/e/LHC_LL2019.

- *Experimental coverage:* In spite of the many successful LLP searches undertaken by the ATLAS, CMS, and LHCb experiments, there remains a need for a systematic study of the complementary coverage of LLP searches to the parameter spaces of LLP models. Having developed a simplified model basis, we provide a comprehensive overview of the sensitivity of existing searches, highlighting gaps in coverage and high-priority searches to be undertaken in the future.
- *Backgrounds to LLP searches:* We provide a summary and analysis of backgrounds for LLP signals at the LHC, sources of which can be rare, unexpected, and largely irrelevant for searches for prompt BSM particles, and thus not fully well understood. We assemble the collected knowledge and experience of backgrounds to prior searches with the intention of providing insight into the opportunities and challenges of searching for LLP signatures.
- *Upgrades and triggering strategies:* We discuss the prospects for LLP searches with upgraded detectors for Phase 2 of LHC running, with a focus on how upgrades can offer new sensitivity to LLPs as well as mitigate the effects of PU. New opportunities for improving sensitivity of triggers and searches to LLPs are additionally presented for the upgrades planned for Run 3. This is tied to the crucial question of triggers for LLPs; we discuss the performance of current triggers for LLPs, as well as the effects of future upgrades to the trigger system. Most importantly, we identify a few concrete upgrade studies that should be performed by the experiments that are of prime interest to the community.
- *Reinterpretation of LLP searches:* Due to the non-standard nature of the objects used in analyses, LLP searches are notoriously hard to reinterpret for models beyond those considered by the experimental collaborations. Designing searches and presenting search results in a way that is broadly applicable to current and yet-to-be-developed LLP models is crucial to the impact and legacy of the LLP search program. We discuss the reinterpretation of the LLP searches by means of concrete examples to illustrate specific challenges and, based on the lessons learned from this procedure, we provide recommendations on the presentation of LLP experimental search results.
- *Dark showers:* Current LLP search strategies have limited sensitivity to models where the LLPs are very soft, highly collimated, and come in large multiplicities, as can occur in models of dark-sector showers. We report on recent progress in theoretically parameterizing the space of dark-shower models and signatures, as well as experimental searches to uncover these signals.

Finally, we provide information about current and proposed experiments to search for LLPs at the LHC via dedicated detectors. These include the MoEDAL monopole search, the milliQan milli-charged particle (mCP) experiment, the MATHUSLA surface detector for ultra-LLPs, the CODEX-b proposal for a new detector near LHCb, and the FASER proposal for a long, narrow detector located in the forward direction well downstream one of the collision points.

This is the first report of the LHC LLP Community initiative, and is expected to be followed by future reports as our collective understanding of these signatures as a means of discovering new physics at the LHC evolves.

2. Simplified models yielding LLPs

Chapter editors: James Beacham, Giovanna Cottin, David Curtin, Jared Evans, Zhen Liu, Michael Ramsey-Musolf, Jessie Shelton, Brian Shuve

Contributors: Oliver Buchmueller, Alessandro Davoli, Andrea De Simone, Kristian Hahn, Jan Heisig, Thomas Jacques, Matthew McCullough, Stephen Mrenna, Marco Trovato, Jiang-Hao Yu

Long-lived particles (LLPs) arise in many well-motivated theories of physics BSM, ranging from heavily studied scenarios such as the minimal supersymmetric SM (MSSM) [8–12] to newer theoretical frameworks such as neutral naturalness [13–15] and hidden sector DM [16–21]. Macroscopic decay lengths of new particles naturally arise from the presence and breaking of symmetries, which can be motivated by cosmology (such as DM and baryogenesis) [22–35], neutrino masses [36–52], as well as solutions to the hierarchy problem [13–15, 53–61] or in asymptotically safe completions of the SM [62]; indeed, LLPs are generically a prediction of new hidden sectors at and below the weak scale [63–71]. An extensive and encyclopedic compilation of theoretical motivations for LLPs has already been performed for the physics case of the proposed MATHUSLA experiment [2], and we refer the reader to this document and the references therein for an in-depth discussion of theoretical motivations for LLPs. Given the large number of theories predicting LLPs, however, it is clear that a comprehensive search program for LLPs is critical to fully leverage the LHC’s immense capability to illuminate the physics of the weak scale and beyond.

The simplified model framework has proven to be a highly successful approach to characterizing signals of BSM physics. Simplified models have driven the development of searches for new signatures at the LHC and allowed existing searches to be reinterpreted for many models beyond the one(s) initially targeted in the analysis. Comprehensive simplified model programs exist for scenarios featuring prompt decays of new particles [72–78] or DM produced at colliders [79–90]. Simplified models are so successful because the majority of search sensitivity is driven by only a few broad aspects of a given BSM signature, such as the production process, overall production rate, and decay topology. Meanwhile, the sensitivity of searches is typically insensitive to other properties such as the spin of the particles involved [91–94].

To extend the simplified model approach to LLP signatures in a systematic way, we develop a proposal for a set of simplified models which aims to ensure that experimental results can be characterized as follows: (i) *powerful*, covering as much territory in model space as possible; (ii) *efficient*, reducing unnecessary redundancy among searches; (iii) *flexible*, so that they are broadly applicable to different types of models; and (iv) *durable*, providing a common framework for MC simulation of signals and facilitating the communication of results of LLP searches so that they may be applied to new models for years to come. We elaborate on these goals in section 2.1. This framework helps illuminate gaps in coverage and highlight areas where new searches are needed, and we undertake such a study in chapter 3. Our efforts build on earlier work proposing simplified model programs for LLPs motivated by particular considerations such as SUSY or DM [95–100].

In our work, we concentrate on establishing an initial basis of simplified models representative of theories giving rise to final states with one or two LLPs¹³⁹. The simplified model approach is very powerful for LLP signatures: the typically lower backgrounds for displaced signatures allow searches to be highly inclusive with respect to other objects in the

¹³⁹ Some models predict moderately higher LLP multiplicities, but the coverage of such signatures from 1-2 LLP searches is good provided the LLPs do not overlap in the detector. Our proposed simplified models are not, however, representative of high-multiplicity signatures such as dark showers (see section 2.6 and chapter 7).

event or the identification of objects originating from the decay of an LLP. This enables a single analysis to have sensitivity to a wide variety of models for LLP production and decay.

We organize our simplified models in terms of LLP channels characterized by a combination of a particular LLP production mode with a particular decay mode. Because the production and decay positions of LLPs are physically distinct¹⁴⁰, it is often possible to factorize and consider separately their production and decay¹⁴¹. For each LLP channel, the lifetime of the LLP is taken to be a free parameter. We emphasize that the LLP channel defined here is *not* the same as an experimental signature that manifests in the detector: a single channel can give rise to many different signatures depending on where (or whether)¹⁴² the LLP decays occur inside the detector, while a single experimental search for a particular signature could potentially cover many simplified model channels. In this chapter, we focus on the construction and simulation of a concrete basis of LLP simplified model channels; a partial mapping of existing searches into our basis of simplified models is discussed in chapter 3, along with the highest-priority gaps in current coverage and proposals for new searches.

As discussed in the existing simplified model literature, simplified models have their own limited range of applicability [78, 86–88, 106]. For example, the presentation of search results in terms of simplified models often assume 100% branching fractions into particular final states. In a UV model where the LLP decays in a very large number of ways, none of the individual simplified model searches may be sufficient to constrain it. Similarly, if the LLP is produced in a UV model with other associated objects that spoil the signal efficiency (for example, the production of energetic, prompt objects collimated with the LLP such that the signal fails isolation or displacement criteria; this is particularly important for high-multiplicity or dark-shower scenarios, as discussed in chapter 7), then the simplified model result does not apply and a more targeted analysis is required to cover the model. Nevertheless, the simplified models framework allows us to organize possible production modes and signatures in a systematic way and identify if there are any interesting signals or parts of parameter space that are missed by current searches. Therefore, we present a proposal for simplified models here with the understanding that there exist scenarios where UV models remain important for developing searches and presenting results.

The basis of simplified models presented here is a starting point, rather than a final statement. The present goal is to provide a set of simplified models that covers the majority of the best-motivated and simplest UV models predicting LLPs, which we outline in section 2.2. Many of these contain singly and doubly produced LLPs (or in some cases, three-to-four relatively isolated LLPs, which are typically covered well by searches for 1–2 LLPs) and so we restrict our simplified model proposal to cover these multiplicities. By design, simplified models do not include all of the specific details and subtle features that may be found in a given complete model. Therefore, the provided list is meant to be

¹⁴⁰ Indeed, the decay position may be so far from the collision point that external detectors can also be used to search for ultra-long-lived neutral or mCPs [101–105].

¹⁴¹ In addition to production and decay, a third consideration is the propagation of particles through the detector. While neutral LLPs undergo straightforward propagation, states with electric or color charge (e.g. SUSY R -hadrons), or particles with exotic charges such as magnetic monopoles or quirks, typically engage in a more complicated and often very uncertain traverse through the detector. This spoils the factorization of LLP production and decay. The subtleties related to LLPs with electric or color charge is discussed more in section 2.4.3. A trickier question is how to best simulate such states: since LLPs with electric or color charge interact with the detector material, there must be an interface between the detector simulation software and the program implementing decay. This is discussed further in section 2.5.2.

¹⁴² The case of detector-stable particles is understood to be included in the simplified models by setting $c\tau \rightarrow \infty$. In this case there is manifestly no dependence on the decay mode. See section 2.3.2 for further details.

expanded to cover new or more refined models as the LLP-search program develops. For instance, extending the simplified model framework to separately treat final states with heavy-flavor particles is of great interest (in analogy with the prompt case [107–109]); see section 2.6 for a discussion of this and other limitations of the current framework along with future opportunities for expansion. High-multiplicity signatures such as dark showers or emerging jets present different experimental and theoretical issues, which are discussed in chapter 7. Finally, a broader set of simplified models may be needed to present the results of experimental searches and to allow ready application of experimental results to UV models of interest (see chapter 6).

2.1. Goals of the present simplified model framework

The purpose of the simplified model framework is to provide a simple, common language that experimentalists and theorists can use to describe theories of LLPs and the corresponding mapping between models and experimental signatures. We therefore want our simplified model space to:

1. Use a minimal but sufficient set of models to cover a wide range of the best-motivated theories of LLPs.
2. Furnish a simple map between models and signatures to enable a clear assessment of existing search coverage and possible gaps.
3. Expand flexibly when needed to incorporate theories and signatures not yet proposed.
4. Provide a concrete MC signal event generation framework for signals.
5. Facilitate the reinterpretation of searches by supplying a sufficiently varied set of standard benchmark models for which experimental efficiencies can be provided for validation purposes.

Note that points #1 and #5 are somewhat in tension with one another: we wish to have a compact set of models that can be the subject of systematic study in terms of experimental signatures, but expressing experimental results in terms of only this set of simplified models may make it challenging to reinterpret experimental searches for UV models that are not precisely described by one of the simplified models. In this section, we prioritize having a minimal set of simplified models for the purpose of studying experimental coverages and generating new search ideas, while we defer a discussion of simplified models in the presentation and reinterpretation of search results to chapter 6¹⁴³.

In the remainder of this chapter, we construct a proposal for a minimal basis of simplified models for events with one or two LLPs. We begin with a discussion of the well-motivated UV theories that predict the existence of LLPs, and identify a set of umbrella models that yield LLPs in section 2.2. We next identify the relevant (simplified) production and decay modes for LLPs in section 2.3, emphasizing that each channel for production and decay has a characteristic set of predictions for the number and nature of *prompt* accompanying objects (AOs) producing along with the LLP. In section 2.4, we combine these production and decay modes into our simplified model basis set and highlight how different umbrella models naturally populate the various LLP channels. Section 2.5 and the appendix present a framework and instructions for how the best-motivated simplified model channels can be

¹⁴³ We note that, in general, more benchmark models may be needed for enabling reliable reinterpretation than the minimal set discussed here. An example where an extended set of simplified models is used can be seen in the heavy stable charged particle (HSCP) reinterpretation in section 6.3.2 (table 5).

simulated in MC using a new model library provided in the [appendix](#). Finally, limitations of the existing framework, along with opportunities for its further development are outlined in section 2.6.

2.2. Existing well-motivated theories for LLPs

Here we provide a brief distillation of many of the best-motivated theories with LLPs into five over-arching categories, focusing in particular on those that give rise to single and double production of LLPs at colliders. We emphasize that each of these categories is a broad umbrella containing many different individual models containing LLPs; in many cases, the motivations and model details among theories within a particular category may be very different, but tend to predict similar types of LLPs. Additionally, the categories are not mutually exclusive, with several examples of UV models falling into one or more category. In all cases, long lifetimes typically arise from some combination of hierarchies of scales in interactions that mediate decays; small couplings; and phase space considerations (such as small mass splittings between particles or large multiplicities of final-state particles in a decay). Many of the broad theoretical motivations for LLPs have recently been summarized in the literature [2].

The UV umbrella models we consider are:

- *Supersymmetry-like theories (SUSY)*. This category contains models with multiple new particles carrying SM gauge charges and a variety of allowed cascade decays. Here LLPs can arise as a result of approximate symmetries (such as R -parity [55, 110, 111] or indeed SUSY itself in the case of gauge mediation [112]) or through a hierarchy of mass scales (such as highly off-shell intermediaries in split SUSY [113], or nearly-degenerate multiplets [63, 64, 114], as in anomaly-mediated SUSY breaking [65]). Finally, models of SUSY hidden sectors such as stealth SUSY [54] generically lead to LLPs. Our terminology classifies any non-SUSY models with new SM gauge-charged particles, such as composite Higgs or extra-dimensional models, under the SUSY-like umbrella because of the prediction of new particles above the weak scale with SM gauge charges. In this category, LLP production is typically dominated by SM gauge interactions, whether of the LLP itself or of a heavy parent (HP) particle that decays to LLPs.
- *Higgs-portal theories (Higgs)*. In this category, LLPs couple predominantly to the SM-like Higgs boson. This possibility is well motivated because the SM Higgs field provides one of the leading renormalizable portals for new gauge-singlet particles to couple to the SM, and the experimental characterization of the Higgs boson leaves much scope for couplings of the Higgs to BSM physics [115, 116]. The most striking signatures here are exotic Higgs decays to low-mass particles [117] (as in many Hidden Valley (HV) scenarios [66, 67]), which can arise in models of neutral naturalness [13, 14, 118] and DM [119], as well as in more exotic scenarios such as relaxion models [120]. The Higgs is also special in that it comes with a rich set of associated production modes in addition to the dominant gluon-fusion process, with vector-boson fusion (VBF) and Higgs-strahlung (VH) production modes allowing novel opportunities for triggering on and suppressing backgrounds to Higgs-portal LLP signatures. Indeed, in many scenarios where LLPs are produced in exotic Higgs decays, associated-production modes can be the only way of triggering on the event.
- *Gauge-portal theories (ZP)*. This category contains scenarios where new vector mediators can produce LLPs. These are similar to Higgs models, although here the vector mediator is predominantly produced from $q\bar{q}$ initial states without other associated

objects except for gluon initial-state radiation (ISR). Examples include models where both SM fermions and LLPs carry a charge associated with a new Z' (for a review, see [121]), as well as either Abelian or non-Abelian dark photon or dark Z models [122] in which the couplings of new vector bosons to the SM are mediated by kinetic mixing. Scenarios with LLPs coupled to new gauge bosons are well motivated by theories of DM, particularly models with significant self-interactions [123–125] and/or sub-weak mass scales [17, 18, 20, 126, 127].

- *DM theories.* Non-SUSY and hidden-sector DM scenarios are collected in this category, which encompasses models where the cosmological DM is produced as a final state in the collider process. Examples of multi-component DM theories include models of new electroweak multiplets [64, 128–130], strongly interacting massive particles (SIMPs) [131], iDM [132–135], models with DM coannihilation partners [98, 136–141] (including scenarios where the coannihilation partners are out of chemical equilibrium, giving distinctly predictions for the relic abundance [142–145]), and non-thermal ‘freeze-in’ scenarios [146–153]. In many of these models, the collider phenomenology and LLP lifetime can be tied to the DM relic abundance [135, 146, 154]. For LLPs decaying inside the detector, an important feature distinguishing this category from the Higgs and gauge scenarios above is that an explicit detector-level signature of a DM candidate, i.e. missing energy (\cancel{E}_T), is a necessary and irreducible component [30, 66, 67, 100, 133, 135, 155–157].
- *Heavy neutrino theories (RH ν).* The see-saw mechanism of SM neutrino mass generation predicts new right-handed neutrino (RHN) states [158–162]. If the RHNs have masses in the GeV to TeV range, they typically have a long lifetime and can be probed at the LHC [38, 43–45, 48, 49, 163–174]. Examples of well-motivated, UV-complete models with RHNs include the neutrino minimal SM (ν MSM) [175, 176] and the left–right symmetric model [177–180]. Characteristic features of models in this category are LLPs produced singly via SM neutral- and charged-current (CC) interactions, and lepton-rich signatures in terms of prompt and displaced objects (often in association with quarks). For example, in extended scenarios like left–right symmetric models, production through new right-handed W and Z bosons can result in between one and four LLPs, and cascade decays between RHNs can lead to phenomena such as doubly displaced decays. Additionally, RHNs can be produced via Higgs decays [40, 41, 44, 170, 172, 181].

It is possible for a given model to fit into two or more of the umbrella UV model categories. For example, a SUSY theory with a stable lightest SUSY particle (LSP) could have the LSP serve as a DM candidate, while alternatively DM could be a new electroweak multiplet, giving rise to SUSY-like signatures [64, 128–130]. In other models featuring particles charged under a confining gauge group (such as ‘quirks’ [182]), there can exist many production possibilities for the LLPs, including via the Higgs portal and the annihilation of new TeV-scale states (see, for example, [183]). Thus, the umbrella models should not be considered as exclusive categories, but rather as over-arching scenarios that motivate particular classes of signatures (such as new SM gauge-charged particles in the SUSY-like category, or presence of \cancel{E}_T in DM models).

In developing our simplified model framework below, we construct maps between these UV model categories and the simplified model channels to illuminate some of the best-motivated combinations of production and decay modes for LLPs. This allows us to focus on the most interesting channels and assess their coverage in chapter 3.

Figure 3. Schematic illustrations of LLP production modes in our simplified model framework. From top to bottom and left to right: direct pair production (DPP); HP; Higgs modes (HIG), including gluon fusion and VBF production (not shown here is VH production); heavy resonance (RES); charged current (CC).

2.3. The simplified model building blocks

As discussed above, production and decay can largely be factorized in LLP searches¹⁴⁴. This allows us to specify the relevant production and decay modes for LLP models separately; we then put them together and map the space of models into the umbrella categories of motivated theories.

2.3.1. Production modes. Motivated by our over-arching UV frameworks, we can identify a minimal set of interesting production modes for LLPs. Schematic diagrams for each production mode are shown in figure 3. These production modes determine LLP signal rates both by relating the LLP production cross section to meaningful theory parameters such as gauge charges or Higgs couplings, and by determining the kinematic distribution of the LLP. Additionally, a given production mechanism also makes clear predictions for the number and type of *prompt* objects accompanying the LLP(s). These prompt AOs can be important for both triggering on events with LLPs and for background rejection, particularly when the LLP has a low mass or decays purely hadronically, and they can be either SM states (leptons, \cancel{E}_T , tagging jets) or BSM objects such as Z' or dark photons [157, 184, 185].

¹⁴⁴ Once again, we comment that non-factorization of production and decay due to LLP interaction with the detector material and non-trivial propagation effects arise in models with LLPs with electric or color charge, and we discuss these subtleties further in section 2.5.2.

- *Direct-pair production (DPP)*: Here the LLP is dominantly pair-produced non-resonantly from SM initial states. This is most straightforwardly obtained when the LLP is charged under a SM gauge interaction. In this case, an irreducible production cross section is then specified by the LLP gauge charge and mass. Such continuum DPP can also occur in the presence of a (heavy, virtual) mediator (e.g. an initial quark–antiquark pair may exchange a virtual squark to pair produce bino-like neutralinos); in this case the production cross section is essentially a free parameter, as it is determined by the unknown heavy mediator masses and couplings.
- *Heavy parent (HP)*: The LLP is produced in the decays of on-shell HP particles that are themselves pair produced from the pp initial state. The production cross section is essentially a free parameter, and is indirectly specified by the gauge charges and masses of the HP particles. Heavy-parent production gives very different kinematics for the LLP than DPP, and often produces additional prompt AOs in the rapid cascade decays of the parents.
- *Higgs (HIG)*: Here the LLP is produced through its couplings to the SM-like Higgs boson. This case has an interesting interplay of possible production modes. The dominant production is via gluon fusion, which features no AOs beyond gluon ISR. Owing to its role in electroweak symmetry breaking, however, the Higgs has associated production modes (VBF, VH), each with its own characteristic features. The best prospects for discovery are for LLP masses below $m_h/2$, in which case the LLPs can be in decays of the on-shell SM-like Higgs boson. Higher-mass LLPs can still be produced via an off-shell Higgs, albeit at substantially lower rates [26, 186]. The LLP can be pair produced or singly produced through the Higgs portal depending on the model; an LLP X can also be produced in association with \cancel{E}_T via $h \rightarrow XX + \cancel{E}_T$ or $h \rightarrow X + \cancel{E}_T$. The cross section (or, equivalently, the Higgs branching fraction into the LLP) is a free parameter of the model. The Higgs mass can also be taken as a free parameter: there exist many theories that predict new exotic scalar states (such as the singlet-scalar extension to the SM [119]), and these new scalars can be produced in the same manner as the SM Higgs.
- *Heavy resonance (RES)*: Here the LLP is produced in the decay of an on-shell resonance, such as a heavy Z' gauge boson initiated by $q\bar{q}$ initial state. Note that production via an off-shell resonance is kinematically similar to the DPP mode. As with HIG, the LLP can be pair produced or singly produced (potentially in association with \cancel{E}_T). In RES models, ISR is the dominant source of prompt AOs. Models with new heavy scalars could conceivably fall into either RES or HIG; the main determining factor according to our organizational scheme is whether the scalar possesses Higgs-like production modes such as VBF and VH. Note that heavy resonance decays to SM particles also occur in these models, and searches for such resonances [187–193] may complement the sensitivity for decays to LLPs.
- *Charged current*: In models with weak-scale RHNs, the LLP can be produced in the leptonic decays of W/W' . Single production is favored. Prompt charged leptons from the CC interaction are typical prompt AOs.

It is important to note that each of the above production mechanisms has its own ‘natural’ set of triggers to record the signal. For example, HIG production can be accompanied by forward jets or leptons that are characteristic of VBF or VH production. Similarly, CC production often results in prompt charged leptons, while HP production comes with AOs from the HP decay. However, the reader should be cautioned that this does not necessarily mean that the ‘natural’ trigger is *optimal* for a particular signal. For example, the HIG modes suggest the use of VBF- or VH-based triggers, but if the LLP decays leptonically, it might be

more efficient to trigger on the lepton from the LLP decay. Thus, the final word on which trigger is most effective for a given simplified model depends on the production mode as well as the nature and kinematics of the LLP decay. The prompt AOs of each production mode could still, however, be used to extend sensitivity to the model (see section 6.3).

We also comment that some models may span several production modes. For example, a charged LLP that is part of an electroweak multiplet and nearly degenerate with a stable, neutral component [63–65, 99, 128–130, 194, 195] gives both DPP signatures (via $pp \rightarrow \chi^+ \chi^-$) and CC production (via associated production $pp \rightarrow \chi^\pm \chi^0$). Comprehensive coverage of each of the above production modes will allow for a conservative determination of sensitivity for models that span many production modes.

2.3.2. Decay modes. We now list a characteristic set of LLP decay modes. As we attempt to construct a minimal, manageable set of decay-mode building blocks, it is important to bear in mind that a given experimental search for LLPs can frequently be sensitive to a variety of possible LLP decay modes. As a result, it is not always necessary to perform separate searches for each possible decay mode as might otherwise be needed for prompt signatures.

The fact that LLP searches can be sensitive to many LLP decay modes is, in part, because LLPs that decay far from the collision point offer fewer avenues for particle identification. For example, for an LLP decaying inside of the calorimeter, most decay products are reconstructed as missing energy, or an energy deposition in the calorimeter. Consequently, particle identification criteria are typically relaxed in comparison to requirements on searches without displaced objects. Indeed, these ‘loose’ collider objects can differ significantly from the corresponding ‘tight’ prompt objects. This leads to more inclusive analyses that can cover a wider range of signatures with a single search.

Additionally, backgrounds for LLP searches are often small; for a comprehensive discussion of backgrounds to LLP searches, see chapter 4. As a result, tight identification and/or reconstruction criteria typically found in exclusive prompt analyses are no longer needed to suppress backgrounds. For example, ATLAS has a displaced vertex (DV) search sensitive to di-lepton and multi-track vertices that is relatively inclusive with respect to other objects originating from near the DV [196]. Similarly, CMS has an analysis sensitive to events with one each of a high-impact-parameter muon and electron without reconstructing a vertex or any other objects [197]. For these examples, the backgrounds are sufficiently low that other requirements may be relaxed and the specific decay mode of the LLP may not be too important so long as certain objects (such as muons) are present or the decay occurs in a specific location. An even more extreme example in this regard is the search for highly-ionizing tracks sensitive to electrically and color-charged LLPs. While the searches are primarily targeted to detector-stable particles (HSCPs or R -hadrons) they can also be used to probe intermediate lifetimes for which only a certain fraction of LLPs traverse the tracker before decaying (see e.g. [142]). Both because of low backgrounds as well as modified particle identification criteria compared to prompt searches, LLP searches can often be inclusive and therefore covered by a more limited range of simplified models.

In some cases, however, the topology of a decay does matter. One potentially important factor that influences the sensitivity of a search to a particular model is whether the LLP decays into two SM objects versus three, because the kinematics of multi-body decay are distinct from two-body decay and this may affect the acceptance of particular search strategies. An additional simplified model featuring a three-body decay of the LLP may consequently be needed to span the space of signatures.

Below, we describe an irreducible set of decay modes that can be used to characterize LLP signatures for various LLP charges (including neutral, electrically charged, and color

charged). For each, we also provide an explicit example for how the decay would appear in a particular UV model. We emphasize that the following decay modes are loosely defined with the understanding that their signatures are also representative of similar, related decay modes; for example $2j$ or $2j + \cancel{E}_T$ can also be proxies for $3j$ because searches for multi-body hadronic LLP decays can be sensitive to both and typically do not require reconstruction of a third jet. It should also be noted that we are not recommending searches to be optimized to the exact, exclusive decay mode because that could suppress sensitivity to related but slightly more complicated LLP decays.

- *Di-photon decays:* The LLP can decay resonantly to $\gamma\gamma$ (like in Higgs-portal models or left–right symmetric models [198]) or to $\gamma\gamma + \text{invisible}$ (in DM models). This latter mode stands as a proxy for other $\gamma\gamma + X$ decays where the third object is not explicitly reconstructed, although whether X is truly invisible can influence the triggers used. *Example: a singlino decaying to a singlet (which decays to $\gamma\gamma$) and a gravitino in Stealth SUSY [54].*
- *Single-photon decays:* The LLP decays to $\gamma + \text{invisible}$ (like in SUSY models). The SUSY model mandates a near-massless invisible particle, while other models (such as DM theories [134, 156]) allow for a heavy invisible particle. *Example: a bino decaying to photon plus gravitino in gauge-mediated models of SUSY breaking [199].*
- *Hadronic decays:* The LLP can decay into two jets (jj) (like in Higgs and gauge-portal models, or RPV SUSY), $jj + \text{invisible}$ (SUSY, DM, or neutrino models), or $j + \text{invisible}$ (SUSY). Here, ‘jet’ (j) means either a light-quark parton, gluon, or b -quark. This category also encompasses decays directly into hadrons (for example, LLP decay into π^+ plus an invisible particle [63–65]). *Example: a scalar LLP decaying to $b\bar{b}$ due to mixing with the SM Higgs boson, as in models of neutral naturalness [13, 14, 118].*
- *Semi-leptonic decays:* The LLP can decay into a lepton + 1 jet (such as in leptoquark (LQs) models) or 2 jets (like in SUSY or neutrino models). *Example: a RHN decaying to a left-handed lepton and an on- or off-shell hadronically decaying W boson (or W' boson in a left–right symmetric model) [163].*
- *Leptonic decays:* The LLP can decay into $\ell^+\ell^- (+\text{invisible})$, or $\ell^\pm + \text{invisible}$ (as in Higgs-portal, gauge-portal, SUSY, or neutrino models). Here the symbol ℓ may be any flavor of charged lepton, but the decays are lepton flavor-universal and (for $\ell^+\ell^-$ decays) flavor-conserving. *Example: a wino decaying to a neutralino and an on- or off-shell leptonic Z boson in SUSY [55].*
- *Flavored leptonic decays:* The LLP can decay into $\ell_\alpha + \text{invisible}$, $\ell_\alpha^+\ell_\beta^-$ or $\ell_\alpha^+\ell_\beta^- + \text{invisible}$ where flavors $\alpha \neq \beta$ (as in SUSY or neutrino models). *Example: a neutralino decaying to two leptons and a neutrino in R -parity-violating SUSY [55]; or a RHN decaying to two leptons and a neutrino [200].*

In all cases, both the LLP mass and proper lifetime are free parameters. Therefore, the case of detector-stable particles is automatically included by taking any of the above decay modes and taking the lifetime to infinity¹⁴⁵. We emphasize that, depending on the location of the LLP within the detector, these decay modes may or may not be individually distinguishable: a displaced di-jet decay will look very different from a displaced di-photon decay in the tracker, but nearly identical if the decay occurs in the calorimeter. The goal here is to identify promising channels (as distinct from detector signatures).

¹⁴⁵ As mentioned earlier, in the $c\tau \rightarrow \infty$ limit the decay mode becomes irrelevant. However, an exception is the search for particles that are stopped inside the detector material and decay out of time, which are discussed in section 3.5.3.

As an example of how the above-listed decay modes cover the most important experimental signatures, we consider a scenario of an LLP decaying to top quarks. This scenario is very well motivated (for instance, with long-lived stops in SUSY) and might appear to merit its own decay category of an LLP decaying to one or more top quarks. However, the top quark immediately decays to final states that *are* covered in the above list, giving an effective semileptonic decay mode ($t \rightarrow b\ell^+\nu$) and a hadronic decay mode ($t \rightarrow bj\bar{j}$) of the LLP. Similarly, LLP decays to four or more final states are typically covered by the above inclusive definitions of decay modes; this provides motivation not to over-optimize experimental searches to the specific, exclusive features of a particular decay mode.

While it would be ideal to have separate experimental searches for each of the above decay modes (when distinguishable), it is rare for specific models to allow the LLP to decay in only one manner; as in the example of an LLP decaying to a top quark, a number of decay modes typically occur with specific predictions for the branching fractions. As another example, if the LLP couples to the SM via mixing with the SM Higgs boson, then the LLP decays via mass-proportional couplings giving rise to b - and τ -rich signatures. If, instead, the LLP decays through a kinetic mixing as in the case of dark photons or Z bosons, then the LLP can decay to any particle charged under the weak interactions, giving rise to a relatively large leptonic branching fraction in addition to hadronic decay modes. This allows some level of prioritization of decay modes based on motivated UV-complete models; for example, the Higgs-portal model prioritizes searches for heavy-flavor quarks and leptons in LLP decay, while the gauge-portal model prioritizes searches for electrons and muons in LLP decay. Ultimately, however, it is desirable to retain independent sensitivity to each individual decay mode as much as possible. Indeed, for each decay mode listed above, models exist for which the given decay mode would be the main discovery channel.

Invisible final-state particles: Where invisible particles appear as products of LLP decays, additional model dependence arises from the unknown mass of the invisible particle. The invisible particle could be a SM neutrino, DM, an LSP in SUSY, or another BSM particle. The phenomenology depends strongly on the mass splitting, $\Delta \equiv M_{\text{LLP}} - M_{\text{invisible}}$. If $\Delta \ll M_{\text{LLP}}$ (i.e. $M_{\text{LLP}} \sim M_{\text{invisible}}$), the spectrum is compressed and the visible decay products of the LLP are soft. This could, for instance, lead to signatures such as disappearing tracks (DTs) or necessitate the use of ISR jets to trigger on the LLP signature. If the mass splitting is large, $M_{\text{invisible}} \ll M_{\text{LLP}}$, then the signatures lose their dependence on the invisible particle mass.

We suggest three possible benchmarks: a compressed spectrum with $\Delta \ll M_{\text{LLP}}$ (example: a nearly degenerate chargino-neutralino pair, giving rise to soft leptons or DTs [63–65, 99, 128–130, 194, 195]); a massless invisible state, $\Delta = M_{\text{LLP}}$ (example: a next-to-lightest SUSY particle (NLSP) decaying to SM particles and a massless gravitino in gauge-mediated SUSY breaking (GMSB) [112, 201–206]); and an intermediate splitting corresponding to a democratic mass hierarchy, $\Delta \approx M_{\text{LLP}}/2$ (example: NLSPs in mini-split SUSY [57, 58, 96]).

2.4. A simplified model proposal

In this section, we present a compact set of simplified model channels that, broadly speaking, covers the space of theoretical models in order to motivate new experimental searches. Such a minimal, compact set may not be optimal for reinterpretation of results (where variations on our listed production and decay modes may influence signal efficiencies and cross section sensitivities), but rather provides a convenient characterization of possible signals to ensure that no major discovery mode is missed. These models may therefore serve as a starting point

for systematically understanding experimental coverage of LLP signatures and devising new searches, but may need to be extended in future for the purposes of facilitating reinterpretation. We undertake an in-depth discussion of these topics in section 6.

We classify LLPs according to their SM gauge charges, as these dictate the dominant or allowed LLP production and decay modes, and can give rise to different signatures (for example, DTs and hadronized LLPs). We separately consider LLPs that are: (a) neutral; (b) electrically charged but color neutral; and (c) color charged. In the latter case, it is important to distinguish between the long-lived parton (which carries a charge under quantum chromodynamics, QCD) that hadronizes prior to decay, and the physical LLP, which is a color-singlet ‘ R -hadron’ (using the standard nomenclature inspired by SUSY). The decays of the R -hadron are still dominated by the parton-level processes.

All of the following models have the LLP mass and lifetime as free parameters. For HP production, the parent mass is an additional parameter, while for invisible decays, several different benchmarks for mass splittings between LLP and invisible final state may have to be separately considered as described in section 2.3.2. The cross section may have a theoretically well-motivated target value depending on UV-model parameters, but phenomenologically can generally be taken as a free parameter.

We emphasize that in spite of the many simplified model channels proposed below, a small number of experimental LLP searches can have excellent coverage over a wide range of channels (at least for certain lifetime ranges). The list is intended to be comprehensive in order to identify whether there are new searches that could have a similarly high impact on the space of simplified models, and identify where the gaps in coverage are.

2.4.1. Neutral LLPs. The simplified model channels for neutral LLPs are shown in table 1, where X indicates the LLP.

In our initial proposal, which is the first iteration of the simplified model framework, it is sufficient to consider as ‘jets’ all of the following: $j = u, d, s, c, b, g$. It is worth commenting that b -quarks pose unique challenges and opportunities. Since b -quarks are themselves LLPs, they appear with an additional displacement relative to the LLP decay location. They also often give rise to soft muons in their decays, which could in principle lead to additional trigger or selection possibilities. However, these subtleties can be addressed in further refinements of the simplified models; we discuss this further in section 2.6. Similarly, we consider e, μ, τ to be included in the broad category of ‘leptons’, with the proviso that searches should be designed where possible with sensitivity to each.

When multiple production modes are specified in one row of the table, this means that multiple especially well-motivated production channels give rise to similar signatures. Typically only one of these simplified model production modes will actually need to be included when developing and assessing sensitivity of an experimental search, but we sometimes include multiple different production modes as individuals may variously prefer one over the other.

In each entry of the table, we indicate which umbrella category of well-motivated UV models (section 2.2) can predict a particular (production) \times (decay) mode. An asterisk (*) on the umbrella model indicates that \cancel{E}_T is required in the decay. A dagger (†) indicates that this particle production \times decay scenario is not present in the *simplest and most minimal* implementations or spectra of the umbrella model, but could be present in extensions of the minimal models. While the HIG production signatures are best-motivated for the SM-like 125 GeV Higgs, exotic Higgses of other masses can still have the same production modes and so m_H can be taken as a free parameter.

Table 1. Simplified model channels for neutral LLPs. The LLP is indicated by X . Each row shows a separate production mode and each column shows a separate possible decay mode, and therefore every cell in the table corresponds to a different simplified model channel of (production) \times (decay). We have cross-referenced the UV models from section 2.2 with cells in the table to show how the most common signatures of complete models populate the simplified model space. The asterisk (*) shows that the model definitively predicts missing energy in the LLP decay. A dagger (\dagger) indicates that this particle production \times decay scenario is not present in the *simplest and most minimal* implementations or spectra of the umbrella model, but could be present in extensions of the minimal models. When two production modes are provided (with an ‘or’), either simplified model can be used to simulate the same simplified model channel.

Production	Decay					
	$\gamma\gamma(+\text{inv.})$	$\gamma + \text{inv.}$	$jj(+\text{inv.})$	$jj\ell$	$\ell^+\ell^- (+\text{inv.})$	$\ell_\alpha^+\ell_{\beta\neq\alpha}^- (+\text{inv.})$
DPP: sneutrino pair or neutralino pair	\dagger	SUSY	SUSY	SUSY	SUSY	SUSY
HP: squark pair, $\tilde{q} \rightarrow jX$ or gluino pair $\tilde{g} \rightarrow jjX$	\dagger	SUSY	SUSY	SUSY	SUSY	SUSY
HP: slepton pair, $\tilde{\ell} \rightarrow \ell X$ or chargino pair, $\tilde{\chi} \rightarrow WX$	\dagger	SUSY	SUSY	SUSY	SUSY	SUSY
HIG: $h \rightarrow XX$ or $\rightarrow XX + \text{inv.}$	Higgs, DM*	\dagger	Higgs, DM*	RH ν	Higgs, DM* RH ν^*	RH ν^*
HIG: $h \rightarrow X + \text{inv.}$	DM*, RH ν	\dagger	DM*	RH ν	DM*	\dagger
RES: $Z(Z') \rightarrow XX$ or $\rightarrow XX + \text{inv.}$	Z', DM^*	\dagger	Z', DM^*	RH ν	Z', DM^*	\dagger
RES: $Z(Z') \rightarrow X + \text{inv.}$	DM	\dagger	DM	RH ν	DM	\dagger
CC: $W(W') \rightarrow \ell X$	\dagger	\dagger	RH ν^*	RH ν	RH ν^*	RH ν^*

We remind the reader that the production modes listed in table 1 encompass also the associated production of characteristic prompt objects. For example, the Higgs production modes not only proceed through gluon fusion, but also through VBF and VH production, each of which results in associated prompt objects such as forward jets in VBF, and leptons or \cancel{E}_T in VH. All of the production modes listed in table 1 could be accompanied by ISR jets that aid in triggering or identifying signal events. It is therefore important that searches are designed to exploit such prompt AOs whenever they can improve signal sensitivity, especially with regard to triggering.

To demonstrate how to map full models onto the list of simplified models (and vice-versa), we consider a few concrete cases. For instance, if we consider a model of neutral naturalness where X is a long-lived scalar that decays via Higgs mixing (for instance, X could be the lightest quasi-stable glueball), then the process where the SM Higgs h decays via $h \rightarrow XX$, $X \rightarrow b\bar{b}$ would be covered with the HIG production mechanism and a di-jet decay. Entirely unrelated models, such as the case where X is a bino-like neutralino with RPV decays $h \rightarrow XX$, $X \rightarrow jjj$ could be covered with the same simplified model because most hadronic LLP searches do not have exclusive requirements on jet multiplicity. Similarly, a hidden-sector model with a dark photon, A' , produced in $h \rightarrow A'A'$, $A' \rightarrow f\bar{f}$ would also give rise to the di-jet signature when f is a quark, whereas it would populate the $\ell^+\ell^-$ column if f is a lepton. Finally, a scenario with multiple hidden-sector states X_1 and X_2 , in which X_2 is an LLP and X_1 is a stable, invisible particle, could give rise to signatures like $h \rightarrow X_2X_2$, $X_2 \rightarrow X_1jj$ that would be covered by the same HIG production, hadronic-decay simplified model; however, we see how \cancel{E}_T can easily appear in the final state, and that the LLP decay products may not be entirely hadronic. Therefore, the simplified models in table 1 can cover an incredibly broad range of signatures, but only if searches are not overly optimized to particular features such as \cancel{E}_T and LLPs decaying entirely visibly (which would allow reconstruction of the LLP mass)¹⁴⁶.

2.4.2. Electrically charged LLPs: $|Q| = 1$. For an electrically charged LLP, we need to consider far fewer production modes because of the irreducible gauge production associated with the electric charge. We still consider the additional possibility of a HP scenario where the parent has a QCD charge, as this could potentially dominate the production cross section, see e.g. [95]. We summarize our proposals in table 2.

Note that we group all resonant production into the Z' simplified model. The reason is that the SM Higgs cannot decay into two on-shell charged particles due to the model-independent limits from LEP on charged particle masses, $M \gtrsim 75\text{--}90$ GeV (see, for example, [207]); because of this lower limit on the LLP mass, it is less important to use AOs for triggering and reconstructing charged LLP signatures than for neutral LLPs. Additionally, there are fewer allowed decay modes because of the requirement of charge conservation.

For concreteness, we recommend using $|Q| = 1$ as a benchmark for charged LLPs for the purpose of determining allowed decay modes. Although other values of Q are possible, these often result in cosmologically stable charged relics or necessitate different decay modes than those listed here. Additionally, LLPs with $|Q| = 1$ are motivated within SUSY [63–65, 208–210] and within Type-III seesaw models of neutrino masses [211–214]. We note that there exist already dedicated searches for heavy quasi-stable charged particles with non-

¹⁴⁶ This should not, of course, be interpreted as saying that searches shouldn't be done that exploit these features. Instead, our position is that experiments should bear in mind the range of topologies and models covered by each cell in table 1 when designing searches, and that some more inclusive signal regions should be established where possible.

Table 2. Simplified model channels for electrically charged LLPs such that $|Q| = 1$. The LLP is indicated by X . Each row shows a separate production mode and each column shows a separate possible decay mode, and therefore every cell in the table corresponds to a different simplified model channel of (production) \times (decay). We have cross-referenced the UV models from section 2.2 with cells in the table to show how the most common signatures of complete models populate the simplified model space. The asterisk (*) shows that the model definitively predicts missing energy in the LLP decay. A dagger (\dagger) indicates that this particle production \times decay scenario is not present in the *simplest and most minimal* implementations or spectra of the umbrella model, but could be present in extensions of the minimal models. When two production modes are provided (with an ‘or’), both production simplified models can be used to cover the same experimental signatures.

Production	Decay			
	$\ell + \text{inv.}$	$jj(+\text{inv.})$	$jj\ell$	$\ell\gamma$

standard charges [215, 216]. Because such searches are by construction not intended to be sensitive to the decays of the LLP, the existing models are sufficient for characterizing these signatures and they do not need to be additionally included in our framework.

For massive particles with $|Q| = 1$ with intermediate or large lifetimes such that the LLP traverses a significant part (or all) of the tracker, the highly ionizing track of the LLP provides a prominent signature. This can be exploited for an efficient suppression of backgrounds while keeping identification and/or reconstruction criteria as loose and, hence, as inclusive as possible. In particular, for decay-lengths of the order of or larger than the detector size, the signature of highly ionizing tracks and anomalous time of flight (TOF) (i.e. searches for HSCPs; see sections 3.5 and 6.4.1) constitute an important search strategy covering a large range of lifetimes present in the parameter space of theoretically motivated models. While the searches for HSCPs are largely inclusive with respect to additional objects in the event, they depend strongly on the velocity of the LLP. For $\beta \rightarrow 1$ one loses the discriminating power against minimally ionizing particles, while for small velocities, $\beta \approx 0.5$, the reconstruction becomes increasingly difficult due to timing issues. It is therefore important to include the HP production scenario which covers a much larger kinematic range than direct production alone and which may feature a much wider range of signal efficiencies than the DPP scenario [97].

While the signatures in table 2 form a minimal set, they also encompass some scenarios that merit special comment. One of these is the DT signature [63–65, 99, 128–130, 194, 195], in which a charged LLP decays to a nearly degenerate neutral particle. The lifetime is long in this scenario due to the tiny mass splitting between the two states. Formally, these are included in the chargino or slepton DPP modes in table 2 with decays to $\ell + \text{inv.}$ or $q\bar{q}' + \text{inv.}$ taken in the limit where the splitting between the charged LLP and the invisible final state is of $\mathcal{O}(200 \text{ MeV})$. In the case of a hadronic decay, X decays to a soft pion that is very challenging to reconstruct and so the track simply disappears. This is an important scenario that is already the topic of existing searches [217, 218]. As the degeneracy between

Table 3. Simplified model channels for LLPs with color charge. The LLP is indicated by X . Each row shows a separate production mode and each column shows a separate possible decay mode, and therefore every cell in the table corresponds to a different simplified model channel of (production) \times (decay). We have cross-referenced the UV models from section 2.2 with cells in the table to show how the most common signatures of complete models populate the simplified model space. A dagger (\dagger) indicates that this particle production \times decay scenario is not present in the *simplest and most minimal* implementations or spectra of the umbrella model, but could be present in extensions of the minimal models. When two production modes are provided (with an ‘or’), both production simplified models can be used to cover the same experimental signatures.

the charged LLP and the neutral state is relaxed, other signatures are possible; this parameter range is well motivated both by SUSY and DM models with coannihilation [98, 136, 137].

Finally, we comment on the challenges of simulating the charged LLP simplified models. Because the LLP bends and interacts with detector material prior to its decay, the simulation of the LLP propagation is important in correctly modeling the experimental signature. The subsequent decay of the LLP must either be hard-coded into the detector simulation, or allow for an interface with programs such as Pythia 8 to implement the decays. We discuss the challenges of simulating signals for LLPs with electric or color charge in section 2.5.2.

2.4.3. LLPs with color charge. An LLP charged under QCD is more constrained than even electrically charged LLPs. Because of the non-Abelian nature of the strong interactions, the gauge pair-production cross section of the LLP is specified by the LLP mass and its representation under the color group, $SU(3)_C$. We do not consider LLP production via a HP particle because that cross section is unlikely to dominate the total production rate at the LHC relative to DPP. The simplified model channels are provided in table 3.

A complication of the QCD-charged LLP is that the LLP hadronizes prior to its decay, forming an R -hadron bound state. The modeling of hadronization and subsequent propagation is directly related to many properties of the long-lived parton, such as electric charge, flavor, and spin. Event generators such as Pythia 8 have routines [219, 220] to simulate LLP hadronization, although it is unclear how precise these predictions are. For a point of comparison, using the default settings of Pythia 8 yields an estimate of the neutral R -hadron fraction from a gluino (color-octet fermion, \tilde{g}) of approximately 54%, while the neutral R -hadron fraction for a stop (scalar top partner) is estimated to be 44% [96]. After hadronization, the charge of the R -hadron may change as it passes through the detector. For instance, some estimates [221, 222] suggest that heavy, color-octet gluinos \tilde{g} would predominantly form mesons (e.g. $(u\tilde{g}\bar{d})$) at first. They eventually drop to the lower-energy neutral singlet baryon $\tilde{\Lambda} = (\tilde{g}uds)$ state when interacting with the protons and neutrons within the calorimeters.

The modeling of LLP hadronization and propagation is crucial to designing searches for color-charged LLPs and assessing their sensitivity. For example, only the charged R -hadrons can be found in HSCP search; if the LLP charge changes as it passes through the detector, HSCP searches may have limited sensitivity. To take this into account, the experimental searches include both tracker-only or tracker + calorimeter signal regions [4, 223], which

enhances sensitivity to the scenario in which R -hadrons lose their charge by the time they reach the calorimeters.

Because no R -hadrons have been discovered to date and hence their properties cannot be directly measured, R -hadron modeling in detector simulations is challenging. We discuss the challenges of simulating the propagation and decays of LLPs with color charge in section 2.5.2.

2.5. Proposal for a simplified model library

The simplified models outlined in the above sections provide a common language for theorists and experimentalists to study the sensitivity of existing searches, propose new search ideas, and interpret results in terms of UV models. Each of these activities demands a simple framework for the simulation of signal events that can be used to evaluate signal efficiencies of different search strategies and map these back onto model parameters. Requiring individual users to create their own MC models for each simplified model is impractical, redundant, and invites the introduction of errors into the analysis process.

In this section, we propose and provide a draft version of a *simplified model library* consisting of model files and MC generator cards that can be used to generate events for various simplified models in a straightforward fashion. Because each experiment uses slightly different MC generators and settings, this allows each collaboration (as well as theorists) to generate events for each simplified model based on the provided files. Depending on how the LLP program expands and develops over the next few years, it may become expedient to expand the simplified model library to include sets of events in a standard format (such as the Les Houches format [224]) that can be directly fed into event-generator and detector-simulation programs. Given the factorization of production and decay of LLPs that is valid for neutral LLPs, this could involve two mini-libraries: a set of production events for LLPs and a set of decay events for LLPs, along with a protocol for ‘stitching’ the events together.

The current version of the library is available at the LHC LLP Community website¹⁴⁷, hosted at CERN. In [appendix](#), we also provide tables that list how to simulate each LLP simplified model channel with one of the specified base models. These proposals are based on the models outlined in section 2.5.1 and often match the best-motivated simplified models from section 2.4, and also building on the DM-inspired LLP simplified models proposed and detailed in [100]. The library currently focuses on models of neutral LLPs; simulating the propagation of charged LLPs along with the full range of decays listed in sections 2.4.2–2.4.3 requires more careful collaboration with detector simulation and other MC programs to ensure that they can practically be used in experimental studies.

We provide model files in the popular universal Feynrules output (UFO) format [225], which is designed to interface easily with parton-level simulation programs such as Mad-Graph5_aMC@NLO [226]. The goal is to cover as many of the simplified models of section 2.4 with as few UFO models as possible; this limits the amount of upkeep needed to maintain the library and develops familiarity with the few UFO models needed to simulate the LLP simplified models. We provide specific instructions for how to simulate each simplified LLP channel along with the UFO models.

2.5.1. Base models for library. In order to reproduce the simplified model channels of section 2.3, we need a collection of models that:

¹⁴⁷ <http://cern.ch/longlivedparticles>

- Includes additional gauge bosons and scalars to allow vector- and scalar-portal production of LLPs (RES and HIG).
- Includes new gauge-charged fermions and scalars to cover direct and simple cascade production modes of LLPs (DPP and HP).
- Includes a RHN-like state with couplings to SM neutrinos and leptons (CC).
- *Recommended, but optional*: Allows for the decays of the LLP particle through all of the decay modes listed in section 2.3, either through renormalizable or higher-dimensional couplings. If couplings that allow LLP decay are included in the UFO model, then the decays can be performed directly at the matrix-element level in programs such as MadGraph5_aMC@NLO [226] and accompanying packages such as MadSpin [227]. Alternatively, it is possible for neutral LLPs to simulate the production and decay as a single process; in such cases, numerical instabilities sometimes arise, for which dedicated event generators are needed [49]. If the couplings needed for LLP are not in the UFO model, then LLPs can be left stable at the matrix-element level and decays implemented via Pythia 8 [219, 220], which allows for the straightforward implementation of decays according to a phase-space model, but does not correctly model the angular distribution of decay products. Instructions for implementing decays in Pythia are included with the model library files.

Fortunately, an extensive set of UFO models is already available for simulating the production of BSM particles. We note that extensions or generalizations of only three already-available UFO models are needed at the present time; the SUSY models in particular can cover many of the simplified models since they contain an enormous collection of new fermions and scalars. We also provide an optional fourth model, the Hidden Abelian Higgs Model, that can be helpful to simulate HIG and ZP theories.

1. *The MSSM*: The use of this model is motivated by and allows for the simulation of SUSY-like theories. The model contains a whole host of new particles with various gauge charges and spins. Therefore, an MSSM-based model allows for the simulation of many of the simplified model channels. In particular, we note that existing UFO variants of the MSSM that include gauge-mediated supersymmetry breaking (GMSB) couplings (including decays to light gravitinos), R -parity violation (making unstable the otherwise stable LSPs [55, 110, 111]), and the phenomenological MSSM (pMSSM) [228, 229] already cover most of the SUSY-motivated LLP scenarios. In some cases, the model is modified to give direct couplings between the Higgs states and gluons/photons.
2. *The left–right symmetric model (LRSM)*: This UFO model is best for simulating UV theories with right-handed neutrinos ($\text{RH}\nu$). The UFO model supplements the SM by an additional $\text{SU}(2)_R$ symmetry, which gives additional charged and neutral gauge bosons. The model is available in the simplified models library and contains a RHN which is the typical LLP candidate. The LLP can be produced via SM W , Z , or via the new gauge and Higgs bosons (both charged and neutral) present in the theory¹⁴⁸. The LRSM therefore contains many of the charged and neutral current LLP production processes outlined in section 2.4.1.
3. *Dark-matter simplified models (DMSM)*: These UFO models are best for simulating UV theories in the DM class. These UFO models have been created by the LHC DM working group [86]. They typically consist of a new BSM mediator particle (such as a scalar of a Z') coupled to invisible DM particles. The UFO models can either be modified to include an unstable LLP, or else the otherwise stable ‘DM’ particle can be decayed via Pythia.

¹⁴⁸ Additional LRSM tools are available at <https://sites.google.com/site/leftrighthep/>.

The utility and applicability of the DM simplified model framework to LLPs has already been demonstrated with a detailed proposal and study of classes of DM simplified models for LLPs [100]. These models are particularly good for simulating LLP production via a heavy resonance (RES), and can also simulate continuum production of LLPs in the limit where the mediator is taken to be light and off-shell (DPP).

4. (Optional) *The hidden abelian Higgs model (HAHM)*: This UFO model contains new scalars and gauge bosons and so can be used to simulate both Higgs-portal and gauge-portal (ZP) theories. The model consists of the SM supplemented by a ‘hidden sector’ consisting of a new U(1) gauge boson and a corresponding Higgs field. The physical gauge and Higgs bosons couple to the SM via kinetic and mass mixing, respectively. The HAHM allows for straightforward simulation of Higgs-portal production of LLPs, as well as Z' models and many hidden sector scenarios. The UFO implementation is from [230].

If additional decay modes are needed beyond those in the specified simplified models, then the library can be updated to include the new couplings mediating the decay. Alternatively, the LLPs can be left stable at parton level and decayed in event generators such as Pythia.

A detailed list of processes that can be used to simulate each simplified model channel is provided in the [appendix](#). The primary purpose of the library is to be used to simulate events for determining acceptances, and, as a result, the signal cross section is not important. Thus, for example, SM gauge interactions can be used as proxies for much weaker exotic interactions. Similarly, the spins of the particles are generally of subdominant importance: replacing the direct production of a fermion with the direct production of a scalar will not fundamentally alter the signature. As long as results are expressed in terms of sensitivity to cross sections and not couplings, the results can be qualitatively (and in many cases, quantitatively) applied to any similar production mode regardless of spin. However, we caution the reader that changing the spin of the LLP (or its parent) can change the angular distribution, and since in some cases LLP searches are typically more sensitive to aspects of event geometry than prompt searches, the second-order effects of spin could have more of an effect than for prompt simplified models.

2.5.2. LLP propagation and interaction with detector material. Long-lived particles with electric or QCD charges interact with the detector material prior to decay, and their propagation through the detector must be correctly modeled. The propagation of both LLPs with color charge (in the form of R -hadrons) and electrically charged LLPs can be implemented in the Geant4 (G4) toolkit [231]. For example, routines exist to simulate the propagation of color-charged LLPs [232, 233]. G4 also includes routines that can implement N -body decays of LLPs using a phase-space model. This works fine for decays of LLPs to leptons, photons, invisible particles such as neutrinos, as well as exclusive hadronic decays.

However, G4 cannot implement decays to partons that subsequently shower and hadronize. One solution to this limitation is employed by CMS [234, 235] and ATLAS [236] in their searches for stopped LLPs. In these analyses, the signal simulation proceeds in two stages. During the first stage, the production of the LLP and its subsequent interactions with the detector are simulated. Once the stopping point of the LLP is determined, a new event is simulated including the LLP decay; the LLP decay products are then manually moved to the stopping point from the first stage. G4 is then run a second time to determine the efficiency for reconstructing the LLP decay signal.

It would be preferable to fully automate the simulation of decays of charged LLPs after propagation in G4. There exists in G4 a class called G4ExtDecayer, which can be used to

implement decays by interfacing with an external generator. This class has been used to interface G4 with Pythia 6¹⁴⁹. The interface with Pythia 6 has been used most recently to model LLP gluino propagation and decay in a search for DV and missing energy in ATLAS [237]. Work is ongoing to extend this functionality to Pythia 8 and to simplify the interface.

An additional challenge of simulating LLP decays is that, if the LLP undergoes a multi-body decay, generators such as Pythia use a phase-space model to implement the decays. If more accuracy is required, it may be preferable to use the full matrix element via generators such as MadGraph5 [226, 238]. If the matrix element is important for computing the decay of the LLP, then either an interface with MadGraph is needed to implement the decay prior to passing the vertex back to Pythia 8 for showering and hadronization, or matrix-element-based methods within the event generator itself must be used.

Because of the need to interface with G4 in simulating the decays of LLPs with electric or color charges, we do not at this point include such decay modes in our simplified model library. The decays of such LLPs will be most easily simulated via an interface with Pythia 8 once it is finalized.

Finally, we comment that LLPs can have even stranger propagation properties than LLPs with electric or color charges. For example, quirks are LLPs that are charged under a hidden-sector gauge interaction that confines at macroscopic scales [182]. Because the confinement scale can be just about any distance, quirks can have very unusual properties; as a specific example, if electrically charged quirk–anti-quirk pairs are bound on the millimeter or centimeter level, they behave as an electric dipole and therefore do not leave conventional tracks that bend in the magnetic field. Other confinement scales give rise to different behaviors, such as meta-stable heavy charged particles and non-helical tracks [239, 240]. In scenarios where the quirks carry color charge, the quirks hadronize and can undergo charge-flipping interactions as they move through the detector. These quirk scenarios can be challenging to model, and no public code exists that allows for the propagation and interaction of quirks with the detector material; we encourage the collaborations to validate and release any internal software they may have to study the propagation of quirks (for more discussion, see the discussion of quirks in section 3.5)¹⁵⁰.

2.6. Limitations of simplified models and future opportunities

We conclude our discussion of simplified models with a more extensive discussion of the limitations of the current simplified model proposal in its application to models of various types, along with opportunities for future development. The presented framework is only the first step of a simplified model program that is comprehensive in terms of generating LHC signatures and allowing straightforward reinterpretation of experimental results for UV models. The framework we have developed with separate, modular components for LLP production and decay is amenable to expansion, and we encourage members of the theory and experimental communities to continue to do so over the coming years to ensure maximal utility of the simplified models framework.

One significant simplification we have undertaken in our framework is to define a ‘jet’ as any of $j = u, c, d, s, b, g$. In reality, different partons give rise to different signatures, especially when one of the ‘jets’ is a heavy-flavor quark. Jets initiated by b and c quarks have some useful distinguishing features, such as the fact that the underlying heavy-flavor meson

¹⁴⁹ See http://geant4-userdoc.web.cern.ch/geant4-userdoc/Doxygen/examples_doc/html/Exampledecayer6.html

¹⁵⁰ Ideally, this software would be well-documented to facilitate sharing between experiments. A successful example of readily shareable software between experiments is the G4 package for R -hadrons and other particles’ interaction with matter, found at <http://r-hadrons.web.cern.ch/r-hadrons/>.

decays at a distance slightly displaced from the proton interaction vertex and that there are often associated soft leptons resulting from meson decays. In particular, it is possible that the soft muons associated with B -meson decays could be used to enhance trigger and reconstruction prospects for LLPs decaying to b -jets [241]. However, heavy quarks also constitute an important background for LLP searches, and so LLPs decaying to b - and c -jets may necessitate dedicated treatment in future. Similarly, LLP decays to τ leptons may merit further specialized studies.

Another property of the current framework is that it is restricted to LLP signatures of low multiplicity. By ‘low multiplicity’, we mean collider signatures with one or two LLPs. Searches inspired by these models are also suitable for many scenarios with three or four LLPs per event (which include models with dark-Higgs decays into lepton-jets (LJs) [155], or left–right symmetric models [169]), since the LLP signatures are generally extremely rare and so only one or two typically need to be identified in a given event to greatly suppress backgrounds. Thus, as long as the search is inclusive with respect to possible additional displaced objects, the signature can be covered with low-multiplicity strategies. As the LLP multiplicity grows, however, the simplified model space we have presented requires modification. This is both because the individual LLPs grow softer, making them harder to reconstruct on an individual level, and they become less separated in the detector, which makes isolation and identification of signal a challenge. On the other hand, the high LLP multiplicity may allow for new handles for further rejecting backgrounds, and the kinematics can vary widely based on the model (for example, in some ‘quirky’ scenarios, LLPs can be produced in a variety of ways with different kinematic distributions [120]). In extreme cases, signals can even mimic PU [242]. High-multiplicity signatures therefore require dedicated modeling, and we defer the study of these signatures to chapter 7.

Finally, we conclude by noting that simplified models are intended to provide a general framework to cover a broad swath of models. Any simplified model set-up, however, cannot cover every single UV model without becoming as complex as the UV model space itself. As with the case of promptly decaying new particles, care must also be taken in the interpretation of simplified models [78, 86–88, 106]: for example, constraints on simplified models assuming 100% branching fractions of LLPs to a particular final state may not accurately represent the constraint on a full model due to the large multiplicity of possible decay modes. There will additionally always be very well-motivated models that predict specific signatures that are challenging to incorporate into the simplified model framework outlined here. Experimental searches for these signatures should still be done where possible, but we encourage theorists and experimentalists alike to think carefully about how to design such searches so as to retain maximal sensitivity to simplified models that may give rise to similar signatures.

3. Experimental coverage of LLP signatures

Chapter editors: Juliette Alimena, Xabier Cid Vidal, Albert de Roeck, Jared Evans, Heather Russell, Jose Zurita

Contributors: David Curtin, Alberto Escalante del Valle, Philippe Mermod, Antonio Policicchio, Brian Shuve

A critical component of any discussion of LLP searches at the LHC is the comprehensive review of the existing searches from ATLAS, CMS, and LHCb, and an assessment of their coverage and any gaps therein. This is an inherently challenging task, given the varied and atypical objects often defined and utilized in LLP analyses and the differences among the

experiments. As such, the following discussion assumes little-to-no background on LLP search strategies and includes a high level of detail regarding the current analyses. The focus of the discussion is on the existing studies, while acknowledging that the landscape for new physics models and LLP signatures can be broader than the ones described here.

Backgrounds to most of these studies are typically small, as most LLP signatures are not naturally mimicked by any irreducible SM processes. Backgrounds for LLP searches typically include peripheral or machine effects, those rarely important for searches for prompt physics, including cosmic muons, beam halo, detector noise, and cavern backgrounds. Such backgrounds are discussed in detail in chapter 4. As rare as these backgrounds typically are, their rates are not completely negligible, and particular, model-dependent selection requirements (based on, for instance, the LLP mass range or specific decay modes) must be made to reduce backgrounds as much as possible and, in some cases, make the searches ‘background-free’. Additionally, many default object reconstruction algorithms are not designed to detect particles originating from decays of LLPs, and so dedicated reconstruction of tracks, jets, leptons, or other objects may be required for LLP searches. Taken altogether, these factors make LLP searches very different from searches for prompt objects, and the following discussion additionally aims to collate and summarize the current techniques for LLP reconstruction at the LHC.

A particular challenge for many LLP signatures is the trigger. With the exception of certain dedicated ATLAS triggers in the calorimeters or MS, there are no Level-1 (L1) triggers that directly exploit the displaced nature of LLP decays, and L1 trigger thresholds must be surpassed by standard objects (such as leptons or high-energy jets) for the event to be recorded¹⁵¹. Throughout this chapter, we highlight the role and limitations of the trigger(s) employed in current searches, and the design of customized LLP triggers is to be encouraged to probe new and otherwise inaccessible regions of parameter space.

A detailed review of all existing searches is presented in sections 3.1 through section 3.5. This survey of the current experimental coverage aims to highlight the highest-priority searches still yet to be performed, which we summarize in section 3.6. In all cases, we focus on the latest version of each analysis. Notably we will typically present searches based on data taken at a center-of-mass energy $\sqrt{s} = 13$ TeV, and discuss searches using Run 1 data only when the newer version is not yet available, or when there are conceptual differences between two versions of the same analysis.

Because LLPs travel macroscopic distances in the detectors, many of the search strategies rely on the identification of displaced objects, namely SM particles (charged leptons, photons, hadrons, jets) that are produced at a location away from the primary vertex (PV) where the hard pp collision takes place. The secondary vertex at which the decay of the LLP occurs is referred to as a DV. As far as possible, our classification of searches is linked to the parton-level objects produced in LLP decays, which allows a relatively straightforward linkage to LLP models (as well as simplified models; see chapter 2). Borrowing the terminology from prompt searches, we consider the following categories for the analogous displaced objects produced in LLP decays: all-hadronic (jets), leptonic, semi-leptonic, and photonic. However, we caution the reader that these ‘jets’ or ‘photons’ may not be of the standard type, and so other objects may pass the selections of these analyses. The remaining searches fall in the ‘other long-lived exotics’ category, mostly consisting of non-standard tracks (DTs, HSCPs, quirks, etc), but also including some trackless signals, such as SPs and SIMPs. These

¹⁵¹ It is true that, depending on the signature, some of these caveats can be circumvented by a sensible use of existing prompt triggers. For example, photon triggers will collect displaced electrons, calorimeter/jet triggers will record displaced hadronic vertices, etc.

categories are not to be interpreted as exclusive; many models and searches could fit into several categories¹⁵². For example, [243–245] show how searches for different signatures and LLP lifetimes can be combined to cover large parts of the parameter spaces of particular UV models.

3.1. All-hadronic decays

ATLAS has several searches for displaced decays with hadronic objects, including searches for two objects decaying in the hadronic calorimeter (HCAL) [246, 247]; decays within the muon system (MS) or ID [248]; ID decays in association with large \cancel{E}_T [237]; and ID decays in association with large \cancel{E}_T , jets, or leptons [196]. CMS has inclusive searches for displaced jets using 13 (8) TeV data [249, 250] [251]. Moreover, the CMS displaced jets searches are relatively inclusive and so also cover LLPs with semi-leptonic decays despite having no specific lepton requirements. CMS also has a search for DV in multijet events [252]. LHCb has searches for both one [253] and two [254] all-hadronic DVs in their detector. Here the discussion is restricted to summarizing the hadronic channels, while those studies including leptons [196, 249] will be revisited in sections 3.2 and 3.3 for the fully-leptonic and semi-leptonic cases, respectively.

3.1.1. ATLAS searches. The reconstruction of displaced tracks in the ATLAS ID [255] follows a two-step procedure. In the first iteration, the default track identification algorithm is applied, which uses hits in the pixel system, semiconductor tracker, and transition radiation tracker (TRT) to reconstruct tracks with a small impact parameter. The hits not associated to a track during the first pass are used in a second run of the track finder, with loose requirements on the transverse and longitudinal impact parameters (d_0 and z_0) and the number of silicon hits that are shared (or not shared) with another track. This two-step procedure is referred to as the *large radius tracking* (LRT) algorithm by the ATLAS collaboration. Applying the LRT procedure is CPU-intensive, and thus it is only run once per data-processing campaign, on a subset of specially-requested events [255].

In searches where the LLPs decay exclusively in the ID, standard triggers are used to select events with high- p_T jets, \cancel{E}_T , or high- p_T leptons [196, 237]. An ATLAS 13 TeV search [237] uses a standard \cancel{E}_T trigger and an offline requirement of $\cancel{E}_T > 250$ GeV. The 8 TeV search [196] covers a larger range of topologies, and the event must have either $\cancel{E}_T > 180$ GeV or contain four, five, or six jets with $p_T > 90, 65, \text{ or } 55$ GeV to pass the trigger. In both searches, the ID vertex is required to have at least 5 tracks and the invariant mass of the DV tracks to fulfill $m_{DV} > 10$ GeV. These searches are interpreted in the context of various SUSY scenarios involving gluinos or squarks decaying into leptons, jets and missing energy, namely R -parity-violating (RPV), general gauge mediation, and split SUSY. In the latter case R -hadrons¹⁵³ are considered. The particular LLP decay topology determines which trigger and analysis mode (specified by jet and lepton multiplicity, small/large \cancel{E}_T , etc) has the best sensitivity. The LLPs covered by these searches are typically high mass (~ 100 GeV), and correspond to the direct-pair-production and HP production modes with hadronic decays (in the language of the simplified models presented in section 2). However,

¹⁵² Another important ingredient of the LLP searches is the possibility to reinterpret their results to a large variety of models, namely be able to *recast* them. While we refer the interested reader to chapter 6 it is worth mentioning here that many existing searches publicly provide useful recasting information, such as efficiency maps or model-independent bounds on production cross sections.

¹⁵³ R -hadrons form when BSM colored particles hadronize due to a lifetime larger than the hadronization scale. In split SUSY the R -hadrons are typically long-lived due to their decays being mediated by heavy squarks.

these searches do not have sensitivity to low-mass LLPs, especially those resulting from the Higgs, Z' , or CC production portals and then decaying hadronically.

For LLPs decaying in the HCAL or MS, dedicated *CalRatio* and *MuonRoI* triggers are employed [246–248, 256], allowing the searches to place limited requirements on the non-displaced portion of the event. We describe these triggers in more detail shortly. The efficiency of these triggers is 50%–70% for decays within the relevant geometric detector region, and negligible outside of them (see figure 3 of [248]). The results of these analyses are interpreted in terms of a $\Phi \rightarrow ss$ model, where Φ is a heavy scalar boson with $100 \text{ GeV} < m_\Phi < 1000 \text{ GeV}$ and s is a long-lived, neutral scalar decaying to hadrons with branching fractions dictated by the Yukawa coupling. This can map to Higgs or Z' production modes and hadronic decay mode in the simplified models.

The CalRatio trigger selects events with at least one trackless jet that has a very low fraction of energy deposited in the ECAL¹⁵⁴. These CalRatio jets are characteristic of an LLP that decays within or just before the HCAL. The 13 TeV analysis [246] requires two CalRatio jets, where the exact CalRatio criteria are determined using a series of machine learning techniques to optimally discriminate the displaced decay signature from QCD jets and beam-induced background. Using the simplified $\Phi \rightarrow ss$ model with $125 \text{ GeV} < m_\Phi < 1000 \text{ GeV}$ and $5 \text{ GeV} < m_s < 400 \text{ GeV}$, good sensitivity is observed for $c\tau$ between 0.05 and 35 m, depending on the Φ and LLP masses. Notably, SM-like Higgs boson decays to LLP pairs are constrained below 10% branching ratio in the most sensitive lifetime ranges, with exact limits dependent on the LLP mass [246]. The 8 TeV result also requires two CalRatio jets, and shows sensitivity for $100 \text{ GeV} < m_\Phi < 900 \text{ GeV}$ and $10 \text{ GeV} < m_s < 150 \text{ GeV}$ [247].

The MuonRoI trigger selects events with clusters of L1 regions of interest (RoIs) in the MS that are isolated from activity in the ID and calorimeters. It is efficient for LLPs that decay between 3 and 7 m transversely or 5–13 m longitudinally from the PV, for LLP masses greater than 10 GeV. After trigger selection, the ATLAS analysis in question requires either two reconstructed DVs in the MS [257] or one ID vertex and one MS vertex [248]. This ID–MS combination provides increased sensitivity to shorter lifetimes than an analysis only considering MS vertices, and shows good sensitivity to $100 \text{ GeV} < m_\Phi < 900 \text{ GeV}$ and $10 \text{ GeV} < m_s < 150 \text{ GeV}$. Decays of a SM-like Higgs boson to LLP pairs are constrained below 1% in the most sensitive $c\tau$ regions (with cross section limits as low as 50 fb). The efficiency degrades for benchmarks with higher LLP boosts or very low mass LLPs, as fewer tracks are reconstructed. Another ATLAS search includes signal regions with only 1 DV in the MS, with sensitivity to SM-like Higgs decays to LLPs extending down to branching fractions of 0.1% [258]; this search also presents constraints on a wide range of models that helps facilitate reinterpretation for other BSM scenarios. In addition, a combination of the results from this search with the results from the 13 TeV CalRatio search was performed in [246] for the models common to both, and provides a summary of the ATLAS results for pair-produced neutral LLPs.

Recently, ATLAS presented a new study for hadronically decaying LLPs produced in association with a leptonically decaying Z boson [259]. In this analysis, the LLP decays inside of the HCAL. The use of lepton triggers on the associated Z decay products gives sensitivity to production of a *single* low-mass LLP, whereas other searches typically require 2 DVs; it is therefore an excellent example of the utility of prompt associated objects in obtaining

¹⁵⁴ The variable used to discriminate between CalRatio jets and standard jets is $\log_{10}(E_{\text{HAD}}/E_{\text{EM}})$, where E_{HAD} and E_{EM} are the fractions of the measured energies of the jets appearing in the HCAL and ECAL, respectively. The trigger selects trackless jets with $\log_{10}(E_{\text{HAD}}/E_{\text{EM}}) > 1.2$, which corresponds to an electromagnetic fraction of 0.067.

sensitivity to low-mass LLPs. The model constraints are expressed in terms of a Higgs portal model where the SM-like Higgs decays to a bosonic LLP.

With the exceptions of [196, 237, 259], which require prompt activity in addition to the DV and have comparatively high trigger thresholds, the ATLAS all-hadronic analyses require two DVs, and thus are insensitive to models that produce a single DV inside the detector¹⁵⁵.

3.1.2. CMS searches. The CMS analyses [249–251] are based on a dedicated offline *displaced jet tagging* algorithm using tracker information to identify pairs of displaced jets. The triggers used here are based on large values of $H_T = \sum |p_{T,j}| = 350(500)$ GeV for 8 (13) TeV, where the H_T sum runs over all jets with $p_{T,j} > 40$ GeV and $|\eta_j| < 3.0$. The trigger for the 13 TeV analysis based on 2015 data additionally requires either two jets with $p_T > 40$ GeV and no more than two associated prompt tracks ($d_0 < 1$ mm) and the H_T threshold is lowered to 350 GeV if the two jets each have at least one track that originates far from the PV¹⁵⁶. Only events with two or more displaced jets are kept in the analysis, while those with only one are used as a control sample to estimate the prompt jet misidentification rate. For $c\tau < 3$ mm¹⁵⁷, the algorithm is inefficient as more than two tracks tend to have impact parameters less than 1 mm; for $c\tau > 1$ m the search is inefficient as most decays occur too far from the PV to form reconstructable tracks. A key difference among these searches is that the 8 TeV [251] and 13 TeV (2016 data) [250] analyses explicitly reconstruct the DV, while the 13 TeV (2015 data) [249] analysis does not.

CMS interprets the signal in several benchmark models that can be mapped to the direct pair production simplified model production mode, including a neutral LLP decaying hadronically and a color-charged LLP decaying into a jet plus a lepton. For neutral LLP pair production decaying democratically into light jets, the trigger efficiencies for $c\tau = 30$ mm are reported to be 2%, 41%, 81%, and 92% for 50, 100, 300, 1000 GeV masses, respectively. It is evident that the requirements on H_T and on $p_{T,j}$ make the search inefficient for low LLP masses. Indeed, a phenomenological recast of the 8 TeV analysis [251] in terms of rare decays of a SM-like Higgs boson with a mass of 125 GeV Higgs sets very mild bounds for LLP masses below $m_h/2$ [260]. Thus, the CMS search has limited sensitivity to low-mass, hadronically decaying LLPs through the Higgs, Z' , or CC simplified production modes.

As mentioned above, CMS also has a search for DV in multijet events [252], which was released near the time of the final editing of this manuscript.

3.1.3. LHCb search. The LHCb searches [253, 254] trigger directly on DVs with a transverse distance of $L_{xy} > 4$ mm) with four or more tracks, vetoing dense material regions in which hadronic interactions with the detector can mimic LLP decays. The trigger thresholds are, however, low. For example, the invariant mass of particles associated with the vertex must exceed 2 GeV and the scalar sum p_T of tracks at the vertex must exceed 3 GeV. Jet reconstruction is then performed offline with standard algorithms. The benchmark model used by these searches is a scalar particle decaying to two neutral LLPs, π_v (dark or ‘valley’ pions), which corresponds to the Higgs simplified model with hadronic decay modes. The parent particle can be either a SM-like 125 GeV Higgs [253] or a Higgs-like scalar with mass in the 80–140 GeV range [254]. The search is performed for π_v masses between 25 and

¹⁵⁵ This may be the result of a signal that produces two DVs, but the lifetime is sufficiently long that only one DV appears inside the detector.

¹⁵⁶ In this case this is defined by requiring that the transverse impact parameter significance $|d_0|/\sigma_{d_0}$ have a value greater than 5.

¹⁵⁷ Note that in principle the low $c\tau$ regime can be covered with standard triggers, however they require higher H_T thresholds.

Figure 4. Comparison of the ATLAS [196], CMS [251] and LHCb [253] reaches for dark pions π_V decaying into jets. The CMS result is taken from the recast done in [260] of the 8 TeV analysis [251]. In the shaded regions $B(H \rightarrow \pi_V \pi_V)$ is constrained to be below 50%. Note that the ATLAS reach extends to higher masses as well; the plot was produced using the benchmark scenarios presented in [196], hence the meaningful bound is on the lifetimes. Taken from [253].

50 GeV and decay lengths between 0.6 and 15 mm. It is expected that LHCb will extend their coverage to shorter lifetimes by improving the understanding of the material and to lower masses by using fat-jets and jet-substructure to access larger boosts [261]. In principle, the search is also sensitive to direct pair production of LLPs.

Because of the low thresholds, the LHCb search focuses on low-mass LLPs with short lifetimes, for which it has excellent sensitivity. However, its sensitivity for other signatures is limited by the geometry of the detector and the LHCb luminosity compared to ATLAS and CMS. A model-dependent direct comparison among the LHCb, ATLAS and CMS reaches for the Higgs production mode decaying into dark pion LLPs can be seen in figure 4.

3.1.4. Summary. Searches in hadronic final states do not currently cover LLP parent masses below ~ 100 GeV in a comprehensive way. This is typically due to the large $p_{T,j}$ requirements at the trigger level, with an exception being the DV reconstruction at LHCb. Additionally, the powerful ATLAS searches for LLPs decaying in the HCAL or MS require two LLP decays in the detector, meaning that as of this writing there is no sensitivity to singly produced long-lifetime LLPs with hadronic decays¹⁵⁸. While the existing searches are typically sensitive to both direct pair production and HP production of LLPs, not all of the searches provide benchmarks with a variety of LLP production kinematics and boost.

A potential way to extend the sensitivity of current analyses is to use other existing triggers exploiting such things as VBF production modes, leptons, \cancel{E}_T , etc, to trigger on associated *prompt* objects and perform the hadronic DV reconstruction offline. The ATLAS 8 TeV study [196] does employ multiple triggers (such as lepton triggers), but in each case the

¹⁵⁸ Highly-inclusive searches for single LLPs decaying in the ATLAS MS have been proposed [262], finding that backgrounds are appreciable and need to be controlled using data-driven methods.

triggered object must be associated with the DV (for a lepton trigger, the lepton must originate from the DV). If, instead, a prompt lepton or VBF trigger were used with the offline reconstruction of a separate displaced object, sensitivity could be recovered to low-mass hadronic DVs in a variety of simplified models, including Higgs production (via VBF or VH associated production modes) [260, 263] or CC production (in association with a prompt lepton) [264]. In particular, triggering on associated prompt objects would improve the efficiency of reconstructing low-mass hadronic LLPs produced in the decays of a SM-like 125 GeV Higgs. As there is no theoretical lower limit on the masses of light neutral LLPs, it is imperative to lower the LLP mass coverage as much as possible. If at all possible, a dedicated *online* reconstruction of DVs would allow for a further reduction on the p_T threshold, giving sensitivity to light LLP masses.

3.2. Leptonic decays

All three experiments have searches for a pair of leptons coming from a DV [196, 265–269]. CMS also has a search requiring exactly one isolated muon and one isolated electron (i.e. events with additional isolated leptons are discarded) with large transverse impact parameters ($0.2 \text{ cm} < |d_0| < 10 \text{ cm}$), but without any other additional requirement including, for example, that the reconstructed tracks do not need to point to a common vertex [197]. This loose selection makes the search sensitive to a variety of new physics scenarios. Light and boosted LLPs can decay into collimated light leptons, dubbed *LJs* [127], which are searched for at both CMS [270, 271] and ATLAS. ATLAS has searches for both displaced [272, 273] and prompt LJs [274]. The LHCb collaboration also looks for light, neutral LLPs decaying into $\mu^+\mu^-$ pairs by studying B -meson decays to kaons, for exclusive decay channels for both neutral [267] and charged [268] B -mesons, as well as dark photons that decay into muon pairs [269].

3.2.1. CMS searches. The CMS searches trigger on leptons reconstructed using information from either the tracker [265] or the muon chambers [266], where the latter search uses only muons. In the tracker-based analysis, the LLP is reconstructed by forming pairs of charged leptons (where muons are required to have opposite signs), with p_T cuts of 26 GeV for muons, and 36 (21) GeV for the leading (subleading) electron. This yields slightly larger efficiencies in the muon channel. The transverse impact parameter $|d_0|$ needs to be 12 times larger than its uncertainty σ_d (approximately corresponding to a distance $\sim 200 \mu\text{m}$) to reject prompt backgrounds. In the MS-based analysis, muon candidates are reconstructed using hits in the muon chambers, and no information from the silicon tracker is used. In order to avoid biases from a loose beamspot constraint in the seeding step, these muons undergo an additional refit step. These candidates are referred to as *re-fitted stand-alone* muons, and they need to fulfill $p_T > 26 \text{ GeV}$, $|\eta| < 2$, and to be separated by $\Delta R > 0.2$. More importantly, these candidates are rejected if they can be matched to a $p_T > 10 \text{ GeV}$ track in the inner tracker, which efficiently excludes prompt muons and also renders this study fully complementary to the tracker-based one. Both these searches are interpreted in terms of decays of an SM-like Higgs H ($H \rightarrow XX$, $X \rightarrow l^+l^-$) and RPV squarks, covering proper lifetimes of $0.01\text{--}10^5 \text{ cm}$ for the Higgs scenario, and $0.1\text{--}10^4 \text{ cm}$ for the SUSY case. The difference in the lower reach of $c\tau$ is due to the larger boost factor of the Higgs. These benchmarks map to the direct pair production, HP and Higgs production simplified models, with flavor-conserving leptonic decays of the LLP. There is good sensitivity down to relatively low masses (LLPs of masses $\sim 20 \text{ GeV}$ produced in Higgs decays) due to the low lepton trigger thresholds.

Additionally, CMS has a search for one electron and one muon, each with large transverse impact parameter ($200 \mu\text{m} < |d_0| < 10 \text{ cm}$) [197]. Events are selected using a dedicated trigger for $e\mu$ pairs that applies a p_T cut on the leptons (42 GeV for electrons, 40 GeV for muons) but, unlike standard triggers, places no restriction on the maximum d_0 or distance from the PV. Events with exactly one muon and exactly one electron are kept, and then separated into ‘prompt’, ‘displaced control’ and ‘signal’ regions, defined as $|d_0| < 100 \mu\text{m}$, $100 \mu\text{m} < |d_0| < 200 \mu\text{m}$, and $|d_0| > 200 \mu\text{m}$, respectively. This selection makes the signal region almost free of leptons coming from SM processes, with rare tau-leptons, B -mesons or D -mesons as the largest remaining background.

Although in the original search the results are interpreted in the context of long-lived RPV stops (excluding masses below 870 GeV for $c\tau = 2 \text{ cm}$)¹⁵⁹, this search has been shown to be sensitive to many scenarios, including long-lived staus in gauge mediated SUSY breaking [205] and RHNs [45]. Indeed, this search has sensitivity to LLPs produced via any of the simplified model production modes and (semi)-leptonic decays that give exactly one electron and one muon. On the other hand, models where LLPs decay only to *either* muons *or* electrons (e.g. $\tilde{\mu} \rightarrow \mu\tilde{G}$) are unconstrained by this search. Furthermore, same-sign lepton signatures and signatures with additional leptons are not constrained by the current search but could be covered by extensions of the search [45, 205]. Due to the generality of tau-specific models, searches for hadronic tau channels is also desirable. This search has sensitivity to relatively low-mass LLPs; however, the 8 TeV analysis [275] has lower thresholds ($p_T > 22 \text{ GeV}$ on both leptons) albeit with a requirement for shorter decay distances ($|d_0| < 2 \text{ cm}$), and so has superior sensitivity to very low- p_T displaced signals. Maintaining low trigger thresholds is necessary to obtain sensitivity to the lowest-mass leptonic LLP signals.

3.2.2. ATLAS searches. The primary ATLAS search for displaced leptons [196] triggers on muons without an ID track, electrons, or photons¹⁶⁰. The trigger and offline p_T criteria are relatively high, requiring one of the following: one muon of at least 50 GeV; one electron of at least 110 GeV; one photon of at least 130 GeV; or two electrons, photons, or an electron and a photon with minimum p_T requirements for both objects in the 38–48 GeV range. The DV is formed from opposite-sign leptons, irrespective of flavor, and needs to be located more than 4 mm away from the PV in the transverse plane. DVs in regions with dense detector material are vetoed to suppression backgrounds from converted photons (e.g. $\gamma p \rightarrow e^+e^-p$). This search is in principle sensitive to events with a reconstructed DV mass $m_{\text{DV}} > 10 \text{ GeV}$, but the high p_T requirements for the leptons restrict the sensitivity to low-mass LLPs.

ATLAS has also recently released a search for pairs of muons that correspond to a DV [276]. This search is sensitive to LLP decays that occur sufficiently far from the IP that the muons are reconstructed only in the MS. The analysis has four separate trigger pathways: $\cancel{E}_T > 110 \text{ GeV}$; one muon with $p_T > 60 \text{ GeV}$ and $|\eta| < 1.05$; two muons with $p_T > 15 \text{ GeV}$ and $\Delta R_{\mu\mu} < 0.5$; or three muons with $p_T > 6 \text{ GeV}$. Thus, the search has sensitivity to final states with high and low masses (down to $m_{\mu\mu} = 15 \text{ GeV}$), as well as with various lepton multiplicities. Offline selections require the muons to have $p_T > 10 \text{ GeV}$ and opposite charge, and the search is efficient at reconstructing muons

¹⁵⁹ We note that a CMS prompt search for LQs has been recasted using the same model, finding stringent constraints for lifetimes below a few millimeters. This reinterpretation is discussed in detail in section 6.7.

¹⁶⁰ Electrons with large transverse impact parameters d_0 tend to be missing a track at trigger level and are reconstructed as photons.

for transverse impact parameters up to $|d_0| = 200$ cm. Muons are also required to satisfy isolation requirements from jets as well as from nearby tracks. The search puts constraints on a SUSY model and a model of dark photon production in Higgs decays; this can be used to determine sensitivity to all of the simplified production modes from chapter 2 in the $\mu\mu$ decay mode (or $\mu\mu$ in association with other objects). It also demonstrates how combining many trigger pathways and loose selection requirements can enhance sensitivity to a wide range of LLP models.

3.2.3. LHCb searches. LHCb has a search that looks for the direct production of both promptly decaying and long-lived dark photons [269]. As a result of the direct production, dark photons do not tend to be highly boosted in the transverse direction. Events¹⁶¹ are required to have a single muon with $p_T > 1.8$ GeV, or two muons with a product of transverse momenta $(1.5 \text{ GeV})^2$. The displaced search constrains previously uncovered dark photon parameter space around masses of ~ 300 MeV.

The LHCb searches for displaced leptons in rare B meson decays [267, 268] rely on standard techniques to identify the B^\pm decay vertex and the kaons and pions in the event, and the di-muon invariant mass $m(\mu^+\mu^-)$ variable is scanned for excesses. The $X \rightarrow \mu^+\mu^-$ vertex is not required to be displaced from the B^\pm vertex, and thus the constraints apply to both prompt and LLPs. The analysis probes LLP masses of 214 (250) MeV $< m_X < 4350$ (4700) MeV for the $B^0 \rightarrow K^*\mu^+\mu^-$ ($B^+ \rightarrow K^+X$, $X \rightarrow \mu^+\mu^-$) process, with the mass range being limited by kinematics.

3.2.4. Lepton-jet searches. Searches for LJs are focused on $\mathcal{O}(\text{GeV})$ LLP masses and distinctly boosted signatures, and thus we treat them separately.

The ATLAS 8 TeV search [272] considers three types of LJs: those containing only muons, only electrons/pions, or a mixture of the two. The muon and electron/pion LJs can contain either two or four leptons, while the mixed LJ must contain two muons and a jet consistent with a displaced electron/pion pair. As these signatures contain relatively soft leptons, the ATLAS 8 TeV analysis uses a trigger that requires three muon tracks in the MS with $p_T > 6$ GeV. There is a built-in limitation to this trigger, which is that the L1 requirement of three separate muon RoIs makes it only sensitive to topologies with two LJs in which one LJ has a wide enough opening angle between two muons to create two level-one RoIs. For the electron LJs, when the electrons are produced in the HCAL they are indistinguishable from a hadronic decay and thus the CalRatio trigger is used.

In the 13 TeV ATLAS analysis [273], a *narrow-scan* muon trigger is additionally used. This trigger starts off by selecting events with one muon with $p_T > 20$ GeV, then requires a second muon with $p_T > 6$ GeV within $\Delta R = 0.5$ of the leading muon.

Both the 8 and 13 TeV ATLAS searches are interpreted for Higgs-like scalar particles (with masses of 125 and 800 GeV) that decay effectively into either two or four lepton pairs, with each lepton pair assumed to come from a low-mass ‘dark’ photon, γ_D . The ATLAS result excludes exotic Higgs branching ratios below 10% for dark photon lifetimes $2 < c\tau < 100$ mm. Note that here γ_D is also allowed to decay to pions and so the results can also be interpreted for hadronically and semi-leptonically decaying LLPs. This corresponds to

¹⁶¹ For the prompt dark photon search, events are reconstructed at trigger level so that all online reconstructed particles are recorded, while the rest of event information is discarded [277]. The prompt search constrains entirely new territory above 10 GeV.

Figure 5. Comparison of the lepton-jet searches at ATLAS [272] and CMS [271] with respect to a dark photon scenario [155] vis-a-vis dark photon limits coming from low-energy experiments. Figure taken from [271].

the Higgs production mode in the simplified models proposal with an admixture of flavor-conserving leptonic and hadronic LLP decays.

The CMS LJ search focuses on fully muonic LJs and has been performed with both the 8 TeV dataset [270] and part of the 13 TeV dataset [271]. The 13 TeV search is sensitive to di-muon parent particle masses up to 8.5 GeV. Events are selected with a di-muon trigger with standard isolation requirements. Further selection requires at least four muons, forming a minimum of two opposite-charged pairs. CMS uses a benchmark model with scalars decaying into either lighter scalars or dark photons, with varying scalar and dark photon mass. For the case of a 125 GeV Higgs they can exclude an exotic branching ratio of below 0.1% for some parameter points. The CMS search can be compared with the ATLAS results, as can be seen in figure 5. We note that this study includes sensitivity to both prompt and displaced muonic lepton jets.

3.2.5. Summary. To summarize, the lepton searches rely on fairly standard lepton identification, with vertex reconstruction being performed mostly offline. Searches for leptonically decaying LLPs typically enjoy low trigger thresholds and good sensitivity to LLP production rates. Extending the success of the leptonic LLP program to future LHC running will necessitate maintaining low-threshold triggers for displaced leptons in a high-luminosity environment; this is a major challenge but one that must be overcome. Another outstanding challenge is coverage of LLP decays to τ leptons, which lie at the interface between hadronic and leptonic searches. Such decays are very well motivated from the theoretical point of view, as a Higgs-like scalar can typically decay about 300 times more often into $\tau^+\tau^-$ if

kinematically allowed, and also one could have large rates into mixed decay modes such as $\tau^+\mu^-$. A displaced hadronic τ is a striking object, and most likely will have few backgrounds. Hence, limits on exclusive displaced τ s would be of utmost importance¹⁶².

As the leptonic searches explicitly require opposite-sign leptons, the same-sign lepton signature (motivated from Majorana neutrinos; see the LHCb search in section 3.3, or heavy, doubly-charged LLPs) is currently neglected. Furthermore, the sensitivity of the CMS search for two high- $|d_0|$ leptons is currently only sensitive to opposite sign $e\mu$ pairs, with a veto on additional leptons. Relaxing these requirements would greatly enhance sensitivity to certain scenarios, especially the simplified models with flavor-conserving leptonic LLP decays.

Lepton-jet searches currently cover only final states with at least two LLPs and some muons in the final state¹⁶³, and the same statement currently applies to both the LHCb searches for dark photons [269, 277] and for LLPs produced in B -meson decays. The existing ATLAS LJ studies express their results in terms of specific dark photon models¹⁶⁴, which makes it complicated to apply the results to other models. We refer the reader to section 6 for a further discussion of this topic. In extending LJ searches, it would be beneficial to have additional searches with a single LJ or low-mass, leptonically-decaying LLP (which are motivated in models with hidden sectors and Majorana neutrinos, for example in [43, 135]). In addition, the status of coverage in the intermediate mass-transition region between ‘standard’ displaced lepton pairs and LJs is unclear, and may potentially harbor a gap; adopting the simplified model approach for leptonic LLP decays with masses varying between the GeV and weak scale would ensure comprehensive coverage of low-mass leptonically decaying LLPs.

Finally, we comment on gaps in sensitivity to very low-mass leptonically decaying LLPs. A benchmark LLP model is the heavy neutral lepton (HNL), which corresponds to the CC production mode with (semi-)leptonic LLP decays in our simplified model framework. HNLs constitute an important physics case that leads to multi-lepton displaced signatures from W decays, with nice prospects at ATLAS and CMS (see, e.g. [43, 48, 49]). While previous searches were not sensitive to this scenario due to either high- p_T requirements or the requirement of two DVs in the same event, the presence of a prompt lepton from the W allows the relaxation of these requirements in a dedicated analysis. Moreover, the prospects of triggering on a prompt lepton in such searches was studied recently in [48] and demonstrated in a prompt search in [278]¹⁶⁵. The identification of two leptons from the vertex is a powerful discriminant against backgrounds from meta-stable particle decays and hadronic interactions in material. This permits a potentially cleaner exploration of the lower HNL mass range (3–6 GeV) than in the semi-leptonic channel (see section 3.3) despite the lower branching ratio. It should be noted that HNL models can predict LLP decays to all three lepton flavors (either democratically or hierarchically), necessitating the capability to reconstruct displaced leptons of all flavors, including taus.

¹⁶² We note that if the τ originates from outside the tracker, the hadronically decaying taus are indistinguishable from other displaced hadrons. For instance, in the ATLAS search utilizing muon RoIs [248] the results are interpreted for a model with a scalar particle with Higgs-like couplings to SM fermions, which includes a branching fraction into $\tau^+\tau^-$. However, if the τ originates from the ID, the low number of tracks associated to it (one to three) will not fulfill the requirements of the ATLAS study of five or more tracks associated to a DV.

¹⁶³ The ATLAS 8 TeV search [272] included a search channel with two electron-only LJs, but the performance was poor and it was excluded from the final result.

¹⁶⁴ Recall that the LJ studies also consider the $\gamma_D \rightarrow \pi^+\pi^-$ decay mode.

¹⁶⁵ Note that the displaced large transverse impact parameter $e\mu$ CMS search [197] fails to cover this scenario due to the aforementioned lepton veto, which eliminates sensitivity to the tri-lepton signals discussed in [43], as well as relatively high lepton p_T trigger thresholds compared to the kinematics of 4-body W decay.

Figure 6. LHCb reach for displaced semi-leptonic decays. Taken from [279].

3.3. Semi-leptonic decays

As semi-leptonic signatures include aspects of both hadronic and leptonic LLP decays, many of the previously discussed searches can partially cover these cases, and some do so explicitly. For instance, the ATLAS search for electrons and muons accompanied by tracks [196], the inclusive CMS search for DVs [249] (which contains a specific model interpretation called ‘*B*-lepton’ addressing precisely this channel), and the search for a large impact parameter $e\mu$ pair by CMS [197] are all inclusive with respect to other hadrons produced in the LLP decay, provided the leptons are sufficiently isolated¹⁶⁶. In addition, LHCb has dedicated searches for semi-leptonically decaying LLPs [279] and semi-leptonic decays of long-lived Majorana neutrinos coming from B^- mesons [280]. The two CMS searches [197, 249] need no further explanation for how they cover semi-leptonic LLPs because of their very inclusive nature (see section 3.2.1), but we now describe the rest of these searches in some detail.

3.3.1. LHCb searches. The LHCb search for semi-leptonic LLP decays selects events with a muon trigger, then reconstructs a DV offline [279]. The results are interpreted in terms of four distinctive topologies: single LLP production in association with a new particle (in this case a gluino), double LLP pair production via direct pair production, Higgs decay, or via squark pair production (HP). The LLP then decays to two quarks and a muon (which maps to the $jj\ell$ simplified model decay). Material regions are vetoed for the DV, which results in the dominant background arising from heavy flavor production either directly or from W/Z decays. The signal discrimination is obtained from a multivariate analysis based on the muon p_T and impact parameter, and subsequently the search is optimized based on the LLP reconstructed mass and the muon isolation. This study is sensitive to low-mass LLPs with lifetimes between 1.5 and 30 mm, as can be seen in figure 6.

The LHCb search for Majorana neutrinos [280], N , probes Majorana neutrinos produced in leptonic B decays, $B^\pm \rightarrow \mu^\pm N$. The Majorana neutrino subsequently decays exclusively to

¹⁶⁶ Note that the lepton isolation affects most of the semi-leptonic searches.

$N \rightarrow \mu^\pm \pi^\mp$; both prompt and displaced decays are considered¹⁶⁷. A same-sign muon requirement, along with the reconstruction of the N and B meson masses, greatly reduces backgrounds to the search. The sensitivity of the search is limited by the restriction to muons in the final state (so models that predominantly decay to e or τ are not constrained), and the same-sign lepton requirement gives sensitivity only to lepton-number-violating processes. More inclusive searches looking for additional N production modes [282], decays with opposite-sign leptons, or searches targeting decays of heavier mesons like B_c [283] could also improve the sensitivity to semi-leptonically decaying LLPs.

3.3.2. ATLAS search. The ATLAS search for semi-leptonic LLP decays [196] looks for a vertex with a lepton accompanied by tracks. This search uses the same trigger as the dilepton vertex search described in section 3.2. The DV is required to have a lepton as well as at least four additional associated displaced tracks, and the invariant mass of the tracks must exceed 10 GeV. Thus, the search in principle can have sensitivity down to masses ~ 10 GeV, although the high p_T threshold for the displaced electron/muon typically limits sensitivity to low-mass LLPs; the vertex must contain a muon with $p_T > 55$ GeV or an electron with $p_T > 125$ GeV.

3.3.3. Summary. When considering the application of inclusive hadronic or leptonic searches to semi-leptonic LLP decays, it is important to understand how the simultaneous presence of leptons and jets in the signal can degrade the sensitivity. For instance, prompt jet searches explicitly can remove non-standard jets through jet cleaning cuts. Lepton isolation criteria can severely reduce the signal acceptance for a highly-boosted LLP decaying into a lepton and a jet, and they might also veto extra tracks in the events. Thus, boosted semi-leptonic decays (as might be found in the displaced decay of a low-mass, RHN produced via W decay) may not be covered by existing searches.

One of the major gaps in semi-leptonic LLP searches is at the smallest LLP masses. In this case, it can be challenging for the leptons from LLP decays to pass trigger thresholds and/or isolation criteria; backgrounds from heavy-flavor and other processes are also higher for semi-leptonic processes than fully leptonic ones. However, there are very good motivations for low-mass semi-leptonic LLPs from the HNL benchmark model¹⁸ introduced in section 3.2.5, which predicts LLPs for HNLs of masses below 30 GeV. The signature of HNLs from W decays with displaced semi-leptonic HNL decays is an important item on the search agenda of ATLAS, CMS and LHCb [38, 43, 48, 49, 284, 285]. Recently, there has also been a proposal to search for low-mass HNLs in heavy ion collisions [286]. The semi-leptonic channel has the highest branching ratio (about 50% in the relevant mass range [287]) and can therefore offer the best discovery prospects at LHC experiments for HNL masses up to 30 GeV as long as a DV mass cut of around 6 GeV is made to mitigate backgrounds from B-mesons, $m_B \sim 5$ GeV, and backgrounds from random-crossings can be suppressed. The lower end of the 6–30 GeV mass range corresponds to a non-perturbative regime for the hadronization of the HNL decay products. As the number of charged hadrons significantly affects the DV reconstruction efficiency, the validation of event generator outputs for this process is an important issue currently being addressed by the community (see e.g. [48]). The ability of LHCb to trigger directly on the HNL decay products and better reconstruct

¹⁶⁷ Some care is required in interpreting the results of the search on a model with a Majorana neutrino, as the original theory interpretation is problematic [281].

¹⁶⁸ In the language of simplified models, this corresponds to the CC production mode, where the HNL LLP is produced in association with a prompt lepton. The HNL then decays semi-leptonically via the $jj\ell$ channel.

Figure 7. Summary of projected experimental sensitivities to HNLs in various experiments, in the coupling strength (U^2 for dominant mixing to ν_μ) versus mass plane. The projections labelled ‘LHC Run 3’ and ‘HL-LHC’ are for HNLs in W decays in general-purpose experiments, and the one labelled ‘MATHUSLA’ assumes the full HL-LHC MATHUSLA dataset. We also show the recent CMS result for the prompt tripton signature [278]. Prospects at proton beam-dump experiments are also shown for an already existing experiment, NA62 [288], and for the planned experiment SHiP [289]. Existing constraints from direct searches are indicated as coloured solid lines [290–294]. The lines labelled ‘Seesaw’ and ‘BBN’ show lower theoretical constraints from the observed neutrino masses (assuming a normal hierarchy) and primordial nucleosynthesis, respectively [295]. The line labelled ‘BAU’ is an upper theoretical constraint in the ν MSM model for accounting for baryon asymmetry in the Universe while the lightest HNL is a dark-matter candidate [295].

displaced tracks can in some cases compensate for its lower acceptance and luminosity, as exemplified by a recent search for DVs composed of one muon and several tracks [279, 285]; similar arguments can be made in the case of heavy ion collisions [286]. This possibly enables LHCb to better probe the more challenging tau channel. Figure 7 shows the overall expected reach of LHC searches in the HNL coupling strength (for the muon channel) versus mass plane, using assumptions detailed in [284], similar to those in [38, 43].

The sensitivity of LHC experiments to HNLs is complementary to that of fixed-target experiments which can probe lower couplings thanks to high-intensity beams albeit at lower mass ranges (i.e. targeting HNLs from c and b decays). The CERN SPS provides great opportunities with the running NA62 experiment [296] and the planned SHiP experiment [289], which comprise a vacuum decay vessel and spectrometer tracker downstream of the target to reconstruct vertices of long-lived neutral particles¹⁶⁹. These provide the best sensitivity to HNL masses up to 2 GeV, where they probe a region of the parameter space favored in models which simultaneously explain neutrino masses, matter–antimatter asymmetry and DM [295, 298–300] (see figure 7).

3.4. Photonic decays

There are two ways in which photons coming from LLP decays do not resemble standard photons. First, they cannot be traced back to the PV, thus giving rise to *non-pointing* photons. Second, they can arrive at the ECAL at a time slightly later than expected because the LLP

¹⁶⁹ The proposed detector FASER would also have the capability to reconstruct such vertices [297].

moves slower than the speed of light; these are referred to as *delayed* photons. We note that both kinds of unusual photons can be vetoed in searches for photons that originate from the PV, and thus prompt searches typically provide weaker bounds on LLP scenarios than for promptly decaying signals. ATLAS has a search for non-pointing and delayed photons [301] using the full 8 TeV dataset, which supersedes the 7 TeV analysis [302]. In CMS there are studies for delayed photons in the ECAL [303] and for non-pointing photons detected via their conversion to e^+e^- pairs [304]. The underlying topology in all these models is the neutralino decay into a gravitino and a photon ($\chi_1^0 \rightarrow \gamma\tilde{G}$), ubiquitous in GMSB scenarios [53, 305]. Hence all these studies require large \cancel{E}_T in the final state. This corresponds to HP production of LLPs with decays to a single photon and \cancel{E}_T in the simplified model framework; all searches described below use the Snowmass Slopes Point 8 benchmark, which is not straightforward to map to a physical spectrum of HP masses.

3.4.1. ATLAS search. The ATLAS study [301] benefits from the capability of the liquid-argon electromagnetic calorimeters (ECALs) to measure the flight direction and the photons' TOF. Resolutions on Δz_γ , the separation between the PV of the event and the extrapolated origin of the photon, and $|\Delta t_\gamma|$, difference of the arrival time of the photon with respect to the prompt case, are as low as 15 mm and 0.25 ns, respectively. The trigger demands two photons within $|\eta| < 2.5$, with transverse energies E_T of 35 and 25 GeV. In addition, to guarantee the event comes from a proton-proton collision, a PV with five or more tracks with $p_T > 0.4$ GeV is required. The offline selection requires two photons with $E_T > 50$ GeV and $|\eta| < 2.3$, not in the barrel-endcap transition region ($1.37 < |\eta| < 1.52$), at least one of them in the barrel ($|\eta| < 1.37$) and with less than 4 GeV of energy deposited in the calorimeter in a cone of $\Delta R = 0.4$ around them (constituting the *isolation* criterion). In addition, the events are binned in \cancel{E}_T : the $\cancel{E}_T < 20$ GeV bin contains the prompt backgrounds, the $25 \text{ GeV} < \cancel{E}_T < 75 \text{ GeV}$ bin is used as the control region, and finally the signal analysis is performed in the $\cancel{E}_T > 75 \text{ GeV}$ bin. This study covers lifetimes from 0.25 to 100 ns in the GMSB framework, the lower limit being a hard cut-off imposed experimentally, as the similarity between background and signal samples in that region makes discrimination rather difficult. The excluded signal rates in this range of lifetimes vary between 0.8 and 150 fb, with the best-constrained value obtained for $\tau \sim 2$ ns.

3.4.2. CMS searches. The CMS study of delayed photons [303] follows a similar approach to ATLAS. The main difference is that it demands only one photon with $p_T > 80$ GeV, but in addition two jets are required. Furthermore, the vector sum of \cancel{E}_T and E_T^γ , which is denoted $\cancel{E}_{T \text{ no } \gamma}$, is additionally used for background discrimination. Collisional backgrounds have small \cancel{E}_T and large $\cancel{E}_{T \text{ no } \gamma}$, while the non-collisional backgrounds are characterised by large \cancel{E}_T and small $\cancel{E}_{T \text{ no } \gamma}$. For the signal events the two variables are large, hence they are both requested to be larger than 60 GeV. The time resolution is 0.372 ns, slightly worse than in the optimal scenario of the ATLAS search. Their reach in lifetimes lies in the 2–30 ns range, excluding signal rates of 10–30 fb.

The CMS study of non-pointing photons [304] relies on the photon converting to e^+e^- pairs. It requires two photons, two additional jets, and $\cancel{E}_T > 60$ GeV. The photon trajectory is obtained from the conversion vertex as the line segment along the momenta of the e^+e^- track pair, and the impact parameter, $|d_{XY}|$, is defined as the closest distance between the photon and the beam axis, which can be determined within approximately 1 mm. A comparison of the reach of these 8 TeV studies, as well as those using the 7 TeV dataset, can be found in figure 8.

Figure 8. Summary of the $\gamma + \cancel{E}_T$ searches from ATLAS and CMS, displayed assuming the same GMSB model. Taken from [303].

3.4.3. Summary. The gaps in these studies are straightforward to identify. The requirement of large \cancel{E}_T is due to the fact that all of these studies have an underlying theoretical picture of neutralinos decaying into gravitinos and photons, motivated from GMSB scenarios. Hence, these searches do not cover cases without the presence of missing energy, including LLPs that decay to $\gamma\gamma$, $l\gamma$ or $j\gamma$. It may be possible to extract a constraint on such LLP decay modes due to mis-measurement of jets or the photon decay geometry which could mimic large missing energy; however, this would be sub-optimal compared to a dedicated search. With the exception of the CMS study [303] which requires two additional hard jets, all of these analyses require two displaced photons. A single displaced photon signature can occur in motivated models: it can easily arise, for example, from a very slightly mixed electroweak triplet and singlet as in SUSY theories (see the UV models in section 2). Furthermore, as discussed in section 3.1, a single LLP in the detector can also arise for very large lifetimes of neutral LLPs, which limits the reach of current searches at longer lifetimes. In such scenarios, it is possible that the photons from LLP decay can be quite soft, and obtaining sensitivity to models with single photons from LLP decay and/or low momenta may require triggering on associated prompt objects, similar to the recommendations in section 3.1.4.

3.5. Other exotic long-lived signatures

In the preceding sections, we presented analyses sensitive to LLPs decaying into objects such as jets, leptons, and photons. In many cases, however, LLPs give rise to signatures that are completely distinct from more conventional prompt signatures. In this section, we present analyses that exploit properties of other exotic long-lived signatures, such as non-standard tracks. We summarize in detail the existing searches for HSCPs; DTs; SPs and monopoles, and describe existing ideas on how to look for quirks and SIMPs.

Note that the terminology employed in some of these searches can be confusing, with occasional conflation of signatures with the underlying model. We provide a detailed explanation of each search, and we attempt a classification here based strictly on signature. We distinguish between three classes of signals: *tracks with anomalous ionization*, *tracks with anomalous geometry*, and finally *out-of-time* decays.

3.5.1. Tracks with anomalous ionization. In this category, we collect all searches for charged-particle tracks with anomalous ionization, i.e. those that are inconsistent with a charge $|Q| = e$. Here we include (i) the so-called HSCPs, which apply to stable, electrically charged particles but also charged particles that decay in the calorimeters and/or MS; and (ii) magnetic monopoles.

3.5.1.1. Heavy stable charged particles. The searches for HSCPs at CMS [4, 306] and ATLAS [223, 307, 308] rely on two key properties. First, particles that are massive and/or electrically charged with $|Q| \neq e$ have a characteristic ionization loss (dE/dx) distinctively different than SM particles. This property can be measured in the tracker. Second, HSCPs are typically heavy and move with a speed less than the speed of light, $\beta = v/c < 1$. Thus, compared to a particle with $\beta \approx 1$, they require a longer TOF to reach the outermost components of the detector (calorimeters and muon chambers). As decays or interactions of the HSCP with the material in the detector can change the electric charge of the HSCP, both CMS and ATLAS perform separate *tracker-only* and *tracker + TOF* studies in the language of CMS¹⁷⁰. The event selection relies on standard single-muon or large-missing-energy triggers. The offline selection relies on identifying the signal events from quality requirements on the tracks using discriminator variables built from track observables.

The HSCP search conducted by LHCb [309] is slightly different. Instead of exploiting dE/dx and TOF, they use the lack of radiation in the ring imaging Cherenkov detector (RICH). Events are required to pass a high- p_T single muon trigger ($p_T(\mu) > 15$ GeV). Two opposite sign ‘muons’ are then required, each with p_T above 50 GeV and an invariant di-muon mass above 100 GeV, to suppress muons coming from DY production, the main background for this search. In addition, particles must have $\beta > 0.8$, set by the efficiency of the muon chambers to reconstruct slow particles. As electrons and hadrons interact more with the calorimeter than an HSCP, a deposit in the calorimeter of less than 1% of the momentum of the particle is required.

The theoretical interpretation of a signal or limit depends on whether the HSCP carries both color and electroweak charges. If it carries a color charge, the default benchmarks correspond to R -hadrons, namely HSCPs that hadronize with SM particles via the strong force, e.g. gluino-gluon or quark-squark states. In the absence of a color charge, the signal is exemplified by long-lived sleptons in the context of gauge-mediated SUSY. Both ATLAS [307] and CMS [4] studies employ these two scenarios, while LHCb [309] uses a stau benchmark model¹⁷¹. Finally, CMS also looks for HSCPs coupling only to hypercharge (and hence possessing only couplings to γ and Z), while ATLAS has a search inspired by electroweakinos in SUSY: it considers the associated production of a neutral and an electrically charged LLP (chargino-neutralino), and thus only one HSCP plus missing energy are required. These scenarios correspond, in our simplified model framework, to the direct

¹⁷⁰ ATLAS measures $\beta\gamma$ from dE/dx and β from TOF and extracts an independent mass, m_β and $m_{\beta\gamma}$, from each measurement.

¹⁷¹ The ATLAS R -hadron searches using the 13 TeV dataset have recently been presented in [223].

production of LLPs with electric or color charges and that do not decay, or decay at very large distances compared to the tracking volume.

To summarize, these searches present no obvious weak points. Standard triggers and tracking algorithms are used, and the analysis methods are well-understood and have been extensively validated against data. HSCP signatures do not suffer from the low-mass gap of many neutral LLPs due to constraints from LEP and other low-energy experiments. However, mCPs are not covered by these searches and require dedicated detectors (see section 5.3.3). While the HSCP search strategies are generally robust, we encourage the experimental collaborations to continue pursuing improvements for these searches. The small number of signal events that would be produced for HSCPs above current limits render the sensitivity highly dependent on the understanding of the background and control of the systematics.

3.5.1.2. Magnetic monopoles. ATLAS [215] has a dedicated search for highly ionizing particles (HIPs), which encompass a variety of new physics scenarios, such as magnetic monopoles, dyons (particles with both magnetic and electric charge), stable microscopic black holes, etc. For the sake of concreteness, we focus on magnetic monopoles but the interpretation in terms of other models is straightforward¹⁷².

The main phenomenological feature is that magnetic charge is quantized in units of $g_D = 2\pi/e \approx 68.5$. Hence, a magnetic monopole behaves as a particle with at least 68.5 electron charges, leading to an unusually large ionization power in matter, so that they would quickly stop in the detector because HIPs lose energy at spectacular rates. Because of the large QED coupling of magnetic monopoles, a perturbative calculation of the cross section is invalid and there is no accurate determination of the production rate, but a naïve Drell–Yan production cross section is provided for the purposes of comparison. The specifics of the detector restrict the sensitivity of this search to magnetic charges $g < 2g_D$ because a large fraction of the monopoles stop in the material upstream of the ECAL, as the latter is used for the L1 trigger [310]. We note that larger magnetic charges can be tested by the MoEDAL experiment [311], which is described in detail in section 5.3.2. Additionally, theories with monopoles can also be tested in heavy ion collisions [312].

ATLAS [215] has a dedicated trigger for HIPs based on identifying relevant RoIs in the ECAL and subsequently counting the number of hits in the TRT. As well, the fraction of TRT hits that are high-threshold (HT), meaning that they have an ionization larger than ~ 3 times that expected from a SM particle, is used as a discriminant. The analysis selects events based on the fraction of TRT-HT hits matched to an EM cluster deposit, and how the energy deposits are distributed in the different layers of the ECAL. It is important to note that due to the lack of a consistent theory, the signal simulation is performed by re-scaling Drell–Yan production at leading order and assuming no coupling to the Z boson. The HIPs are assumed to have either spin-0 or $1/2$. The spin does not affect the interaction with the material, but the angular distributions are different according to angular momentum conservation (keeping in mind that there is, of course, no perturbative theoretical prediction for the angular distribution). Cross section limits for $0.5 < |g|/g_D < 2$ are set for masses in the 890–1050 (1180–1340) GeV range for the spin-0 ($1/2$) case.

The coverage in LHC Run 2 of magnetic monopoles in the g_D – σ plane is displayed in figure 9.

¹⁷² At the time of writing there was no public result on a monopole search from CMS.

Figure 9. Comparison of the MoEDAL, ATLAS and CMS reaches for magnetic monopoles. The curves assume three signal events and a total integrated luminosity of 50 fb^{-1} for 13 TeV collisions. Updated version of existing figure in [310]. Note that the CMS curve relies on the expected performance of their detector.

3.5.2. Tracks with anomalous geometry. In this category we group searches where the tracks have an anomalous geometry, namely they disappear (track \rightarrow nothing), or follow non-standard trajectories (such as quirks). There are additional anomalous track signatures that we do not cover such as kinked tracks, where a charged LLP decays to another charged particle that travels at a non-zero angle with respect to the LLP direction [112, 313–315]; however, there are currently no dedicated searches for such signatures.

Within this category we also have the emerging jets signature that has been recently studied by CMS [316]. Since emerging jets arise from dark sector radiation, they are described in detail in chapter 7 in conjunction with the theoretical and phenomenological aspects of dark showers.

3.5.2.1. Disappearing tracks. Massive charged particles traveling in the detector can decay to a lighter, almost mass-degenerate neutral state, emitting a soft SM charged particle (typically a pion or a muon). While at first glance a small mass gap naïvely seems like a hallmark of tuning, near degeneracies often occur naturally as a result of a symmetry. In fact, electroweak symmetry generically leads to small mass splittings between components of a single electroweak multiplet. For example, $\mathcal{O}(100 \text{ MeV})$ splittings arise between the different components of an electroweak multiplet [64, 128] due to EW gauge boson loops¹⁷³. If the SM particle is sufficiently soft it cannot be reconstructed, and then a charged track seems to vanish: this is thus referred to as a DT¹⁷⁴. The actual lifetime of the charged particle is highly sensitive to the precise value of the mass splitting. For instance, the well studied cases of a fermionic doublet with $Y = 1/2$ and a fermionic triplet with $Y = 0$, reminiscent of a Higgsino and Wino in supersymmetry, respectively, have mass splittings of $\Delta = 355$ and 166 MeV , up to small corrections, but the corresponding $c\tau$ values differ by almost an order

¹⁷³ For a single fermion multiplet, the splitting can only be altered by higher-dimensional operators, and thus it is harder to vary Δ from the 1-loop EW value. For other cases, such as mixing with additional particles, the actual splitting can differ more substantially from this 1-loop EW value.

¹⁷⁴ If the charged particle could be reconstructed this case is often referred to as a *kinked track*. However, as the kinked portion has a very large impact parameter, without a serious attempt to capture the kink these tracks, too, simply disappear.

of magnitude: 6.6 mm versus 5.5 cm¹⁷⁵. This is because the lifetime, $c\tau$, depends on the third power of the mass splitting in these scenarios when the charged LLP decays to a charged pion [64, 128].

Before 2017, both ATLAS [317] and CMS [217] required a track to travel about 30 cm in order to be reconstructed, giving good coverage of the Wino scenario. This 30 cm value corresponds to four hits at ATLAS, three in the pixel layers plus one in the silicon tracker, and to seven hits in the pixel and trackers of CMS. The search employs a trigger requiring an ISR jet against which the charged particle recoils, along with the presence of large \cancel{E}_T . The DT is reconstructed offline and needs to fulfill quality criteria (isolation, p_T threshold, etc). A phenomenological study [99] has shown that reducing the distance from 30 to 10 cm would give coverage to the elusive Higgsino scenario, moving the expected reach up to 400 GeV, surpassing the expected mono-jet reach of 250 GeV [318–320]. Later, ATLAS presented a study [218, 321] using 13 TeV data and exploiting the presence of a new innermost pixel layer (IBL). This addition allows for all four hits to be in the pixel, with the outermost pixel layer now at 12.25 cm, enhancing sensitivity to lower values of $c\tau$. The summary for DTs at ATLAS for the Wino case can be seen in the left panel of figure 10, while in the right panel we show the constraints for Higgsinos from [99]. CMS also has a DTs search using 2015 and 2016 data at a center-of-mass energy of 13 TeV [322].

At LHCb the prospects for a DT analysis with the present detector are poor. Currently, the momentum of the track can only be measured if the particle passes through the tracking station (TT), which is about 3 m away from the IP. Particles decaying in the vertex locator (VELO) or RICH1 system will not leave a fully-measurable track and will be swamped in a background of SM processes such as kaon decays, which would give a similar signature in the detector components before the magnet. Detector improvements (additional magnets, better PID at low momentum, additional layers) might lead to some sensitivity for $\mathcal{O}(\text{cm})$ lived tracks, a golden opportunity for potential LLP discoveries at LHCb in the HL-LHC era.

To summarize, the search for DTs presents a few challenges. Using an ISR jet trigger means a price is paid in terms of signal efficiency. For example, [99] has shown that significantly lowering the p_T threshold of the jet or directly triggering on the momentum of the DT¹⁷⁶ would lead to a factor of two increase in the number of signal events. It is also clear that better access to lower lifetimes is needed; this may only be possible, for instance, by adding new tracking layers as close as possible to the beampipe (and/or having double layers instead of single ones).

3.5.2.2. Strongly interacting massive particles. SIMPs can be motivated by astrophysical observations of DM that do not fully agree with the WIMP paradigm (e.g. missing satellites, the core versus cusp problem; see, e.g. [327–330] for further discussion). These particles are assumed to interact strongly with baryons. Consequently, the experimental signature is little to no signal in the tracker and the ECAL, and large energy deposits in the HCAL. Such a final state with trackless jets also arises in the context of emerging jets [331], and ATLAS has a trigger for trackless jets in association with a soft muon (where the muon is required to fire L1 of the trigger) [256]. Additionally, the CalRatio trigger and associated search for displaced

¹⁷⁵ While these values set a concrete physics target, we stress again that the mass splitting can be arbitrary in other corners of the BSM parameter space (even within SUSY). For instance, $\tilde{\tau} \rightarrow \tau \tilde{\nu}$ (where the stau and sneutrino masses are free independent parameters) or for scalar particles (e.g. $H^+ \rightarrow \mu^+ H^0$), where the mass splitting and the overall mass scale are set by arbitrary quartic couplings.

¹⁷⁶ While currently there are some proposals to trigger on tracks [324], those predominantly apply to standard tracks. In particular, the new fast track reconstruction (FTK) system at ATLAS requires 10 hits in ID silicon, which corresponds to a decay radius of less than 9 cm. However, pattern banks for hits including high- $|d_0|$ tracks are currently being considered out to $d_0 \sim 2$ cm [325, 326].

Figure 10. Top: summary of ATLAS disappearing-track searches as applied to a Wino (electroweak triplet) benchmark scenario [323]. Bottom: HL-LHC projected constraints on the Higgsino scenario [99].

hadronic decays (addressed in section 3.1) is designed to be sensitive to a similar signature and could provide some coverage of this signature as well. Strictly speaking, SIMPs are not a track-based signature, but we include them here because the interactions of the SIMPs with the tracker are different from usual hadrons in jets, while the calorimeter signatures are similar.

An LHC phenomenological study of SIMPs was carried out in [332]. We summarize the main points of the study here. In their setup, SIMPs interact with the SM via an attractive potential (either scalar or vector mediator) coupling SIMP pairs to $q\bar{q}$ pairs. The proposed analysis selects events with high- p_T , back-to-back jets within the tracker, exploiting the charged energy fraction within a jet to discriminate signal from background. The astrophysical experimental constraints on this scenario are compared with the expected

Figure 11. Astrophysical and collider constraints on a simple SIMP setup. Note that the relevance of the astrophysical constraints depends on the contribution of the SIMPs to the relic density. Taken from [332].

reach of this search and that of mono-jets in figure 11. Currently there is an ongoing analysis in CMS pursuing this strategy.

3.5.2.3. Quirks. Quirks are particles charged under both the SM and a new confining gauge group [182], referred to here as ‘infracolor’ (IC). The defining property of quirks is that the tree-level quirk masses m_Q are above the confinement scale Λ_{IC} (and thus similar to QCD but with no light-flavored quarks), so that there is never enough local energy density to create new quirks out of the vacuum. A pair consisting of a quirk and an anti-quirk can live in a quantum-mechanical bound state where the constituents are separated by macroscopic distances $\ell \sim \frac{m_Q}{\Lambda_{IC}^2}$, remaining connected by an IC flux tube. The IC flux tube exerts a force on each quirk that causes its trajectory to differ from the expected helicoidal ones for SM particles.

The collider phenomenology depends greatly on the size of ℓ . If ℓ is much less than an \AA , the rapid emission of IC glueballs results in the quirks annihilating before ever reaching the beampipe. For large enough confinement scales, the IC glueballs can decay back into SM particles on sufficiently long time scales that they can be distinguished from prompt signatures. While in this specific case, quirks produce hidden valley [66] or emerging jet [331] signatures due to these long-lived IC glueballs (see chapter 7), we stress that elsewhere in parameter space quirks exhibit their own distinct phenomenology and are not merely a subset of hidden valleys, contrary to popular lore.

If ℓ is larger than an \AA but below the mm scale, the individual quirks are not distinguished from one another. However, the pair (which is overall neutral, and therefore does not bend in the magnetic field of the tracker) appears as a single, highly ionizing straight track with missing energy aligned with it, the latter arising from mis-measurement of the track

momentum. The *D0* collaboration has searched for precisely this signature [333], requiring an additional jet for trigger purposes. This search obtained lower bounds on quirk masses of 107, 119 and 133 GeV for SU(2), SU(3) and SU(5) gauge groups, respectively. However, no extensions of this search to higher mass have been performed at the LHC, and the existing HSCP searches require low uncertainties on the track momentum that a straight quirk track would not satisfy.

Conversely, if ℓ is very large then the existence of the confining force has no effect on the quirk motions, and HSCP searches apply directly to the quirk case, with quirks charged under QCD yielding *R*-hadrons and uncolored quirks leading to slepton-like signatures. We refer the reader to the section 3.5.1.1 for more information.

For intermediate values of ℓ , there are interesting phenomenological prospects at the LHC that have been recently studied theoretically [239, 240, 334], but for which there are no current public searches by the LHC collaborations. The first study [239] has recast mono-jet and HSCP searches, finding bounds up to 1.7 TeV for colored quirk masses. In addition, it has also proposed using the CMS dataset taken with zero magnetic field. In this dataset, all SM particles are expected to follow a straight trajectory, but the quirks would still bend due to the string tension. The second study [240] has proposed a new algorithm to search for quirks, exploiting the fact that the quirk and anti-quirk pair should lie in the same plane with the highest sensitivity in the $\ell \sim 1\text{--}10$ mm range. This avoids the necessity of fitting non-helicoidal trajectories, and has the potential to extend the sensitivity to quirks well beyond the current mono-jet and HSCP limits. The third study [334] considers quirks that lose energy through material interactions with the detector. A charged or colored quirk pair can come to a stop within the detector, and annihilate out-of-time with active *pp* collisions, allowing for sensitivity from SP searches across a wide range of characteristic length scales, $\ell \sim \text{\AA}$ km range. We refer the reader to the section 3.5.3 for more information on SP searches.

Because of the non-standard nature of the tracks, quirk phenomenology poses substantial challenges in their experimental reconstruction, and the lack of constraints on quirks have already attracted the attention of the ATLAS, CMS and LHCb experiments. It would be desirable to test how the phenomenological proposals in [239, 240, 334], among others, can perform in a realistic detector simulation of one of the LHC experiments.

3.5.3. Out-of-time decays of SPs. This category is unique because LLP decays occur out-of-time with the collision. Indeed, decays can even occur when the LHC is not running! The only member of this class is the search for SPs, which we describe below.

If an HSCP is produced with very low kinetic energy, it can come to rest in the detector due to interactions with the detector materials. This most likely occurs in the calorimeters or the steel yoke in the MS as a result of their high material densities. The HSCP can then decay at a later time when no collision is taking place (known as an out-of-time decay). This experimental restriction reduces the types of background processes affecting the search, with the dominant backgrounds coming from cosmic rays (CRs), beam halo, and instrumental noise.

In the Run 1 analyses from ATLAS [236] and CMS [234], events are selected with a dedicated trigger selecting bunch crossings which are empty and have no bunches of protons nearby. The analyses require a jet with $p_T(E)$ above 30 (50) GeV at ATLAS (CMS). ATLAS further supplements the hardware trigger by requiring $p_T(j) > 50$ GeV, $|\eta| < 1.3$ and $E_T > 50$ GeV, rejecting instrumental noise. In addition, CMS has updated the jet search in Run 2 and also provided a search that triggers on out-of-time muons, both of which use the 13 TeV dataset [235]. The latter also employs the displaced stand-alone (DSA) muon reconstruction algorithm [335].

An offline selection procedure is aimed at reducing the main backgrounds. Muons coming from CRs can be identified due to their distinctive topology. The ‘beam halo’ background is the result of protons interacting with residual gas in the beampipe, the beampipe itself, or collimators upstream from the IP. Most particles will not travel far before being absorbed by various structures, but muons will travel parallel to the beam and can leave calorimeter deposits out of time with a proton–proton collision. However, these deposits will often be accompanied by corresponding horizontal tracks in the MSs and can thus be efficiently vetoed. Instrumental noise is rejected in CMS by exploiting the anomalous response in the HCAL.

Stopped particle searches provide an alternative way of probing charged particles besides more conventional HSCP searches. HSCP searches are typically more sensitive to any signature with a charged particle, so SP searches are not often expected to be a discovery mode for most simple new physics scenarios with charged LLPs¹⁷⁷. The typical added value of SP searches is that they can help identify and characterise positive signals in HSCPs, for instance by providing a cleaner extraction of the lifetime and also to properly identify the decay products. However, in some cases (such as for quirks, where HSCP searches are insensitive in much of parameter space), it has been argued that an SP search could actually be a discovery mode if modifications are made to the search strategy to improve sensitivity to quirks [334]. These modifications that would increase quirk acceptance or lower backgrounds include expanding the η range, implementing higher energy thresholds, using the timing information, and considering shower evolution in the new CMS endcap calorimeter [336].

3.6. Discovery opportunities: overview of gaps in coverage

In the preceding sections 3.1–3.5.3, we have examined the so-called ‘coverage’ of existing searches for LLPs at the LHC with the explicit and express purpose of identifying uncovered realms and places where discoveries could be hiding. Here, we summarize these gaps and potential opportunities for LLP discovery in bullet form, as a to-do list for the experimental community.

1. All-hadronic LLP decays

- Associated-object triggers (especially motivated by Higgs-like VBF and VH production modes) need to be more comprehensively used to improve sensitivity to low- p_T objects.
- Improvements are needed in sensitivity at lower masses and lifetimes (e.g. for LLPs produced in Higgs decays).
- Single hadronic DVs need to be looked for in searches that currently use two (such as decays in ATLAS HCAL and MS).
- Possibilities need to be explored for ATLAS and CMS for online reconstruction of hadronic displaced objects, as the inclusive H_T triggers used by the two collaborations miss these objects unless they have a large p_T . (By contrast, LHCb can trigger on a displaced hadronic vertex [253, 254].)
- Low-mass hadronically decaying LLPs can look somewhat like tau leptons, so the question remains as to whether there is any possibility of using, for example, L1 tau triggers to seed displaced jet triggers at HLT and improve trigger efficiency; studies need to be performed by the experimental collaborations.

¹⁷⁷ The reason why the SP searches are less efficient than the HSCP ones is twofold. On one hand, only a fraction of LLPs stop in the detector, while the HSCP search only requires that the LLP crosses the detector. On the other hand, the SP is only looked for in a specific time-window that might fail to catch a large fraction of them.

- The prospects for dedicated searches for displaced hadronic taus need to be investigated, since no dedicated searches currently exist.
 - The potential for flavor-tagging displaced jets (b-displaced jets, c-displaced jets, etc) needs to be explored.
2. Leptonic
- Coverage needs to be provided for the intermediate region between boosted, low-mass LLPs (lepton jets) and high-mass, resolved LLPs (resolved ATLAS/CMS searches).
 - Improvements need to be made to extend coverage to lower masses and to lower p_T thresholds. Currently no prescription or plan for this exists, and so dedicated studies need to be done.
 - Searches need to be done for different combinations of charge and flavor of displaced leptons (e.g. same-sign versus opposite-sign, opposite-flavor versus same-flavor).
 - Searches need to be done for tau leptons in LLP decays, in particular if they come from the ID; an unanswered question remains as to whether displaced-jet triggers can be used for this purpose.
3. Semi-leptonic
- Searches do not exist and need to be done for LLP masses below about 30 GeV; this mass range is theoretically well motivated by Majorana neutrinos.
 - Searches need to be performed for all flavor combinations (for example, one CMS search only covers $e^\pm\mu^\mp$), as well as same-sign versus opposite-sign leptons.
 - Currently unknown improvements need to be made to relax or modify isolation criteria wherever possible to recover sensitivity to boosted semi-leptonic decays.
 - Searches need to be done that better exploit triggering on associated objects for improved sensitivity to low-mass objects, or to employ high-multiplicity lepton triggers if there are multiple LLPs.
4. Photonic
- There is currently no coverage for LLPs decaying into $l\gamma$, $j\gamma$, or without \cancel{E}_T , and searches urgently need to be performed for this decay topology.
 - There is currently poor coverage (i.e. there exists no dedicated search) for single- γ topologies. The only searches with sensitivity require two jets to be present in addition to \cancel{E}_T [303]. Studies are needed to assess the sensitivity of this search to signals with only one delayed photon and different jet multiplicities.
 - There is currently no coverage for softer non-pointing or delayed photons, and searches need to be performed for these kinematic realms.
 - Studies need to be performed to determine if triggers on associated objects may improve sensitivity to signals with a single photon, without \cancel{E}_T , or for lower- p_T photons
5. Other exotic long-lived signatures
- Disappearing tracks with $c\tau \sim \text{mm}$ are very hard to probe, and new ideas and detector components are needed to extend sensitivity to this potential discovery regime. It is unclear if the ATLAS insertable B-layer will be present in HL-LHC run and how sensitivity to the DT topology will improve with the replacement of the current ID with the new inner tracker (ITk), or whether new tracking layers very close to the beam line can be added. It is an open question as to what is the lowest distance at which new layers (or double layers) can be inserted. Another open question that needs to be answered is whether there are any prospects for DTs at LHCb with an upgraded detector.

- No dedicated searches for quirks exist at the LHC, a huge, open discovery possibility for ATLAS, CMS, and LHCb. Some LHC constraints exist by reinterpreting HSCP searches, but dedicated searches need to be performed. There are significant challenges in modeling the propagation and interaction of quirks with the detector, as well as in fitting tracks to their trajectories, but new ideas have been proposed that need to be explored by the experimental collaborations that might allow improved sensitivity to quirks with less ambitious analysis methods.

4. Common sources of backgrounds for LLP searches

Chapter editors: Juliette Alimena, Martino Borsato, Zhen Liu, Sascha Mehlhase

4.1. Introduction

For many searches for LLPs, the main backgrounds do not stem from irreducible SM processes, but arise instead from *external sources*. Indeed, there can even be backgrounds of instrumental and/or algorithmic nature. Often, LLP searches are designed to have a very small number of background events, sometimes even zero events, that pass the full selection criteria. This chapter gives an overview of common LLP search backgrounds and the means to estimate or control them.

4.2. Long-lived particles in the SM

Weak decays of SM particles can naturally give rise to DV at the boosts typically encountered at the LHC. Searches for LLP signatures at sufficiently low LLP mass and lifetime suffer from large backgrounds due to displaced SM decays. One simple example is found in the search for long-lived dark photons decaying to $\mu^+\mu^-$ at LHCb [269], which drastically loses sensitivity when the dark photon mass gets too close to the $K_S \rightarrow \pi^+\pi^-$ invariant mass, despite the very low $\pi \rightarrow \mu$ misidentification rate.

Moreover, b -hadrons can decay at displacements of a few mm and can be challenging to distinguish from LLPs with masses of a few tens of GeV that decay to a pair of jets. Requiring a large track multiplicity of the DV and performing a mass fit to the dijet invariant mass can help to significantly reduce the effect of this background (see, for example, [251, 253]). Backgrounds from heavy flavors are typically more abundant in the forward region, as arises, for example, if the signature under study is an LLP from the decay of a SM-like Higgs boson. However, the LHCb forward detector, which was designed to study these SM decays, is, in most cases, capable of rejecting heavy flavor backgrounds more effectively than can be done in ATLAS or CMS. Furthermore, displaced tracks from b -mesons, which usually have impact parameters (d_0) of less than 2 mm, can be rejected by using a larger criterion for the minimum track d_0 .

4.3. Real particles produced via interactions with the detector

Particles produced in the pp collision can interact with nuclei of the detector material, giving rise to DV, and can mimic LLP signals. Vertices from these interactions will be positioned in regions of the detector containing high densities of detector material and are therefore effectively vetoed by using detailed material maps.

The LHC detectors have developed tools internal to the collaborations to define a material volume to be vetoed. As the detector configurations changed slightly from Run 1 to Run

Figure 12. An example of a material map from ATLAS [237].

Figure 13. An example of a material map from CMS [339].

2, material maps have been determined separately for each data-taking period for both the ATLAS and CMS collaborations, using collision data. Maps can be found for ATLAS for Run 1 in [337], CMS for Run 1 in [338], ATLAS for Run 2 in [237], and CMS for Run 2 in [339]. Additionally, the Run 2 maps for both are shown here in figures 12 and 13 for ATLAS and CMS, respectively.

LHCb recently developed a precise material map of the VELO using beam-gas collisions [340], shown in figure 14. Beam-gas collisions can be distinguished from long-lived heavy flavor backgrounds and their utilization allows the map to cover precisely the whole VELO

Figure 14. Reconstructed secondary vertices in the LHCb VELO from beam-gas collisions in the zr plane integrated over ϕ . These vertices are used to build the material map [340] to veto backgrounds from material interactions.

geometry, not only the region close to the IP. This map was used to veto photon conversions to di-muons, which is the main background affecting displaced dark-photon searches at low mass [269]. In analyses, this material map, together with properties of a reconstructed secondary vertex and its constituent tracks, is used to construct a p -value that is assigned to the hypothesis that the secondary vertex originates from a material interaction. As a rule of thumb, LHCb material interaction background is dominant for vertices at a distance from the beam axis larger than 6 mm (where the VELO material begins). Below 6 mm the background is dominated by heavy flavor decays [341].

Because accurate material maps are essential to performing fully reliable sensitivity studies to signatures with DV, making them publicly available to the broader LLP community is of the highest priority. The availability of such tools in fast parametric simulations such as Delphes [342] would be very useful to reinterpret LLP search results. In section 6.4.6.2, an example of a reinterpretation of an LLP search is presented, where a rough material veto was performed because these material maps were not publicly available, highlighting the shortcomings of such approaches in the absence of accurate material maps and emphasizing the benefits of making them available.

High-energy collision muons originating mainly from W decays and creating secondary interactions in the tracker, calorimeters or MS can be an additional source for DV mimicking LLP signals. This mostly minor background arises as vetoing these DV is based on a not 100% efficient detection of the high- p_T track in the tracker.

Another important background, mainly for analyses targeting the reconstruction of decay vertices of LLPs reaching the MSs, is hadronic or electromagnetic showers not contained in the calorimeter volume, so-called punch-through jets [248]. These punch-through jets occur especially in regions of reduced total interaction length in the calorimeters (e.g. transition regions between the barrel and the end-caps) and can be suppressed by either rejecting these $|\eta|$ regions or requiring a minimal number of hits in the MS and isolating the DV from calorimeter jets as well as high-energy tracks and significant track activity in the inner tracking system. In order to not reject true vertices from displaced decays that occur near the end of the calorimeters, the calorimeter-jets veto should only consider jets with a minimum total energy deposit and, e.g. a minimum electromagnetic fraction of the total energy. The track isolation requirement aims at regions with a poor calorimeter measurement (again, transition regions in the calorimeters), where a single high-energy track or the sum of the track activity in a small cone around the DV could indicate a (punch-through) jet. On the other hand, punch-through jets, given their similarity to signal signatures, can also be used to evaluate systematic uncertainties due to imperfect modeling in the muon-system simulation.

4.4. Real particles originating from outside the detector

There are several types of real particles generated outside the detector that could be sources of background in an LLP search.

4.4.1. Cosmic muons. Cosmic rays from the atmosphere can enter the detector as cosmic-ray muons. These cosmic-ray muons can be reconstructed as displaced muons in the MS or as displaced jets in the calorimeters. If cosmic-ray muons are reconstructed in the MSs, they will typically appear as two back-to-back muons with ϕ values near $\pm\pi/2$. The rate of cosmic muons in the detector is about 500 Hz at L1, but depending on the HLT path and the offline selection used, the rate of cosmic-ray muons entering a given LLP analysis is generally much less.

Cosmic-ray muons are typically an important background source to consider for displaced signatures, especially those with large displacements [234, 236, 343–345]. Cosmic-ray muons are generally only an issue for LLP analyses in CMS and ATLAS since LHCb has coverage only in the forward direction.

For many analyses, cosmic-ray muons can be rejected with a simple veto on back-to-back dimuons. However, in some LLP analyses, this veto is not optimal for the signal acceptance or it is insufficient to suppress cosmic-ray backgrounds. Another often-used way to minimize the contribution from cosmic-ray muons is requiring high-momentum muons and/or high-energy jets, since cosmic-ray muons have a rapidly falling p_T spectrum. In addition, if a search primarily looks for inner-tracker or calorimeter objects, cosmic-ray-muon events can be rejected by requiring little MS activity [234, 343, 344].

If the cosmic-ray muon background is significant for an analysis, it can be estimated using data from dedicated cosmic data-taking runs or from empty bunches in pp collision runs [234, 343, 344]. Cosmic ray muon simulations can be made, but in many LLP analyses, a data-driven approach is favoured if the simulation modeling is found to be insufficient. Timing information in the calorimeters or the MSs can be used to discriminate the signal from cosmic-ray muons, sometimes in conjunction with impact parameter variables.

4.4.2. Beam halo. Another type of real particle generated outside the detector that could be a significant source of background for LLP searches is beam halo. Beam halo is produced when protons from the LHC beam scatter off the LHC collimators and produce debris, which can appear in the detector. Beam halo can create energy deposits in the calorimeters or hits in the MS, both of which would be largely in the beam direction. These energy deposits or MS hits would appear earlier than if they had been made from particles coming from the collision (see figure 15). Beam halo is usually not modelled in MC simulation, since it is highly dependent on the beam parameters.

Beam halo is most relevant for searches for displaced signatures without tracks in the inner tracker and for searches for decays in non-collision bunches (e.g. from SPs) [234, 343, 344], which are described in section 3.5.

The contribution from beam halo can often be reduced by requiring high-momentum or high-energy reconstructed objects. One can also decrease the number of beam halo events by requiring central objects or vetoing forward MS activity, since beam halo is usually in the very forward direction [234, 343, 344]. For inner tracker-based signatures, events from beam halo are rejected by requiring a minimum number of early hits; in this way beam halo is rejected due to its anomalous timing.

Figure 15. A sketch illustrating the timing differences due to the shorter, more direct path to the calorimeter cells between a beam-halo muon and a particle originating from the collision. The beam-halo muon is detected earlier than the particle from the collision.

Beam halo background can be estimated using data control regions near $\phi = 0$ and π . One could also identify cells with a low number of (or zero) tracks that are assigned an early time.

4.4.3. Cavern radiation. Diffuse backgrounds can also arise from proton–proton collisions filling the LHC caverns, consisting mostly of neutral, low-energy, and long-lived SM particles (i.e. neutrons and photons), leading to an overall increase in occupancy, especially in the MSs. This so-called ‘cavern background’ or ‘cavern radiation’ can constitute a significant background in a LLP search. As simulations are resource-intensive, it is usually not at all modelled in MC simulation samples.

Cavern radiation is most relevant for searches looking in non-collision data, that is, stopped-particle searches, and for searches using MS information to form tracks and vertices. It can be estimated from data by collecting events triggered by random triggers when there are no collisions, as was done in [236]¹⁷⁸. Cavern radiation can also be estimated by overlaying a cavern radiation simulation with minimum-bias events from data.

4.5. Fake-particle signatures

Another type of background for LLP searches is that from signatures that mimic real particles in the detector, but are in fact fake. Fake particles can originate from spurious detector noise. Noise appears differently for each detector, but in general, it is characterized by a single and concentrated energy deposit or hit that does not correspond in time or space to any other energy deposits or hits in the detector. Noise is usually difficult to model with MC simulation.

Calorimeter detector noise is most relevant for searches looking in non-collision bunches and low-energy collisions [234, 343, 344]. Muon system noise is most relevant for searches that are also highly affected by cosmic-ray muons.

Calorimeter noise can be rejected by vetoing single and concentrated energy deposits [234, 343, 344]. Muon system noise can be rejected by requiring high-quality muon tracks.

Noise in both the calorimeters and the MSs could be estimated by looking at dedicated cosmic data-taking runs and then applying some selection criteria to reject cosmic-ray muons. The remaining events would most likely be noise.

¹⁷⁸ Note that these triggers are unlike those used to collect the search data for stopped-particle searches, which instead select events with physics objects during empty bunch crossings.

Figure 16. Illustration of two close-by, low-mass vertices being reconstructed as one high-mass vertex.

4.6. Algorithmically induced fakes

For searches that aim to reconstruct the decay vertex of an LLP, and especially for LLPs decaying in the proximity of the interaction region, algorithmically induced fakes and/or instrumental backgrounds can be of importance. Algorithmic fakes can still be a significant background to LLP searches, even if a given detector is noise-free.

4.6.1. Random/Merged vertices. This type of background, illustrated in figure 16, is especially important in the environment close to the interaction region that experiences a high track density, and arises from two main sources. First, two or more individual tracks can cross each other and can be reconstructed as a DV. Second, two close-by, low-mass vertices can be reconstructed as one high-mass DV; such a final merging/cleaning step is often part of vertexing algorithms to reduce fakes in standard vertexing.

The former source is mostly suppressed by requirements originally targeting the removal of meta-stable SM particles: a minimum transverse impact parameter, $|d_0|$, for tracks and a minimum distance between the PV and a given DV.

The latter source is harder to suppress, though can be estimated by randomly merging vertices from distinct events. By studying the number of reconstructed ‘merged’ high-mass vertices as a function of distance between the two low-multiplicity low-mass vertices that were ‘merged’—both with vertices from the same event, as well as from different events and scaling them accordingly—an estimate for this background can be derived. This method has been successfully used in the ATLAS search for DV [237] and the ATLAS multitrack analysis [196].

4.6.2. Randomly crossing tracks. A background that is typically more relevant than merged vertices is the background stemming from low-mass DV crossed by unrelated tracks, resulting in the reconstruction of a high-mass vertex, as illustrated in figure 17. The mass of the reconstructed DV is especially increased when the random track crosses the vertex in a direction that is perpendicular to the distance vector pointing from the PV to the displaced one.

As demonstrated in detail in [196, 237], this background can be estimated by constructing vertices (n -track) from lower-multiplicity ones ($n - 1$ -track) by adding pseudo-tracks, drawn randomly from data-driven track templates derived for various radial detector regions. The normalization of the prediction is performed by comparing the $n - 1$ -track-based constructed vertices with the actual n -track vertices in all radial detector regions. One

Figure 17. Illustration of a low-mass vertex crossed by an unrelated track and being reconstructed as a high-mass vertex instead.

potential method for suppressing such backgrounds is to veto vertices where removing one track substantially decreases the mass of tracks associated with the vertex.

4.7. Summary

LLP searches often have very low backgrounds, as opposed to searches for prompt particles. This makes LLP searches highly sensitive to signals of new physics.

There are, however, a few common sources of background that arise in different LLP searches: other, known, LLPs such as b -hadrons; real particles produced in the detector, such as particles produced in collisions that interact with the nuclei of the detector material; real particles produced outside the detector, such as cosmic muons or beam halo; fake particles, such as detector noise; and algorithmically induced fakes, such as two tracks that cross and are reconstructed as a DV, as described above. These backgrounds are generally atypical, difficult to model in simulation, and challenging to estimate. Thus, the possible appearance of unexpected background sources should be taken into account in any new LLP search, and the development of novel techniques and methods to estimate them is encouraged.

5. Detector upgrades

Chapter editors: Juliette Alimena, Martino Borsato, Yangyang Cheng, Monica Verducci

Contributors: Cristiano Alpigiani, Xabier Cid Vidal, David Curtin, Elena Dall’Occo, Sven Dildick, Jonathan L Feng, Iftah Galon, Christopher Hill, Henning Keller, Felix Kling, Simon Knapen, Zhen Liu, Henry Lubatti, Philippe Mermod, Vasiliki A Mitsou, James L Pinfold, Jessica Prisciandaro, Dean Robinson, Livia Soffi, Sebastian Trojanowski, Carlos Vázquez Sierra, Si Xie, Charlie Young

The experimental searches for LLPs outlined in chapter 3 are limited by the abilities of the ATLAS, CMS, and LHCb experiments to trigger on and reconstruct the objects that are associated with each signature. In the Phase 2 high-luminosity upgrade of the LHC (HL-LHC), the extremely high PU conditions necessitate the upgrade of all three detectors to maintain triggers at thresholds needed for sensitivity to electroweak, Higgs, and BSM physics (see [346, 347] for an overview); to reject particles originating from PU vertices; and to maintain object reconstruction in the high-luminosity environment. These upgrades include the addition of tracking layers to the forward regions of ATLAS and CMS, improvements to

timing reconstruction in events, and the inclusion of tracking information at earlier stages of the trigger (or, in the case of LHCb, the full online reconstruction of every event).

While these upgrades are crucial to the success of the HL-LHC physics goals for conventional searches (such as for electroweak, Higgs, or SUSY signatures), they have the opportunity to be transformative for searches for LLPs. Signatures involving LLPs are often subject to small-to-negligible irreducible backgrounds, and improvements to the reconstruction, timing, and vertexing of displaced objects can typically suppress any instrumental or fake backgrounds. (See chapter 4 for a discussion of sources of backgrounds for LLP searches.) At the same time, the introduction of tracking information to earlier stages of the trigger could be used to trigger on events that may contain hadronically decaying LLPs that must otherwise pass jet triggers, leading to an improvement in sensitivity to low-mass LLPs. Indeed, many of the gaps in coverage from current searches identified in section 3.6 can be closed or reduced using the new technology from detector upgrades. Even more uniquely, LLP signatures may themselves motivate the introduction of new detector elements that are dedicated to exploring new lifetime frontiers in particle physics.

This chapter summarizes current and proposed plans for detector upgrades for the HL-LHC, paying special attention to those features of the detector upgrades that are most relevant for LLP searches. Where available, we show the results of projections for the sensitivity to various LLP scenarios of different improvements to the detector. We also highlight LLP studies for the Phase 2 upgrades that are not yet publicly available that should be done in order to assess (and, where possible, improve) the sensitivity of planned upgrades to LLP signatures. Finally, we include contributions from a number of existing and proposed experimental collaborations whose primary purposes are to search for LLPs produced at LHC IPs using additional, dedicated detectors. These detectors complement the capabilities of ATLAS, CMS, and LHCb, allowing sensitivity to signatures that are otherwise not possible to reconstruct at the main detectors.

In section 5.1, we combine the discussions of the planned ATLAS and CMS upgrades, facilitating for each detector component a direct comparison between the features of the upgraded detectors of both ATLAS and CMS. Since LHCb has a very different geometry and physics program from ATLAS and CMS, we have a separate discussion of planned LHCb upgrades in section 5.2. Finally, we present the contributions of the dedicated LLP experiments in section 5.3.

5.1. The ATLAS and CMS experiments

The planned upgrades to the ATLAS and CMS experiments for the HL-LHC will give the detectors increased coverage in the forward regions, better spatial and timing resolutions, and other new features including track triggers. The improved hardware capabilities, combined with software developments, give rise to exciting new prospects for future LLP searches. This section gives an overview of the upgrade scope (section 5.1.1), discusses their physics potential (sections 5.1.2 and 5.1.3), and presents new ideas for detector upgrade and LLP searches (section 5.1.4).

Unless specified otherwise, the subsequent CMS experimental results are from its Technical Design Reports for the different sub-detector upgrades at HL-LHC, namely tracker [348], barrel calorimeter [349], endcap calorimeter [336], muon detectors [350], timing detector (Technical Proposal, [351]), and Level-1 Trigger (Interim Technical Design Report, [352]). ATLAS results are from the Technical Design Reports for the inner tracker pixel detector [353], the TDAQ system [354], the tile calorimeter [355], LAr calorimeter [356], MS [357], and inner tracker strip detector [358].

5.1.1. Detector and trigger upgrades for high-luminosity LHC. The high luminosity LHC (HL-LHC) will begin with the third long shutdown (LS3) of the LHC in the coming decade (as of this writing estimated to begin at the end of 2023), where the machine and detectors will be upgraded to allow for pp running at a luminosity of $5 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ in the nominal scenario, or potentially $7.5 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ in the ultimate performance scenario. This will allow the ATLAS and CMS experiments to collect integrated luminosities ten times that of the current operations, which amounts to around 300 fb^{-1} per year and 3000 fb^{-1} during the projected HL-LHC lifetime of ten years (up to 4000 fb^{-1} if the ultimate instantaneous luminosity can be achieved).

The HL-LHC conditions create unique challenges in terms of high PU levels and high radiation dosage. About 140 PU events per bunch crossing, on average, are expected in the nominal scenario, and up to 200 PU events in the ultimate luminosity scenario. The radiation levels will be unprecedented: for the design integrated luminosity of 3000 fb^{-1} , a 1 MeV neutron equivalent fluence of $2.3 \times 10^{16} n_{\text{eq}} \text{ cm}^{-2}$ and a total ionizing dose of 12 MGy (1.2 Grad) is expected at the centre of the detectors, where the innermost silicon pixel tracking layers will be installed.

To meet the challenges of the HL-LHC operating conditions, and to fully profit from its physics capabilities, comprehensive upgrade programmes are planned for both the ATLAS and CMS experiments. This section summarizes the main detector and trigger upgrade plans for each sub-detector component of both experiments.

5.1.1.1. Tracker. By the start of the HL-LHC, the inner trackers of both experiments must be replaced due to the significant radiation damage and performance degradation they have suffered. To maintain tracking performance in the high-density environment, and to cope with the increase of approximately a factor of ten in the integrated radiation dose, both the ATLAS and CMS experiments will entirely replace their inner tracking detectors.

CMS upgrade. The CMS tracker is composed of the inner pixel detector and the outer tracker. At the HL-LHC, the CMS inner pixel detector will include four cylindrical barrel layers covering the region of $|z| < 200 \text{ mm}$, and forward extensions of up to twelve endcap disks on both sides (compared to the current configuration with three disks), which will extend its $|\eta|$ coverage from the current value of 2.4 to approximately 4. To maintain radiation hardness and reasonable occupancy, as well as to improve resolution, small, thin pixels will be used. For the studies in the CMS tracker TDR [348], pixels with a thickness of $150 \mu\text{m}$ and $25 \times 100 \mu\text{m}^2$ in size are used in the simulation¹⁷⁹. The first layer of the barrel inner pixel detector will be positioned at a radius of 28 mm.

The CMS outer tracker is composed of six cylindrical barrel layers in the central region, covering the region of $|z| < 1200 \text{ mm}$, complemented on each side by five endcap double-disks, in the region of $1200 < |z| < 2700 \text{ mm}$. Modules are installed between $r \sim 21 \text{ cm}$ and $r \sim 112 \text{ cm}$. Three sub-detectors are distinguished: the Tracker Barrel with pixel-strip modules (TBPS), the Tracker Barrel with strip-strip modules, and the tracker endcap double-disks (TEDD). The inner rings of the TEDD disks use pixel-strip (PS) modules up to $r \sim 60 \text{ cm}$, and the rest use strip-strip modules. The outer tracker modules, called p_{T} modules, are composed of two single-sided, closely-spaced (1–4 mm separation) small pitch sensors read out by a set of front-end ASICs that correlate the signals in the two sensors and select the hit pairs (referred to as ‘stubs’) compatible with particles above the chosen p_{T}

¹⁷⁹ An alternative option being considered is that of $50 \times 50 \mu\text{m}^2$. Larger pixel sizes of $50 \times 200 \mu\text{m}^2$ or $100 \times 100 \mu\text{m}^2$ are being considered in outer barrel layers and outer rings of the endcap as a potential option to reduce power consumption.

threshold. A p_T threshold of 2 GeV corresponds to a data volume reduction of roughly one order of magnitude, which is sufficient to enable transmission of the stubs at 40 MHz. The ‘stubs’ are used as input to the hardware trigger at Level-1 (L1), which enables track-finding at L1 for all tracks with a p_T of 2 GeV or above. To improve the ‘stub’-finding efficiency and also to reduce material, the inner three outer tracker barrel layers, the TBPS, are made with flat modules in the center and tilted modules in the regions with larger z .

ATLAS upgrade The ATLAS collaboration will replace its ID with a new, all-silicon tracker to maintain tracking performance in HL-LHC conditions.

The new ATLAS ITk will consist of a greatly enlarged pixel system extending to roughly twice the radius and four times the length of the current pixel array, coupled with a much more finely-segmented strip detector. In total, the coverage of the full radius of the inner solenoid requires over three times the silicon area of the current detector.

The new system will consist of silicon barrel layers and disks (strips) or rings (pixels) with the possibility of inclined pixel modules to better cover the transition from the barrel to the end-cap regions. In detail, the strip detector has four barrel layers and six end-cap petal-design disks, both having double modules each with a small stereo angle. The strip detector, covering $|\eta| < 2.7$, is complemented by a five-layer pixel detector extending the coverage to $|\eta| < 4$. The combined strip-plus-pixel detectors provide a total of 13 hits for $|\eta| < 2.6$, with the exception of the barrel/end-cap transition of the strip detector, where the hit count is 11.

5.1.1.2. Calorimetry. Both the ATLAS and CMS calorimetry consist of ECALs and HCALs. Different materials and designs are used for the two experiments.

CMS upgrade. For the CMS detector, the existing scintillating crystals in its ECAL (ECAL) barrel (EB) will be kept for the duration of LHC. On the other hand, both front-end and back-end electronics will be replaced [349], which allows for higher transfer rates and more precise timing. The target timing resolution for the upgraded ECAL electronics is ~ 30 ps for particles with $p_T \approx 30$ GeV, which is the fundamental limit allowed by hardware and an order of magnitude smaller than the current limit. Current studies on the CMS HCAL barrel radiation damage suggest there is no need for replacement at HL-LHC.

The CMS endcap calorimeter, including both the electromagnetic (EE) and the hadronic sections, will be replaced with a high-granularity, silicon-based calorimeter (HGCAL). The HGCAL, with fine granularity in both the lateral and longitudinal directions, enables 3D imaging in reconstructing energy clusters. The intrinsic high-precision timing capabilities of the silicon sensors will add an extra dimension to event reconstruction. The HGCAL is expected to provide a timing resolution of ~ 10 s of ps for high-energy particles with p_T of tens of GeV.

ATLAS upgrade. The ATLAS liquid argon (LAr) calorimeter will be improved in Phase 2 with an electronics upgrade that will provide optimized super cells and full-granularity data to the trigger system by means of a new pre-processor. A similar upgrade of the ATLAS Tile calorimeter readout will use on-detector digitization and a new back end pre-processor. Both the LAr and Tile calorimeters expect to implement a 40 MHz readout system for Phase 2. The transmission of high-granularity calorimeter data (all cells with a transverse energy of two times the noise threshold) drives the bandwidth requirement for the upgraded trigger and data acquisition (TDAQ) system.

In addition, the outermost Tile calorimeter layer can be used to identify muons in the range $|\eta| < 1.3$ by better identifying particle energy depositions above the minimum ionizing particle (MIP) threshold.

5.1.1.3. Muon system. The MS will be upgraded at both experiments to meet HL-LHC conditions, extend geometric coverage, and improve detector performance and trigger capabilities.

CMS upgrade. For the CMS detector, its current MS consists of three different types of muon detectors. In the barrel region, drift tubes (DTs) are installed along with resistive plate chambers (RPCs). In the endcaps, there are cathode strip chambers (CSCs) together with RPCs. At the HL-LHC, the existing muon detectors will be improved with upgraded electronics to enable 40 MHz readout, as well as improve the timing resolution from the current 12.5–1 ns [350]. New muon detectors, namely gas electron multipliers and a new version of RPCs, will be added to the endcaps, covering the regions of $1.6 < |\eta| < 2.4$. Additional muon chambers, labeled ME0, will cover the very forward regions of $2.4 < |\eta| < 2.8$, a region also covered by the upgraded inner tracker. This will be used for the muon trigger at L1. The additional muon detectors are essential to achieve a high trigger efficiency with an acceptable rate, especially in the forward region. The additional hits in the new endcap muon stations, combined with improved algorithms, permit efficient triggering on displaced muon tracks even in the harsh environment of the HL-LHC.

ATLAS upgrade. Most of the front-end and detector readout of the ATLAS MS, including the trigger electronics for the RPC, thin gap chambers (TGCs), and monitored drift tube (MDT) chambers, will be replaced to face the higher trigger rates and longer latencies necessary for the new Level-0 (L0) trigger required by the HL-LHC conditions. The MDT chambers will be integrated into the L0 trigger in order to sharpen the momentum threshold. Some of the MDT chambers in the inner barrel layer will be replaced with new, small-diameter MDTs. Additional RPC chambers will be installed in the inner barrel layer to increase the acceptance and robustness of the trigger, and some chambers in high-rate regions will be refurbished. New TGC triplet chambers in the barrel–endcap transition region will replace the current TGC doublets to suppress the high trigger rate from random coincidences in this region. The electronics of all the sub-detectors will need to be replaced due to obsolescence, aging, and radiation damage. During the Phase 1 upgrade (to take place from 2019 to 2021) the new small wheel chambers will replace the CSC and the MDT chambers of the innermost endcap wheel by micromegas and small-strip TGCs. The replacement of the MDT front-end readout will address the trigger rate and latency requirements of the TDAQ system in Phase 2 and allow the use of MDT hit information to improve the muon p_T resolution in the L0 trigger. Additionally, in the upgraded detector all data from the barrel and endcap detectors will be transmitted to FPGAs at L0, which can be used to implement more advanced and flexible algorithms for muon reconstruction, including the use of neural networks and/or dedicated tracking for non-pointing muons [354].

Some LLP scenarios (e.g. HV models [66]) predict muon-jet final states, which result in collimated muons that are not identified with high efficiency by the current triggers (see section 3.2). In figure 18, the opening angle between muons in a HV model is shown, for a particular combination of particle masses and parameters. The di-muon separation is much smaller than the current system can resolve (approximately 0.2 in $\Delta\phi(\mu, \mu)$). In the no-upgrade scenario, these can only be recorded by the single muon trigger. In the upgraded scenario, a dedicated trigger is under development for a dimuon trigger with a p_T threshold of ≈ 10 GeV.

5.1.1.4. Timing detector. Precision timing can be provided by the aforementioned calorimetry upgrades. However, the tens of ps timing resolution in the upgraded calorimeters is only achievable for particles with energy above tens of GeV. Moreover, timing information for delayed objects from calorimetry alone will be affected by the

Figure 18. Opening angle between muons in a Hidden Valley model, where a sub-GeV-mass particle decays to $\mu^+\mu^-$. The opening angle is well below the resolution of the current system. From [359].

beamspot smearing, which corresponds to about 180 ps of uncertainty. Therefore, global event timing with the ability to reconstruct the vertex time and exploit time information in charged particle reconstruction requires a dedicated fast timing detector.

CMS upgrade. For the CMS experiment, the proposed MIP timing detector (MTD) will comprise a barrel and an endcap region made up of a single layer device between the tracker and calorimeters, and cover $|\eta|$ up to ~ 3 . In the barrel, the proposal is to adapt the present Tracker Support Tube (TST) design by instrumenting the current location of the thermal screen with a thin, actively-cooled, stand-alone (SA) detector, based on lutetium–yttrium orthosilicate crystals activated with cerium (LYSO:Ce) and read-out with silicon photomultipliers. The endcap region can be instrumented with a hermetic, single layer of MIP-sensitive silicon devices with high timing resolution, with a pseudorapidity acceptance from about $|\eta| = 1.6$ to $|\eta| = 2.9$. The MTD is designed to provide timing resolution of a few tens of ps for charged tracks throughout the detector lifetime. The performance projection in section 5.1.3 is evaluated with a 30 ps resolution for a p_T threshold of 0.7 GeV in the barrel and a p threshold of 0.7 GeV in the endcap, and covering the expected MTD fiducial region of $|\eta| < 3$.

ATLAS upgrade. The high-granularity timing detector (HGTD) is intended to distinguish between collisions occurring very close in space but well-separated in time. Currently there is not yet a TDR for this project. The current proposed detector design is based on low-gain avalanche detector technology that will cover the $|\eta|$ region between 2.4 and 4, with a timing resolution of 30 ps for MIPs. High-precision timing will improve the track-to-vertex association in the forward region, impacting jet and lepton reconstruction, as well as offering unique capabilities for online and offline luminosity determination.

5.1.1.5. Trigger. The ATLAS and CMS experiments adopt a two-level trigger system: the hardware-based Level-1 trigger (L1) and the software-based high-level trigger (HLT).

CMS upgrade. For the CMS experiment, the L1 trigger currently only uses calorimeter and muon information. At the HL-LHC, with the aforementioned outer tracker upgrade of p_T modules and stub-finding capabilities, tracking information will be included at L1 [352]. The

L1 track trigger uses parallel processing and pattern recognition on stub information to achieve track finding at an output rate of 750 kHz.

The L1 tracking capability will be further complemented by the calorimeter and muon upgrades, which provide more precise position and momentum resolution, calorimeter shower shape, and more muon hits in the forward region. In the L1 trigger, the electron and photon trigger algorithms for HL-LHC will use information from the ECAL as well as from the outer tracking detectors. The algorithm should preserve the ability to reconstruct electromagnetic clusters with p_T above a few GeV with high efficiency (95% or greater above 10 GeV) as well as achieve high spatial resolution which should be as close as possible to the offline reconstruction. Following the upgrade of both on-detector and off-detector electronics for the barrel calorimeters at the HL-LHC, the EB will provide energy measurements with a granularity of (0.0174, 0.0174) in (η, ϕ) , as opposed to the current input to the L1 trigger consisting of trigger towers with a granularity of (0.087, 0.087). The much finer granularity and resulting improvement in position resolution of the electromagnetic trigger algorithms is critical in improving electron/photon trigger efficiency and suppressing background at high PU.

The L1 global trigger (GT) will be upgraded with more sophisticated and effective global trigger calculations based on topology, plus an additional intermediate correlator trigger to fully exploit the increased information in the trigger objects, such as matching tracking info with finely-grained calorimeter information, or a combination of muon and track information. The upgraded detector readout and DAQ systems will allow 12.5 μ s latency and a L1 rate of 750 kHz; the latter may be substantially reduced by adding L1 tracking information matched to improved L1 trigger objects from the calorimeters and MS. At the HLT, the processing power is expected to scale up by PU and L1 rate, with an output rate of 7.5 kHz and up to 10 kHz.

ATLAS Upgrade. The ATLAS trigger and the data acquisition system are being planned with the intention of fully exploiting the physics potential of the HL-LHC. A baseline architecture has been proposed and documented in [354].

The hardware-based Level-0 Trigger system will be composed of separate calorimeter and muon triggers, as well as a GT and Central Trigger sub-systems. The result of the Level-0 trigger decision is transmitted to the data acquisition system at 1 MHz, and is followed by an upgraded Event Filter system to achieve a maximum stored event rate of 10 kHz.

The upgraded trigger system will take advantage of increased granularity provided by the calorimeters, will improve efficiency for muon-based triggers and perform hardware-based tracking profiting from the extended coverage of the planned silicon ITk. Options exist to further develop a hardware-based track trigger for quicker and less CPU-intensive rejection of the expected large increase in PU at the HL-LHC, to take full advantage of extended coverage provided by the ITk. Such a hardware track trigger (HTT) would be an evolution of the current ATLAS FTK reconstruction system.

5.1.2. Object performance: tracking and vertexing. The ability of the detectors to reconstruct tracks and find vertices with high precision and efficiency in a high-density environment underlies the experimental reach for displaced objects. This section reviews the ATLAS and CMS experiments' projected tracking performance at the HL-LHC, highlighting improvements and new features with the upgrades.

5.1.2.1. CMS performance. L1 tracking. With the aforementioned tracker and L1 track trigger upgrades, the CMS experiment will be able to do track finding at L1 as well as offline at HL-LHC. Both L1 and offline tracking performance are discussed here.

Figure 19. Left: L1 tracking efficiency versus generated particle p_T for $|\eta| < 2.4$. Right: L1 tracking efficiency versus η for $p_T > 3$ GeV. Results for muons (electrons) are shown as filled black (open red) circles, and are produced with $t\bar{t}$ events in a scenario with 200 pile-up events per bunch crossing, on average [348].

Figure 20. Relative p_T (left) and z_0 resolution versus pseudorapidity for muons in $t\bar{t}$ events with zero (black dots), 140 (red triangles), and 200 (blue squares) pile-up events per bunch crossing, on average. Results are shown for scenarios in which truncation effects are (markers) or are not (lines) considered in the emulation of L1 track processing. The resolutions correspond to intervals in the track parameter distributions that encompass 68% (filled markers and solid lines) or 90% (open markers and dashed lines) of all tracks with $p_T > 3$ GeV [348].

All L1 tracking studies have been performed assuming 3 GeV stub p_T thresholds. In figure 19, the L1 tracking efficiency for prompt muons and electrons for $t\bar{t}$ events in a scenario with 200 PU interactions per bunch crossing, on average, is presented. The tracking efficiency for muons exhibits a sharp turn-on at the 3 GeV stub p_T threshold, and saturates at approximately 98%. The tracking efficiency for electrons turns on more slowly and flattens out at 90%, mostly due to interaction with the detector material.

In figure 20, the L1 tracking resolutions of the p_T and z_0 parameters of muons with $p_T > 10$ GeV in $t\bar{t}$ events is shown for various average PU scenarios. The resolutions are defined in terms of an interval centered on the residual distribution that contains 68% or 90% of the tracks. Loss in tracking efficiency due to truncation effects (where there is insufficient time to transfer all the stub data) is determined from hardware and emulation to be at the level of 10^{-3} when considering $t\bar{t}$ samples with a PU rate of 200. As expected, resolutions degrade at forward pseudorapidity due to a corresponding increase in multiple scattering. In general,

Figure 21. Relative resolution of the transverse momentum (left) and transverse impact parameter (right) as a function of the pseudorapidity for the current (black dots) and the upgraded (red triangles) CMS tracker, using single isolated muons with a transverse momentum of 10 GeV [348].

L1 parameter resolutions are excellent, which will provide for robust trigger object matching and charged particle reconstruction in the L1 trigger.

Offline tracking. Preliminary results on the offline tracking performance over the full acceptance of the CMS tracker are excellent, with further improvements expected as the detector design and simulation algorithms are optimized. In figure 21, the resolution of the transverse momentum and the transverse impact parameter for single muons with $p_T = 10$ GeV as a function of the pseudorapidity, both with the current detector and after the implementation of the HL-LHC upgrades, is shown. The better hit resolution of the HL-LHC tracker and the reduction of the material budget result in a significantly improved p_T resolution. The transverse impact parameter resolution is also improved with respect to the current detector, ranging from below $10 \mu\text{m}$ in the central region to about $20 \mu\text{m}$ at the edge of the acceptance.

For $t\bar{t}$ events, the efficiency to identify the PV correctly is $\sim 95\%$ at an average PU level of 140, and $\sim 93\%$ at an average PU level of 200. The vertex algorithm used is the same as the one used in Run 2 for a PU of about 35, therefore it is not yet optimized for vertex reconstruction at very high PU. In figure 22 the resolution of the vertex position in the x , y , and z coordinates is shown as a function of the number of tracks associated to the vertex. The vertex position resolution is almost independent of the amount of PU in the event and the longitudinal resolution is only 50% worse than the transverse one, as expected given the pixel dimensions of the inner tracker modules.

Given that the CMS HLT tracking is based on the offline tracking code, a similar level of performance is expected. Because of HLT time constraints, a parallelization of the algorithms is already under development and will be applied also in the HLT track reconstruction at HL-LHC.

5.1.2.2. ATLAS performance. Excellent tracking performance is also expected with the ITk upgrade of the ATLAS experiment for the HL-LHC era. The left panel of figure 23 shows the track reconstruction efficiency for jets in $Z' \rightarrow t\bar{t}$ events with 200 PU for different η ranges. The right panel of figure 23 shows the fake rate for reconstructed tracks in $t\bar{t}$ events, and there

Figure 22. Vertex position resolution in x and y (left) and z (right) as a function of the number of tracks associated to the vertex, for $t\bar{t}$ events with an average of 140 (full circles) and 200 (open circles) pile-up interactions per bunch crossing [348].

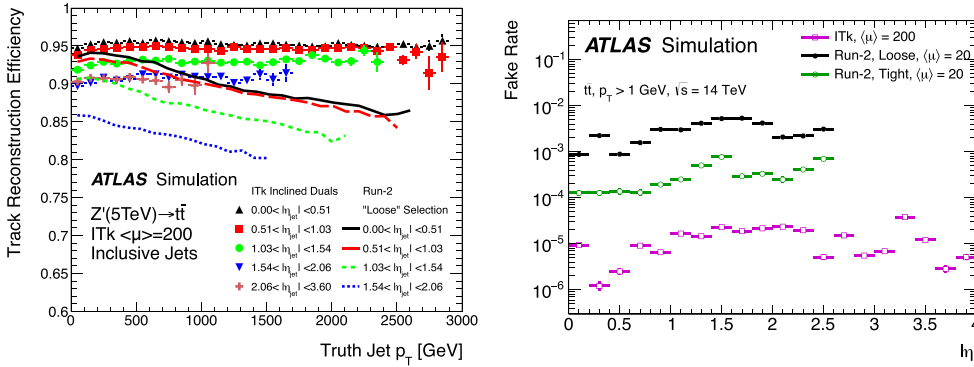

Figure 23. Left: track reconstruction efficiency for tracks in jets from $Z' \rightarrow t\bar{t}$ with 200 average pile-up events. The efficiency is shown as a function of jet p_T for different η ranges, and $M_{Z'} = 5$ TeV. Right: fake rate for tracks in $t\bar{t}$ events with 200 average pile-up events using ITk; Run 2 detector results are shown for comparison. Both figures are from [353].

is clearly substantial improvement over the Run 2 detector performance along with the improved coverage in the forward region.

In figure 24, the resolution of the transverse momentum and the longitudinal impact parameter for single muons with various p_T values is shown as a function of the pseudorapidity both with the current detector and projections for after the HL-LHC upgrade using digital clustering to find the tracks. The improvement is even more marked with analogue clustering: the transverse and longitudinal impact parameter resolutions are shown for different pixel pitches in figure 25.

5.1.3. Upgrade projection: LLP searches. Searches for LLPs are well motivated by various classes of extensions of the SM, discussed at length in chapter 2.2. Often, the production cross section for such processes is expected to be very small. The HL-LHC will allow for the

Figure 24. Resolution of the transverse momentum (left) and longitudinal impact parameter (right) as a function of the pseudorapidity for the current (solid line) and the upgraded (points) ATLAS tracker [353].

Figure 25. Track parameter resolutions using analogue clustering for (left) transverse impact parameter; (right) longitudinal impact parameter. The resolutions are shown for single muons with $p_T = 100$ GeV. The results of ITk are shown for $25 \times 100 \mu\text{m}^2$ and $50 \times 50 \mu\text{m}^2$ pixels, along with the current Run 2 detector performance [353].

collection of much larger data sets needed to reach better sensitivity to such BSM scenarios. The prospects are further strengthened with detector and trigger upgrades. This section discusses these potential improvements, and presents sensitivity projections on a number of benchmark LLP search channels with the aforementioned upgrades at the HL-LHC.

5.1.3.1. Heavy stable charged particles in CMS. A number of new physics scenarios give rise to HSCPs with long lifetimes that move with subrelativistic speed through the detector, heavily ionizing the sensor material as they pass through. In split SUSY models, the

Figure 26. Left: distribution in CMS of the dE/dx discriminator versus track momentum (p) for tracks with high momentum ($p_T > 55$ GeV) in background events (red) and for candidate signal particles. Pair produced $\tilde{\tau}_5$ with a mass of 871 GeV (blue), and a gluino with a mass of 1400 GeV (green), are shown. Right: the performance of the dE/dx discriminator for selecting gluinos in events at rates of 0 pile-up (PU) and 200 PU. The signal versus background efficiency performance curves for a discriminator making use of both the pixel information and the outer tracker HIP flag (red and magenta) demonstrate a better performance compared to a discriminator trained to exploit only the dE/dx information from the pixel modules (blue and green), for a background rejection of 10^{-6} [348].

supersymmetric particles known as the stau ($\tilde{\tau}$) and the gluino (\tilde{g}) can have such characteristic signatures. The relevant simplified models are described in sections 2.4.2–2.4.3, and current searches are described in section 3.5.1.1.

Sensitivity projection with tracker upgrade. Depending on the mass and charge of the new particles, HSCPs experience anomalously high energy losses through ionization (dE/dx) in the silicon sensors with respect to the typical energy losses of SM particles, as can be seen in figure 26 (left). At the CMS experiment, the current strip tracker features analog readout. Furthermore, the pixel detector featured analog readout during Phase 0 in 2016 and before, and currently features digital readout during Phase 1, which started at the beginning of the 2017 LHC run. Therefore, these detectors allow for excellent dE/dx measurements.

At the HL-LHC, the upgraded CMS inner pixel detector will continue providing dE/dx measurements, enabled by its time-over-threshold readout, while the outer tracker cannot provide such information, given that the readout is binary. To increase the sensitivity for signatures with anomalously high ionization loss, a second, programmable, threshold has been implemented in the short strip ASICs of the PS modules of the outer tracker, and a dedicated readout bit signals if a hit is above this second threshold.

Searches for HSCPs can thus be performed by measuring the energy loss in the inner pixel detector and by discriminating HSCPs from minimum ionizing particles based on the ‘HIP flag’ in the outer tracker. The threshold of the minimum ionization needed to set the HIP flag is an adjustable parameter in each PS module independently. A threshold corresponding to the charge per unit length of 1.4 MIPs, resulting from preliminary optimization studies, is used in the simulation, and the gain in sensitivity obtained by using the HIP flag is studied.

An estimator of the degree of compatibility of the track with the MIP hypothesis is defined to separate candidate HSCPs from tracks from SM background sources. The high resolution dE/dx measurements provided by the inner pixel modules are used for the computation of the dE/dx discriminator. The tracks in background events have a low number of HT clusters with HIP flag, compared to those observed for tracks in HSCP signal events and slow-moving protons and kaons in minimum bias events.

In figure 26 (right), the performance of the discriminator is shown by evaluating the signal versus background efficiency curves to identify tracks from signal events and reject those originating from backgrounds. The performance curves are evaluated for two different strategies for the discriminator: the dE/dx discriminator, which relies solely on the inner pixel modules (dE/dx -only, ignoring the HIP flags), and a recomputed discriminator which includes the HIP flags from the outer tracker PS modules ($dE/dx + \text{HIP flags}$). The signal versus background efficiency performance curves demonstrate that for a background efficiency of 10^{-6} , analogous to the current analysis performance, the $dE/dx + \text{HIP}$ -based discriminator leads to an expected signal efficiency of 40%, around 4–8 times better than the dE/dx -only discriminator. In the dE/dx -only scenario, the efficiency for the HSCP signal is about 8 times smaller than that obtained in current data. The inclusion of the HIP flag for the PS modules of the Outer Tracker restores much of the efficiency, so that the same sensitivity as in Phase 1 will be realized with about four times the luminosity of Phase 1. The Phase 1 sensitivity will be surpassed with the full expected integrated luminosity of the HL-LHC. This study demonstrates the critical impact of the HIP flag in restoring the sensitivity of the CMS tracker for searches for HIPs in the HL-LHC era.

Additionally, the current CMS inner pixel detector provides measurements of charge deposits in each pixel up to 9600 electrons over a range of 4 bits in the digitizer. While it may be difficult to increase the number of bits used to store the charge information due to data rate constraints, it is possible to adopt a dual-slope mapping from charge deposit to ADC counts in the digitizer, which will preserve the granularity for lower charge deposits, while giving more information for HIPs such as HSCPs. This option is currently being studied to evaluate the potential improvement to dE/dx measurements. Furthermore, tuning of the HIP flag threshold may bring additional improvements.

HSCP trigger with muon detector upgrade. The upgrade of the RPC system will allow the trigger and identification of slowly moving particles by measuring their TOF to each RPC station with a resolution of $\mathcal{O}(1)$ ns. The new RPC detectors have a two-end strip readout, which provides precise measurements of the hit position in the local y or the global η coordinate. The speed of muon-like particles and the time (bunch crossing) of their origin will be computed with a fast algorithm to be implemented in the Level-1 trigger at the HL-LHC.

The RPC detectors are synchronized to register muons moving at the speed of light with a local time equal to zero with respect to the collision event that produced the trigger. Slow-moving particles, as HSCPs, will arrive with a delay depending on their speed as shown in figure 27. This time delay, measured by each RPC layer crossed by the HSCP, is exploited in order to trigger on and reconstruct such particles.

The principles of the proposed HSCP trigger algorithm are illustrated in figure 28. In this figure, the vertical axis is the time of signals measured in RPC chambers, as synchronized so that muons moving nearly at the speed of light from a particular collision are measured at the time of the collision. The horizontal axis is the distance from the collision point to the position of the RPC at which the time is measured. The diagram shows three successive bunch crossings, two of which contain muons represented at horizontal lines. The diagram also shows the RPC time measurements from two HSCPs having slopes different from zero due to their traveling significantly slower than the speed of light. The time delay Δt is related to the

Figure 27. RPC hit time measurement distribution in CMS for muons from $Z \rightarrow \mu\mu$ events and for semi-stable $\tilde{\tau}$ particles with $m \approx 1600\text{ GeV}$, produced in $pp \rightarrow \tilde{\tau}\tilde{\tau}$ processes [350].

Figure 28. Diagram showing times measured at different RPC stations for particles originating at different bunch crossings and with different velocities in CMS. The x -axis represents the distances from IP to RPC detectors, while the y -axis corresponds to time. The clock at each RPC station is tuned so that particles moving with the speed of light are registered with the exact same ‘local’ times. Hence, relativistic particles are represented by horizontal lines on this diagram [350].

Figure 29. Left: resolution of a particle-speed measurement at L1 trigger with Phase 1 and upgraded RPC Link Board System. Right: the efficiency as a function of β of the standard L1 muon trigger without any p_T threshold, and the RPC-HSCP Phase 2 trigger with 1.56 ns sampling time. For both plots, an HSCP signal is shown [350].

speed v of an HSCP via the following equation:

$$\Delta t = d \left(\frac{1}{v} - \frac{1}{c} \right). \quad (5.1)$$

Here d is the distance between the IP and the point where an HSCP crosses an RPC. For RE4/1 chambers and $\beta = v/c = 0.2$, the delay time is > 6 bunch crossings, comparable to 150 ns.

A penetrating charged particle leaves a trail of hits in RPC chambers along its trajectory. The TOF can be computed in each RPC station with respect to a number of bunch crossing hypotheses. Should there be a common velocity solution, derived from equation (5.1), with $\beta < 0.6$, a trigger is formed. For $\beta > 0.6$, the delays are small and can be handled by the Phase 1 trigger. The performance of this algorithm has been studied with the CMS full simulation. All the detector effects (e.g. electronics jitter, signal time propagation along strips) are considered. A particle-speed measurement resolution is shown in figure 29 (right) for the case of 25 ns signal sampling time (Phase 1) and 1.56 ns sampling time provided with the upgraded RPC Link Board System. For both plots, an HSCP signal is shown.

The efficiency of the RPC-HSCP algorithm as a function of β is studied and compared with the standard L1 muon trigger. The results are shown in figure 29 (right). The current CMS-HSCP Phase 1 trigger performs well down to $\beta \approx 0.75$. The upgraded RPC Link Board System will allow for the triggering, at the correct bunch crossing, on possible HSCPs with velocities as low as $\beta \sim 0.25$.

Possible improvements for this trigger proposal in the β measurement could be achieved by matching tracks in the track trigger to the HSCP muon trigger.

5.1.3.2. Displaced muons in CMS. Many BSM theories predict particle decays with displaced muon or muon pairs in its final state, such as dark SUSY and GMSB with smuons. In order to demonstrate the physics potential of displaced muons at the HL-LHC with the CMS detector, a particular SUSY model is selected where the displaced signature consists of a dimuon final state emerging from the decay of heavy sparticles (smuons). Searches for the direct production of heavy sparticles with long lifetimes are difficult in the present LHC runs, owing to small cross sections and limited integrated luminosity, and will only become possible at the HL-LHC.

Figure 30. Left: the muon transverse impact parameter, $|d_0|$, for several simulated smuon decay lengths, $c\tau$, at the generator level. Right: distribution of the minimum number of valid hits in the CMS Phase 2 muon system for a SUSY $\tilde{\mu}$ with $m_{\tilde{\mu}} = 500$ GeV and $\tau = 1000$ mm for the Run 2 (blue) and Phase 2 (red) detectors [350].

In GMSB models, smuons can be (co-)NLSPs (next to lightest supersymmetric particles) and decay to a muon and a gravitino [360]. When the slepton is long lived, the final state signature is two displaced oppositely charged muons and significant missing transverse energy. The smuon pair production has the advantage that it can be characterized by a very clean final state topology, and we will therefore focus on the process $q\bar{q} \rightarrow \tilde{\mu}\tilde{\mu}$, where the two smuons decay far from the primary interaction vertex. For this process, the muon $|d_0|$ can reach up to approximately one meter (or longer) for sufficiently large lifetimes, as shown in figure 30 (left). Figure 30 (right) compares the number of hits created by these displaced muons in the CMS MS in Phase 2 and the current CMS detector. The hits plotted here are those associated with the DSA muon tracks, which is a muon track reconstruction algorithm specifically designed for displaced muons that can only be reconstructed in the MS [335].

Standard triggers and reconstruction algorithms that use the position of the PV will not efficiently reconstruct tracks with large impact parameters. Consequently, triggering on and reconstructing muons produced far from the IP is challenging and requires dedicated triggers and reconstruction algorithms. The upgrades to the MS in CMS, as well as the L1 tracking capabilities, significantly improve the experiment's ability to search for displaced muons at the HL-LHC.

Triggering on displaced muons. The momentum resolution of the L1 muon trigger for muons coming from the PV will be greatly improved by adding information from the L1 track trigger, discussed previously. The L1 track trigger can also be directly combined with trigger primitives at the first stage of the muon track-finder electronics; this would mirror the offline reconstruction of ‘Tracker Muons’ which improve the efficiency for very low- p_T muons, especially in the barrel region.

To trigger on both prompt and non-prompt muons effectively at L1, a SA L1 muon generates two p_T measurements for each muon, prompt and non-prompt, which are matched with L1 tracks. If the track match is successful, the L1 track trigger p_T is used and a prompt

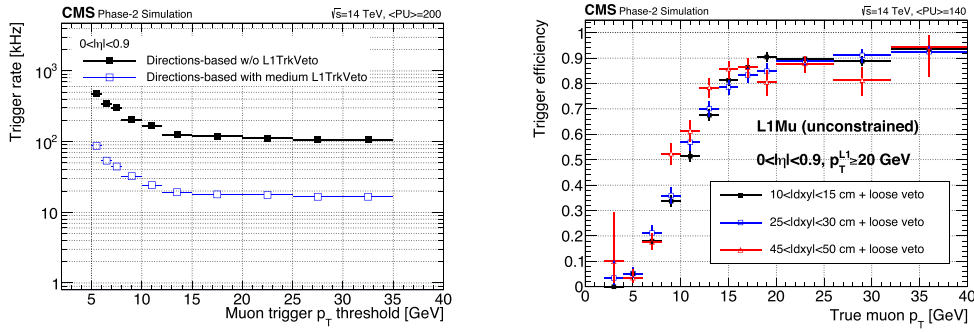

Figure 31. L1 Muon trigger rate (left) and efficiency (right) versus muon p_T threshold for the barrel displaced muon algorithm [350].

candidate is formed. If the match is unsuccessful and the muon is not vetoed by L1 tracks, the non-prompt L1 muon p_T is used to form a displaced muon candidate. Figure 31 shows good performance for displaced muons with this method, i.e. there is a reasonably high efficiency and a trigger rate for a single muon trigger of around 10 kHz under HL-LHC conditions. Further improvements to the algorithm are underway to accommodate high PU conditions. The upgrade of the RPC system will allow slowly-moving particles to pass the trigger and be identified by measuring their TOF to each RPC station with a resolution of $\mathcal{O}(1)$ ns. The speed of muon-like particles and the time (bunch crossing) of their origin will be computed with a fast algorithm to be implemented in the L1 trigger for the HL-LHC.

Reconstruction. A dedicated muon reconstruction algorithm was designed for non-prompt muons that leave hits only in the MS. This DSA algorithm is seeded by groups of track segments in the muon chambers. For each seed, a muon track is reconstructed with the same Kalman-filter technique as for the standard SA muon reconstruction algorithm, but without constraining the IP. Figure 30 (right) shows the distribution of the number of hits in the Run 2 and HL-LHC detectors for displaced muons. The impact of the new stations is clearly visible. The charge mis-identification probability is expected to further decrease with the additional hits.

Sensitivity projection with a GMSB model. To study the impact on physics sensitivity, a particular GMSB model is selected where the displaced signature consists of a dimuon final state plus gravitinos, emerging from the decay of heavy long-lived sparticles (smuons), where the gravitinos escape detection. This maps to the direct pair production simplified model with neutral LLP decays to muon + invisible in section 2.4. This signal can serve as a proxy for other models with two LLPs decaying into muons. The final-state signature is then given by two displaced, oppositely-charged muons and significant \cancel{E}_T . Example LLPs with $c\tau = 10, 100, 1000$ mm and several mass hypotheses (0.2, 0.5, 1 TeV) are simulated.

The main background for this search comes from multi-jet production (QCD), $t\bar{t}$ production, and $Z/\text{DY} \rightarrow \ell\ell$ events where large impact parameters are (mis)reconstructed. Cosmic-ray muons have been studied in Run 2 and these studies can be directly applied to Phase 2 running. In the barrel, they are efficiently rejected by the timing of the hits in the upper leg. Cosmic-ray muons do not originate at the vertex and therefore pass the upper-barrel sectors in reverse direction from outside in. The fraction of cosmic-ray muons in the endcaps is negligible.

Given the very low cross section of the signal process, it is essential to reduce the background efficiently. The best background discriminator is the impact parameter

Figure 32. The 95% C.L. projected upper limits at CMS for $q\bar{q} \rightarrow \tilde{\mu}\tilde{\mu}$, $\tilde{\mu} \rightarrow \mu\tilde{G}$ for various mass hypotheses for $c\tau = 1$ m (left), and as a function of the decay length for $m_{\tilde{\mu}} = 200$ GeV (right). In both panels, the theoretical cross section for the specific model is represented by the blue solid line. For different SUSY breaking scales, $\tan\beta$ or otherwise modified parameters, the cross sections may be 100 times larger, reflected by the blue dashed–dotted line. Green (yellow) shaded bands show the one (two) sigma range of variation of the expected 95% C.L. limits. Phase 2 results with an average of 200 pile-up collisions per bunch crossing and an integrated luminosity of 300 fb^{-1} are compared to results obtained with 3000 fb^{-1} . The black line shows the sensitivity without the DSA algorithm, which reduces the reconstruction efficiency by a factor three [350].

significance $d_0/\sigma(d_0) \approx 5$. Given the signal kinematics, the muons from a signal process are expected to move in roughly opposite directions and E_T can be expected to be larger than 50 GeV. After this selection the signal efficiency is about 4%–5% for $c\tau \approx 1000$ mm, nearly independent of the smuon mass, and 10^{-5} – 10^{-4} for QCD, $t\bar{t}$, and DY backgrounds.

In figure 32, the expected exclusion limits are shown for the GMSB model in which the smuon is a (co-)next-to-lightest supersymmetric particle (NLSP, where ‘LSP’ indicates the lightest supersymmetric particle), for the predicted cross section as well as for a factor 100 larger cross section. The exclusion limits are shown as functions of smuon mass in figure 32 (left) and decay length in figure 32 (right).

The sensitivity depends on $c\tau$ because shorter decay lengths shift the signal closer to background. In figure 32 (right), the resulting physics sensitivities in terms of production cross section for the HL-LHC, normalized to 3000 fb^{-1} , are shown for the dedicated reconstruction of displaced muons and for the standard reconstruction. Also shown is the expected sensitivity at the end of Phase 1. Systematic uncertainties for the Phase 1 scenario are taken from current Run 2 analyses and adapted for expected HL-LHC conditions based on the assumptions of reduced systematics described in [361]. Clearly, only the HL-LHC will allow this process to be studied. The expected exclusion limit is around 200 GeV for $c\tau = 1000$ mm with 3000 fb^{-1} . This also illustrates the importance of keeping lepton trigger thresholds at several tens of GeV, even in the environment of 200 PU interactions per bunch crossing. Similarly, the discovery sensitivity is assessed assuming that a signal is present in data, and is shown as a function of smuon decay length in figure 33.

Sensitivity projection with a dark SUSY model. The analysis presented above was reinterpreted using a Dark SUSY model [30, 155], in which an additional dark $U_D(1)$

Figure 33. The projected discovery sensitivity at CMS for $q\bar{q} \rightarrow \tilde{\mu}\tilde{\mu}$, $\tilde{\mu} \rightarrow \mu\tilde{G}$ as a function of the decay length for $m_{\tilde{\mu}} = 200$ GeV. Together with the discovery sensitivity the corresponding p -value is shown. Phase 2 results with an average of 200 pile-up interactions per bunch crossing and an integrated luminosity of 3000 fb^{-1} are compared to results obtained with 300 fb^{-1} . The black line shows the sensitivity without the DSA algorithm, which reduces the reconstruction efficiency by a factor three [362].

symmetry is added as a supersymmetric SM extension. Breaking this symmetry gives rise to an additional massive boson, the so-called dark photon (γ_D), which couples to SM particles via a small kinetic mixing parameter ϵ . If ϵ is very weak, the lifetime of the dark photon can range from a few millimeters up to several meters. The lower ϵ , the longer is the dark photon lifetime which then decays displaced from the PV. A golden channel for such searches is the decay to displaced muons.

In the model studied here [362], dark photons are produced in cascade decays of the SM Higgs boson that would first decay to a pair of MSSM-like lightest neutralinos (n_1), each of which can decay further to a dark sector neutralino (n_D) and the dark photon.

For the branching fraction $\text{BR}(H \rightarrow 2\gamma_D + X)$, where X denotes the particles produced in the decay of the SM Higgs boson apart from the dark photons, 20% is used. Neutralino masses $m(n_1) = 50$ GeV and $m(n_D) = 1$ GeV are assumed. Final states with two and four muons are included in the analysis. In the former case, one dark photon decays to a pair of muons while the other dark photon decays to some other fermions (2-muon final state). In the latter case, both dark photons decay to muon pairs (4-muon final state).

The main background for this search comes from multi-jet production (QCD), $t\bar{t}$ production, and $Z/\text{DY} \rightarrow \ell\ell$ events where large impact parameters are (mis)reconstructed. Cosmic ray muons can travel through the detector far away from the PV and mimic the signature of displaced muons. However, thanks to their striking detector signature, muons from CRs can be suppressed by rejecting back-to-back kinematics.

Figure 34. Left: distance of the closest approach of the displaced muon track with maximum p_T to the primary interaction vertex, $R_{\text{Muon}-1}$, for signal and background after the final event selection. Right: parameter scan in the $\epsilon - m_{\gamma_D}$ plane. The grey lines indicate the regions of narrow hadronic resonances where the analysis does not claim any sensitivity [362].

For each event, at least two DSA muons are required. If more than two, the ones with the highest p_T are chosen. The two muons must have opposite charge ($q_{\mu,1} \cdot q_{\mu,2} = -1$) and must be separated by $\Delta R = \sqrt{\Delta\phi^2 + \Delta\eta^2} > 0.05$. The three-dimensional angle between the two displaced muons is required to be less than $\pi - 0.05$ (not back-to-back) in order to suppress CR backgrounds. Additionally, $E_T > 50$ GeV is imposed to account for the dark neutralinos escaping the detector without leaving any signal.

In order to discriminate between background and signal, the three-dimensional distance from the PV to the point of closest approach of the extrapolated displaced muon track, called R_{Muon} , is used. The event yield after full event selection of both selected muons as a function of $R_{\text{Muon}-1}$ and $R_{\text{Muon}-2}$ is used to search for the signal. The left panel of figure 34 shows $R_{\text{Muon}-1}$ of the first selected muon for signal and background samples.

The search is performed using a simple counting experiment approach. In presence of the expected signal, significance of the corresponding event excess over the expected background is assessed using the likelihood method. In order to evaluate the discovery sensitivity the same input is used as in the limit calculation, now with the assumption that one would have such a signal in the data. The discovery sensitivity is shown in the two-dimensional $m_{\gamma_D} - c\tau$ plane in the right panel of figure 34. This search is sensitive to large decay length of the dark photon.

In absence of a signal, upper limits at 95% C.L. are obtained on a signal event yield with respect to the one expected for the considered model. A Bayesian method with a uniform prior for the signal event rate is used and the nuisance parameters associated with the systematic uncertainties are modeled with log-normal distributions. The resulting limits for the Dark SUSY models are depicted in figure 35. While the results shown in the left panel of figure 35 are for a dark photon with a decay length of 1 m as a function of the dark photon mass, the right panel of figure 35 shows the results for a dark photon mass of 20 GeV as a function of the decay length [362].

Figure 35. Upper limits at 95% C.L. on production cross section $\sigma/\sigma_{\text{theory}}$ for various dark photon mass hypotheses and a fixed decay length of $c\tau = 1000$ mm (left) and a fixed mass of $M_{\gamma_D} = 20$ GeV (right). Green and yellow shaded bands show the one and two sigma range of variation of the expected 95% C.L. limits, respectively. The grey lines indicate the regions of narrow hadronic resonances where the analysis does not claim any sensitivity [362].

5.1.3.3. Displaced photons at CMS. A number of new physics scenarios predict new particles that, upon decay, result in displaced photons in the final state (see sections 2.4 and 3.4). At the CMS experiment, with the scintillating crystal design of the ECAL that provides excellent resolution but lacks pointing capability, the photon arrival time in the ECAL is the main observable used to distinguish signal from background in displaced photon searches.

One benchmark model for displaced photon searches is the GMSB model where the lightest neutralino ($\tilde{\chi}_0^1$) is the NLSP, can be long-lived, and decays to a photon and a gravitino (\tilde{G}), which is the LSP, as illustrated in figure 36 (left). For a long-lived neutralino, the photon from the $\tilde{\chi}_0^1 \rightarrow \tilde{G} + \gamma$ decay is produced at the $\tilde{\chi}_0^1$ decay vertex, at some distance from the beam line, and reaches the detector at a time later than that of prompt, relativistic particles produced at the IP. The time of arrival of the photon at the detector can be used to discriminate the signal from the background. The aforementioned upgrade to the ECAL electronics in the barrel region, and the HGCal upgrade in the endcaps, will improve photon timing resolution at HL-LHC by an order of magnitude to as little as ~ 30 ps for photons with p_T of tens of GeV or above, hence significantly improve the experimental reach of displaced photon searches.

Moreover, the proposed MTD will be able to provide another dimension of information to reconstruct LLP decays. The TOF of the photon inside the detector is the sum of the TOF of the neutralino before its decay and the TOF of the photon itself, until it reaches the detector. Since the neutralino is a massive particle the latter is clearly negligible with respect to the former. In order to be sensitive to short neutralino lifetimes of order 1 cm, the performance of the measurement of the photon TOF is a crucial ingredient of the analysis. Therefore, the excellent resolution of the MTD apparatus can be exploited to determine with high accuracy the TOF of the neutralino, and similarly the photon, also in case of a short lifetime.

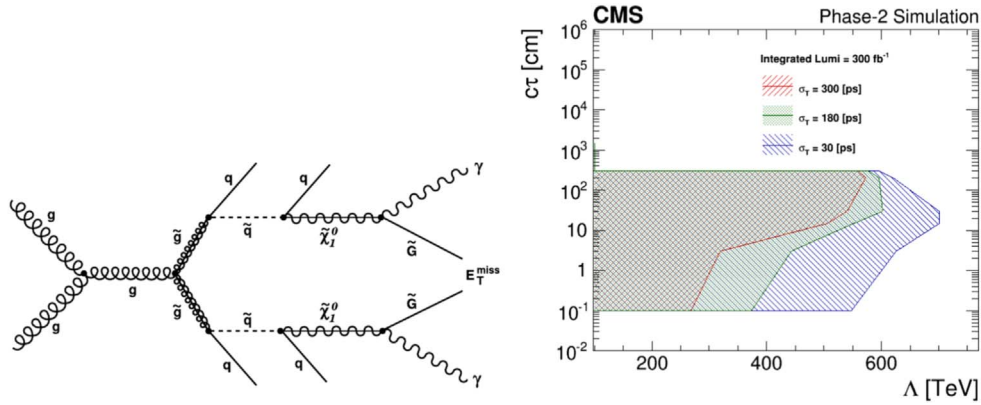

Figure 36. Left: diagrams for a SUSY process that results in a diphoton final state through gluino production at the LHC. Right: sensitivity to GMSB $\tilde{\chi}_0^1 \rightarrow \tilde{G} + \gamma$ signals expressed in terms of neutralino lifetimes for 300, 180 and 30 ps resolution, corresponding to the current detector, the HL-LHC detector with photon timing without MTD and with MTD, respectively [351].

An analysis has been performed at generator level in order to evaluate the sensitivity power of a search for displaced photons at CMS in the scenario where a 30 ps timing resolution is available from the MTD [351]. The events were generated with Pythia 8 [219], exploring neutralino lifetimes ($c\tau$) in the range 0.1–300 cm. The values of the Λ scale parameter were considered in the range 100–500 TeV, which is relevant for this model to be consistent with the observation of a 125 GeV Higgs boson. After requiring the neutralino to decay within the CMS ECAL acceptance and the photon energy being above a ‘trigger-like’ threshold, the generator-level photon TOF was smeared according to the expected experimental resolutions. A cutoff at a photon time greater than 3σ of the timing resolution is applied and the ‘signal region’ is assumed to be background free to estimate the sensitivity. The signal efficiency of such a requirement is computed and translated, assuming the theoretical cross sections provided in [66], to an upper limit, at 95% C.L., on the production cross section of the $\tilde{\chi}_0^1 \rightarrow \tilde{G} + \gamma$ process.

In figure 36 (right), the analysis sensitivity in terms of the Λ scale (and therefore of the neutralino mass) and lifetime is shown for three different assumptions on the timing resolution. The 300 ps resolution is representative of the TOF resolution consistent with current CMS detector performance. The 180 ps resolution is representative of the TOF resolution of the upgraded CMS detector without the MTD, in which case the TOF measurement will be dominated by the time spread of the luminous region. The vertex timing provided by the MTD detector will bring the TOF resolution to about 30 ps. As visible in the figure, a full-scope upgrade of the CMS detector with photon and track timing will provide a dramatic increase in sensitivity at short lifetimes and high masses, even with the first 300 fb^{-1} of integrated luminosity.

5.1.3.4. Displaced jets in ATLAS. Neutral LLPs that can decay into jets displaced from the proton–proton IP arise in many BSM theories (see chapter 2 for an extensive discussion). For example, in hidden sector models a new set of particles and forces is proposed that is weakly coupled to the SM via a communicator particle. The hidden sector is otherwise invisible to the SM sector, but its particles (some of which can be long-lived) may decay to SM particles via

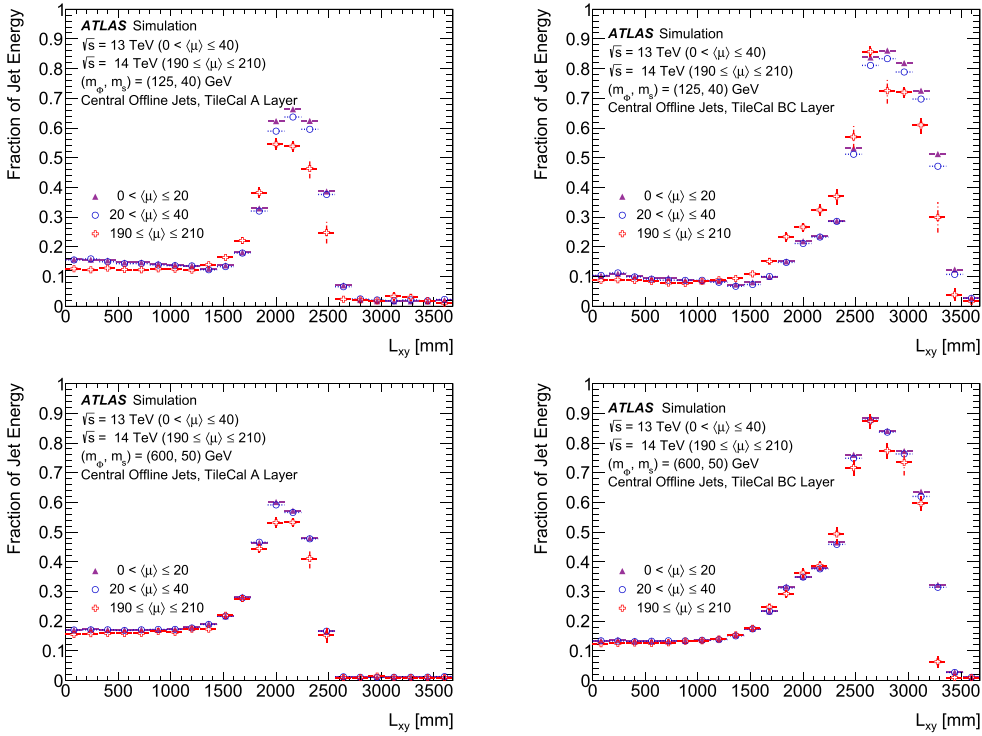

Figure 37. Simulation projections of the sensitivity of the ATLAS experiment upgrade plans to neutral LLPs. Top: the fraction of the jet energy deposited in the A-layer (left) and BC-layers (right) of the ATLAS tile calorimeter as a function of the transverse decay position of the LLP in events with a 125 GeV Higgs-like boson decaying to two 40 GeV LLPs. Bottom: the same for events with a 600 GeV Higgs-like boson decaying to two 50 GeV LLPs.

the communicator. The lifetimes of these LLPs are typically unconstrained and could be long enough for the LLPs to decay inside the ATLAS detector volume. Such particles produce unique signatures which may have been overlooked by more traditional searches for new physics. One ATLAS search for such displaced jet signatures focuses on LLPs which decay in the ATLAS HCal and consequently deposit most of their energy there and very little or none in the ECAL, and also have few or no charged tracks pointing at the hadronic energy deposits. A signature-driven trigger that optimizes the acceptance for this class of events is required for the online selection.

The existing ATLAS analysis described in section 3.1 can likely be improved by planned upgrades by using HCal information splitting the B-C layers in the calorimeter to identify the LLP decay position. The splitting between B-C layers will provide more information on the longitudinal shower profile, see figure 37.

This analysis uses a hidden sector benchmark model and considers the decay of a heavy boson to two long-lived neutral scalars; this maps to the simplified model with Higgs boson production of hadronically decaying LLPs in section 2.4. The heavy scalar bosons decaying into LLPs have masses ranging from 125 to 1000 GeV, and the LLP scalars have masses ranging between 5 and 400 GeV. Background processes, dominated by QCD dijet production,

Figure 38. Reconstruction efficiency of the disappearing chargino as a function of decay radius using two track reconstruction techniques: ‘tracklets’ refers to the short tracks mentioned in the text, while ‘tracks’ refers to standard track reconstruction. The corresponding reconstruction efficiencies for Run 2 are also shown [353].

are suppressed in this analysis by requiring both scalars to decay in the calorimeter. Final results of the sensitivity projections are pending.

5.1.3.5. Disappearing tracks. In the ATLAS experiment, the planned ITk upgrade of the tracking volume for the HL-LHC can be exploited to improve the existing searches for BSM particles with a DT [353].

Such particles are predicted by many well-motivated supersymmetric models such as anomaly-mediated SUSY-breaking scenarios, where the supersymmetric partners of the SM W bosons, the wino fermions, are the lightest SUSY state. In such models, the lightest neutralino and chargino can be nearly mass-degenerate, with a mass splitting around 160 MeV, and the chargino is consequently long lived. The combination of long lifetime and boost when produced in a high-energy collider allows the chargino to leave multiple hits in the traversed tracking layers before decaying. When performing searches for such signatures in ATLAS, selected events are typically required to contain at least one short track, hereafter called a tracklet. To study how such searches can be improved with the ITk upgrade, some assumptions have been made for simulating events and projected detector response. The detector response is parametrised by using response functions based on studies performed with Geant4 simulations of the upgraded detector in high-luminosity PU conditions.

The tracklet reconstruction efficiency for signal charginos as a function of the decay radius inside the detector is shown in figure 38. A 30% systematic uncertainty on the background yields is assumed, as observed for the Run 2 analysis. The expected background is largely dominated by fake tracklets due to random crossings.

Expected limits at 95% C.L. are shown in figure 39 as a function of the chargino mass and lifetime for a pure wino and a pure Higgsino LSP scenario. For comparison, the current Run 2 limit for 36.1 fb^{-1} in the wino LSP scenario is also shown. The HL-LHC dataset of 3000 fb^{-1} extends the sensitivity of neutrinos and charginos up to 250 GeV, assuming a pure Higgsino scenario.

Figure 39. Projected 95% C.L. limits on a degenerate chargino-neutralino scenario assuming the chargino is a (left) pure wino; (right) pure neutralino. The limits include both pair production $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and associated production $\tilde{\chi}_1^\pm\tilde{\chi}_1^0$ (the Higgsino model also includes the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ mode) [353].

5.1.3.6. Displaced vertices in ATLAS. Massive, LLPs with lifetimes of the order of $O(10)$ ps to $O(10)$ ns can decay inside the inner tracker into charged and stable particles. The products of these decays are reconstructed as tracks with measurably distant impact parameters with respect to the IP. The reconstruction of such displaced tracks is very challenging compared to the track reconstruction of prompt particles, due to fewer hits along the track and a larger parameter phase space for track finding. In order to identify a DV, one must first identify the tracks from the decaying LLP.

Several physics models predict the existence of long-lived, massive particles. For example, a standard SUSY scenario can contain a gluino with a mass of 2 TeV and a lifetime of 1 ns. The long-lived gluino hadronises into an R -hadron, which then decays into a 100 GeV neutralino and hadrons.

In ATLAS, this topology has been investigated in Run 2 by using a dedicated algorithm for reconstructing DV [255]. The performance expected to be achieved for the ITk upgrade for this signal has been tested with a simplified simulation which has a description of the ITk active sensors and a modeling of the magnetic field. The kinematics and location of the decay products of the R -hadron are injected into the simulation and their trajectories are extrapolated through the detector model. The probability of producing at least seven silicon hits in the ITk geometry is shown in figure 40 for a 2 TeV R -hadron with $\tau = 1$ ns. The increased volume and number of ITk layers leads to improved efficiency for the reconstruction of tracks from DV (and hence the vertices themselves) out to radial distances of up to 550 mm. The increased number of silicon layers also gives more room to veto tracks with missing hits, further suppressing backgrounds.

5.1.3.7. LLP searches with precision timing at CMS. The CMS MTD will provide new, powerful information in searches for LLPs. In addition to the aforementioned displaced photon search, the additional timing information can be used to provide full kinematic reconstruction of LLP decays, and can be a powerful tool in background suppression.

Possible improvements in the ability to reconstruct LLP mass. A precision MTD allows each reconstructed vertex to be assigned a time and therefore to measure the TOF of LLPs between primary and secondary vertices. Using the measured displacement between primary and secondary vertices in space and time, the velocity of an LLP in the laboratory frame, $\vec{\beta}_{\text{LAB}}^p$ (or, equivalently, the boost γ^p), can be measured. In such scenarios, the LLP can decay to

Figure 40. Probability that tracks with $p_T > 1 \text{ GeV}$ will traverse at least seven silicon ITk layers if they are produced in the decay of an R -hadron with mass 2 TeV and $\tau = 1 \text{ ns}$. The probability is also shown for at least seven hits with the Run 2 layout [353].

fully visible or partially invisible systems. Using the measured energy and momentum of the visible portion of the decay, one can calculate its energy in the LLP rest frame and reconstruct the mass of the LLP, assuming that the mass of the invisible system is known.

This capability can be demonstrated in scenarios where the LLP decay produces a Z boson, which then decays to an electron–positron pair. For example, in the GMSB model where the $\tilde{\chi}_0^1$ couples to the gravitino \tilde{G} via higher-dimension operators sensitive to the SUSY breaking scale, the $\tilde{\chi}_0^1$ may have a long lifetime, and can be produced in top-squark pair production with $\tilde{t} \rightarrow t + \tilde{\chi}_0^1$, $\tilde{\chi}_0^1 \rightarrow Z + \tilde{G}$, $Z \rightarrow ee$.

Studies with simulated event samples have been performed to estimate the possible improved sensitivity of the search with the CMS MTD upgrade. The events are generated with Pythia 8, and the masses of the top-squark and neutralino are set to 1000 GeV and 700 GeV , respectively. Generator-level quantities are smeared according to the expected experimental resolutions. A position resolution of $12 \mu\text{m}$ in each of the three spatial directions is assumed for the PV. The secondary vertex position for the electron–positron pair is reconstructed assuming $30 \mu\text{m}$ position resolution in the transverse direction. The momentum resolution for electrons is assumed to be 2% . Finally, the time resolution of charged tracks at the DV is assumed to be 30 ps .

The mass of the LLP is reconstructed assuming that the gravitino is massless. The fraction of events with separation between primary and secondary vertices exceeding 3σ in both space and time as a function of the MTD resolution is shown in figure 41 (left). The mass resolution, defined as half of the shortest mass interval that contains 68% of events with 3σ displacement is shown in figure 41 (right), as a function of the MTD resolution.

A similar study has been performed with another SUSY scenario where the two lightest neutralinos and light chargino are Higgsino-like. The light charginos and neutralinos are nearly mass degenerate and may become long-lived as a consequence of the heavy higgsinos. Figure 42 shows the mass resolution as a function of the MTD resolution in this SUSY scenario. In both studies, the additional timing information from the MTD facilitates the reconstruction of the LLP mass, the resolution and efficiency of which are further improved with the excellent timing resolution of the MTD.

Figure 41. Efficiency (left) and mass resolution (right) as a function of the timing resolution of the MTD for reconstruction of the $\tilde{\chi}_0^1$ mass in the SUSY GMSB example of $\tilde{\chi}_0^1 \rightarrow \tilde{G}e^+e^-$, with mass of $\tilde{\chi}_0^1 = 700$ GeV, considering events with a separation of primary and secondary vertices by more than 3σ in both space and time [351].

Figure 42. Resolution for the reconstruction of the LLP mass in the Higgsino scenario outlined in this section. The LLP mass resolution is shown as a function of lifetime and the MTD resolution [351].

Possible improvement to LLPs searches in general using timing information. Precision timing at CMS will provide a new tool to suppress the background and enhance the reach for LLPs in the HL-LHC era.

A schematic of a typical signal event containing an LLP is shown in figure 43. An LLP, denoted as X , travels a distance ℓ_X into a detector volume and decays into two light SM particles a and b , which then reach a timing layer at a transverse distance L_{T_2} away from the beam axis. In a typical hard collision, the SM particles generally travel very close to the speed of light. Hence, the decay products of X (using particle a as an example) arrives at the timing layer with a time delay of

Figure 43. An event topology with an LLP X decaying to two light SM particles a and b . A timing layer, at a transverse distance L_{T_2} away from the beam axis (horizontal gray dotted line), is placed at the end of the detector volume (shaded region). The trajectory of a potential SM background particle is also shown (blue dashed line). The gray polygon indicates the primary vertex. Taken from [363].

$$\Delta t = \frac{\ell_X}{\beta_X} + \frac{\ell_a}{\beta_a} - \frac{\ell_{SM}}{\beta_{SM}}, \quad (5.2)$$

with $\beta_a \simeq \beta_{SM} \simeq 1$. An ISR jet could easily be present for all processes, and can be used to ‘timestamp’, i.e. to derive the time of the hard collision at the PV.

For the CMS MTD located just outside the tracker volume, ℓ_{SM}/β_{SM} is about $O(1 \text{ ns})$. As a result, with tens of picosecond (ps) timing resolution, a sensitivity to percent-level time delay caused by slow LLP motion, e.g. $1 - \beta_X > 0.01$ with boost factor $\gamma < 7$, is expected to be achieved.

A theory study has been done in [363] examining potential gains in sensitivity for hadronic DV reconstruction using timing information. A new trigger strategy for a delayed jet is studied by comparing the prompt jet with $p_T > 30 \text{ GeV}$ that reconstructs the four-dimensional primary vertex (PV4d) with the arrival time of another jet at the timing layer. The delayed and displaced jet signal, after requiring a minimal decay transverse distance of 0.2 m (L_{T_1}), will typically not have good tracks associated with it. Consequently, the major SM background is from trackless jets. The origins of this background can be classified into two categories: hard collision from a same vertex (SV), and PU from different vertices. Other types of background such as CRs, beam halo, material interactions, etc, are out-of-time and will become important after most of the hard collision background is removed using selections based on reconstructing vertices and timing delay. Out-of-time backgrounds may have other distinctive features that would allow their effective suppression. While the study in [363] can serve as an optimistic inspiration for increasing LLP sensitivity with timing information, detailed experimental studies are needed to determine the actual sensitivity gain.

The jet faking a displaced signal, behaving as a trackless jet, has an intrinsic time delay $\Delta t = 0$. However, due to the limited timing resolution in reconstructing the PV4d, it can have a time spread. The background differential distribution with respect to apparent delay time (Δt) can be estimated as

$$\frac{\partial N_{\text{bkg}}(t)^{\text{SV}}}{\partial \Delta t} = N_{\text{bkg}}^{\text{SV}} \mathcal{P}(\Delta t; \delta_t^{\text{SV}}). \quad (5.3)$$

Figure 44. Theory projection from [363] of the 95% C.L. limit on $BR(h \rightarrow XX)$, where X is an LLP, for the production of $pp \rightarrow jh$ with the subsequent decay of $h \rightarrow XX$ and $X \rightarrow jj$ subject to assumptions in the text (one ISR jet with $p_{T,j} = 30$ GeV and $|\eta_j| < 2.5$, and at least one LLP inside the detector). Different colors indicate different masses of the particle X . The thick, long-dashed lines indicate searches with the CMS MTD plus the timing requirements. The thick solid and dotted lines indicate searches with a hypothetical timing layer outside the ATLAS muon spectrometer plus timing requirements. The numbers in parentheses are the assumed timing resolutions. This provides motivation to see whether these gains can be realized by studies from within the collaborations.

The time delay selection on Δt reduces such a background through a very small factor of $\mathcal{P}(\Delta t; \delta_t^{SV})$ for large $\Delta t/\delta_t^{SV}$, where δ_t^{SV} is the timing resolution for the SV background, dominant by the timing detector resolution. The LLP signal pays a much smaller penalty factor than the background due to its intrinsic delay.

The background from the PU requires the coincidence of a triggered hard event and objects from a PU (hard) collision whose PV4d fails to be reconstructed and that can mimic a signal. The differential background from PU can be estimated as

$$\frac{\partial N_{\text{bkg}}^{\text{PU}}(\Delta t)}{\partial \Delta t} \simeq N_{\text{bkg}}^{\text{PU}} \mathcal{P}(\Delta t; \delta_t^{\text{PU}}). \quad (5.4)$$

Similar to equation (5.3), δ_t^{PU} is the timing resolution for the PU background, dominated by the beam spread. The key difference between the background from the PU and the background from the same hard collision is that the typical time spread is determined by the beam property for the former, and by the timing resolution for the latter. They typically differ by a factor of a few, e.g. 190 versus 30 ps for CMS with the current upgrade plan.

Using this estimation, a sensitivity projection is presented with an example signal of a Higgs boson decaying to LLPs with the subsequent decay of the LLPs into $b\bar{b}$ pairs, with only minimal requirements of one low- p_T ISR jet, with $p_{T,j} > 30$ GeV and $|\eta_j| < 2.5$, and at least one LLP decay inside the detector. Timing information is used to suppress backgrounds. The 95% C.L. sensitivity is shown in figure 44. The decay branching ratio of the LLP $X \rightarrow jj$ is assumed to be 100%. The projection with 30 ps timing resolution of the CMS MTD is plotted with thick dashed lines. Compared to other 13 TeV HL-LHC projections (with 3 ab^{-1} of integrated luminosity) without the timing information (shown in thinner, dotted and dashed

lines), it is suggested that the addition of a selection on timing, under the set of assumptions described above, greatly reduces background and improves sensitivity. The possibility of such a significant improvement is enticing; this projection is determined from theoretical studies [363], however, and it remains to be seen whether it is possible to realize these gains in the experiment. For example, the low threshold of the single jet would require timing information at early levels of the trigger, and out-of-time backgrounds could also reduce the gains from timing information. Nevertheless, this high-level theory analysis provides an inspiration to the experimental collaborations to perform more detailed, internal studies that will ultimately determine how realistic the projections are.

In general, the prospect of improvements in LLP searches at the HL-LHC due to precision timing upgrades for CMS (and ATLAS) remains understudied, and deserves more comprehensive experimental and phenomenological studies, including understanding and reducing out-of-time backgrounds.

5.1.3.8. LLP searches with a level-1 track trigger in CMS. As discussed in section 5.1.1, a central feature of the CMS upgrade at the HL-LHC will be a new silicon outer tracker which allows track reconstruction for every LHC bunch crossing (at a rate of 40 MHz). The p_T selection for stubs (hit pairs in the p_T modules of the outer tracker) to be read out is determined by the bandwidth from the detector to the back end electronics, and is fixed at about 2 GeV. On the other hand, the choice of track finding algorithm and hardware is still being finalized, and there could be significant benefits to extending the L1 track trigger capabilities to trigger on off-pointing tracks.

To illustrate the case, a simple toy simulation to study rare Higgs boson decays into new particles with lifetimes of order of a few mm has been performed [364]. This study considers all-hadronic final states with low H_T , taking SM Higgs boson decays into four jets as an example. Theoretical motivation to look for such decays is very strong; see section 2.2 for a detailed discussion. In particular, there is currently a blind spot for lifetimes of order 1 cm in searches for new long-lived scalars in Higgs decays, i.e. $h \rightarrow \phi\phi$. The goal is to probe very small branching fractions of the Higgs boson, so for this study, $BR[h \rightarrow \phi\phi \rightarrow 4q] = 10^{-5}$ is assumed. For prompt decays, the background is overwhelming, but if the ϕ has $c\tau$ of a few mm, the offline analysis has very low backgrounds. The problem is getting such events on tape, in particular through L1. This toy study estimates how an off-pointing track reconstruction at L1 can help. To estimate the efficacy of the approach, the resulting projections are compared with the best alternatives in the absence of an off-pointing track trigger, by using associated Higgs boson production with a W boson that decays leptonically to pass a lepton trigger, or considering L1 calorimeter jets with no associated prompt tracks.

Once these positive results were obtained, a more detailed study using the full Phase 2 simulation of the CMS detector was performed [365]. The more mature exploration found that a plausible extension of the L1 track trigger to tracks with an impact parameter of a few centimeters results in dramatic gains in the trigger efficiency. The gains are even larger for additional heavy SM-like Higgs bosons with the same decay. These results are in agreement with the toy study described above. A few details of the mature study will be described below.

The study focuses on small or moderate decay lengths of the new particles, 1–50 mm, and assumes that the offline selection can remove all SM backgrounds with only a moderate loss of efficiency. While this study focuses on the specific Higgs boson decay to light scalars, the results and the proposed triggers are relevant for a broad spectrum of new physics searches, with or without macroscopic decay lengths.

The authors propose a simple jet clustering algorithm implementable in firmware, and compare it with anti- k_r jets [366] with a size parameter of $R = 0.3$, as produced by FASTJET

[367]. This simple algorithm produces a similar performance, in both L1 trigger efficiency and rate, to the full jet clustering using the anti- k_t algorithm.

Then, the performance of an algorithm for reconstruction of tracks with non-zero impact parameter is presented. This approach extends the baseline CMS L1 Track Trigger design to handle tracks with non-zero impact parameter and to include the impact parameter in the track fit. This enhanced design is feasible without greatly altering the track finding approach, but will require more FPGA computational power than the current proposal, which only considers only prompt tracks. Tracks passing the selection are clustered using the same algorithm as described above, and clusters containing tracks with high impact parameters are flagged as displaced jets. Though the baseline design of the L1 Track Trigger currently is optimized to find prompt tracks, these studies show that an enhanced L1 Track Trigger can extend the L1 trigger acceptance to include new BSM physics signals.

For now, the extended L1 track reconstruction is limited to the barrel region. In order to compare the results with prompt and extended track reconstruction, one needs to make a correction for the rapidity coverage: prompt tracks are found in $|\eta| < 2.4$, while the extended track algorithm currently only reconstructs tracks in $|\eta| < 1.0$. To scale the efficiency for finding track jets to the full $|\eta| < 2.4$ range, a scale factor based on efficiency in the full η range and the central η range was used. The scale factor was comparable to the increase in L1 rate.

Figure 45 shows the expected trigger rate as a function of efficiency for the SM and the heavy SM-like Higgs bosons.

The available bandwidth for the triggers described above, if implemented, will be decided as a part of the full trigger menu optimization. Here, two cases are considered: 5 and 25 kHz. The expected event yield for triggers using extended and prompt tracking are shown in figure 46, assuming branching fraction $\mathcal{B}[h \rightarrow \phi\phi] = 10^{-5}$ for the SM Higgs boson. For the heavy Higgs boson, the expected number of produced signal events is set to be the same as for the SM Higgs by requiring $\sigma_{pp \rightarrow h(250)} \mathcal{B}[\Phi \rightarrow \phi\phi] = 10^{-5} \sigma_{pp \rightarrow h(125)}$.

For the exotic Higgs decays considered, given the expected total dataset for the HL-LHC of 3 ab^{-1} , and assuming a branching fraction of 10^{-5} , CMS would collect $\mathcal{O}(10)$ events, which should be sufficient for discovery. A plausible extension of the L1 track finder was considered, to select tracks with impact parameters of a few cm. That approach improves the yield by more than an order of magnitude. The gains for the extended L1 track finding are even larger for the events with larger H_T , as demonstrated by the simulations of heavy Higgs boson decays.

5.1.4. Open questions and new ideas. The higher data rate and more powerful machinery in the high-luminosity era bring new prospects to LLP searches. Searches that are too challenging for the current machine may become feasible with the HL-LHC upgrades, and it is important to explore such possibilities to the full extent. Existing search methods, triggering, and reconstruction algorithms should also be updated to take full advantage of the new hardware capabilities. As the upgrade scope is being defined and finalized in the near future, it is of particular importance to evaluate the physics cases, which will also motivate the upgrade and inform its designs.

5.1.4.1. New studies for the HL-LHC. In section 5.1.3, various analyses with displaced signatures are presented in the context of how detector and trigger upgrades at the ATLAS and CMS experiments for the HL-LHC can improve their sensitivity. As was shown in section 5.1.1, while the upgrades for both experiments differ in detail, they are similar in concept and scope. It is therefore important to perform the same LLP search projections for

Figure 45. The rate of the track jet H_T trigger as a function of signal efficiency using extended track finding for the SM Higgs (left) and the heavy SM-like Higgs (right). The extended track finding performance is extrapolated to the full outer tracker acceptance as described in the text and in [365].

both experiments to compare performance and evaluate the complementarity of the two experiments.

For example, both experiments explore the idea of a fast timing detector at HL-LHC. The CMS MTD aims for full-coverage of a barrel layer plus endcap disks, while the ATLAS HGTD plans for multiple layers of endcaps. How the different η coverage of the timing layer might impact LLP searches will be an interesting question to answer. In the case of calorimetry, the ATLAS LAr ECAL is segmented in z , providing the additional pointing capability to find displaced photons. On the other hand, the CMS ECAL electronics upgrade in the barrel, and HGCAL upgrade in the endcaps, will considerably improve its timing resolution to identify photons that are out-of-time. A sensitivity comparison of both experiments will provide helpful information in understanding photon reconstruction and the combined reach of both experiments.

Additional opportunities exist for improving LLP sensitivity in Run 3 or at the HL-LHC, such as the ability to perform an analysis using physics objects at the trigger level, rather than

Figure 46. The number of triggered Higgs events (assuming $\mathcal{B}[h \rightarrow \phi\phi] = 10^{-5}$, corresponding to 1700 events) as a function of $c\tau$ for two choices for the trigger rates: 25 kHz (left), 5 kHz (right). Two triggers are compared: one based on prompt track finding (dotted lines) and another that is based on extended track finding with a displaced jet tag (solid lines) [365].

their more complex, offline counterparts. This analysis method—sometimes referred to as *trigger-level analysis* or *data-scouting*—has been used in searches for di-jet resonances using data from Runs 1 and 2 by the CMS Collaboration [368, 369], data from Run 2 by the ATLAS Collaboration [370] and by the LHCb Collaboration for the searches for dark photons [269]. Such data-scouting methods can be used, for example, to reduce the p_T thresholds of jets and muons used in dark photon or hidden particle searches. Such possibilities could potentially assist searches for LLPs by, for example, allowing changes in the L1 muon patterns in order to trigger on non-pointing muons.

Moreover, the applications of machine learning techniques to LLP searches is a currently under-studied realm. Such techniques could be used in the context of LLPs in particle identification, reconstruction, or generation, in addition to analysis or reinterpretation. Further studies to supplement those that already exist are of high priority for the community.

Furthermore, as new models are being proposed and new channels open up in the realm of LLP searches, many with final states challenging for the current detector conditions, it is important to evaluate their sensitivities in the HL era. Here are a few such interesting searches that are on the agenda.

- *Inelastic DM (iDM)*. While stringent limits are currently placed on WIMP-type DM from direct detection, indirect detection, and collider searches, DM particles can exist in a hidden sector with additional particles and forces. A representative example of a hidden sector consists of a DM particle which is charged under a hidden gauge or global symmetry. The DM can have both a symmetry-preserving mass and, if the symmetry is spontaneously broken, also a symmetry-violating mass, which splits the mass eigenstates. This iDM scenario [132, 133, 135] consists of two DM states that couple only off-diagonally to one another. Such iDM can be probed at colliders with the production of $DM + DM^*$ (where DM^* denotes the heavier DM state) in association with a hard SM object X , followed by the subsequent decay of $DM^* \rightarrow DM + Y$ for some potentially different SM states Y . The production is summarized as

$$\begin{aligned} pp &\rightarrow X + DM + DM^* \\ &\rightarrow X + DM + (DM^* \rightarrow DM + Y) \equiv X + \cancel{E}_T + Y, \end{aligned}$$

where X is any state that can be used to trigger on the event and reconstruct \cancel{E}_T , such as an ISR jet, and Y depends on the mode by which DM couples inelastically to the SM. One concrete, representative version of such models can be realized when the mediator is a dark photon and Y is a pair of leptons. The weak coupling between the SM and the hidden sector suggest the heavy eigenstate is meta-stable, creating a displaced signature. Because the mass splitting is small between the two eigenstates, the lepton pair is also typically softer compared with GMSB models, with p_T values of a few to tens of GeV for a $O(10 \text{ GeV})$ DM. The displaced muon trigger and reconstruction strategy with the MS upgrade at CMS can likely improve searches for this scenario. The soft p_T spectrum in this case particularly motivates the lowering of the p_T threshold in the displaced muon trigger turn-on. Moreover, the additional timing information from the fast-timing detector opens up the possibility of reconstructing the mass splitting, while taking advantage of the good resolution of the timing detector for even low- p_T particles. Sensitivity studies for iDM with a dark photon mediator are planned for the CMS MTD upgrade. The projections will also be of value to searches for other types of dark sector models, such as self-interacting DM [371], that give rise to soft displaced lepton pairs.

- *Dark showers*. If the hidden sector has a QCD-like structure with dark quarks and hidden forces, a mediator between the SM and the hidden sector, such as a Z' or heavy Higgs boson, can decay into some number of dark quarks that subsequently shower and hadronize into dark mesons, some of which are meta-stable and decay back into SM particles after a macroscopic distance from the proton–proton IP. A showering dark sector can yield a particularly rich collider phenomenology that may give rise to a high multiplicity of displaced objects often low in p_T . Depending on the final state, searches for a hadronic shower with emerging [331] or semi-visible [372] jets can be improved with the increased acceptance and enhanced resolution due to the tracker upgrades at both ATLAS and CMS, as well as the finer granularity endcap calorimeter (HGCAL) at CMS. A dark shower with displaced photon pairs can benefit from the improved timing resolution with the ECAL electronics upgrade, as well as the new timing detectors. A dark shower with displaced lepton pairs, similar to the aforementioned case of iDM, can

be probed with better sensitivity with the MS upgrades, as well as the fast timing information. For more details on dark showers, see chapter 7.

5.1.4.2. New detectors at future collider. If we are only limited by our imagination, what new detectors may exist at a future collider that can open up new capabilities for LLP searches? Regardless of practical constraints, studies for such bold new proposals also help us understand our current experimental reach and optimize our search strategies.

- *Four-dimensional tracker with timing.* Extending from the ‘timing layer’ approach for HL-LHC upgrades, it is clear more time measurements on the track are favorable. In particular, the TOF between layers is a powerful discriminant for choosing hits on a track. A future tracker that provides four-dimensional information, including precise timing information for every layer, can significantly improve track reconstruction by reducing combinatorics, providing purer track seeds, and remove fake stubs. Assuming high- p_T particles, each layer’s time measurement is advanced by 30 ps and so preserves the differences in vertex times. Low p_T particles will have even more discrimination power since their paths leave longer times between hits in consecutive layers of the tracker. Major technical advances will need to happen to achieve such an implementation, including development of fine-pitch sensors with good timing resolution, improvements in scaling and power consumption, electronics upgrade, and alterations to present pattern recognition methods in track finding.
- *Timing detector outside ATLAS muon system.* As discussed in section 5.1.3, by using a prompt object, such as an ISR jet, to ‘timestamp’ an event, and requiring a timing delay from the LLP, the new timing layer (MTD) at CMS can help significantly reduce the background and improve LLP search sensitivity. The CMS MTD is located between the tracker and the ECAL with a distance to the beamline of about 1.2 m. If one imagines a fast timing layer outside the ATLAS MS with a distance of approximately 10 m [363], timing information at such distances could provide additional discriminating power for particles with longer lifetimes. In figure 44, the projection with a 30 ps timing resolution of such a hypothetical detector outside the ATLAS MS is plotted in a thick solid line. A less-precise timing resolution (150 ps) has been also considered with a selection $\Delta t > 1$ ns to suppress background. While this study is optimistic in assuming that selections on timing can eliminate all backgrounds to the LLP search, it nevertheless serves as important inspiration for more detailed experimental studies to understand the actual extent of the sensitivity gain. The LLP efficiency is largely unaffected by this change, while low-mass LLPs lose sensitivity by a factor of a few. The CMS MTD timing upgrade for the HL-LHC already provides significant improvement [363]. The timing detector outside the ATLAS MS has the notable benefits of lower background, a larger volume for the LLP to decay and more substantial time delay for the LLP signal due to longer travel distance. Moreover, due to the extended time delay of the LLPs in the volume of the MS, less-precise timing can still achieve similar physics goals. As a result, with the above caveats it can serve as an estimate of the best achievable sensitivity using timing information in LLP searches.
- *New double-sided tracking layer very close to the beamline.* Inspired by the L1 track trigger design at CMS for the HL-LHC, a scenario may be imagined where an additional tracking layer close to the beamline is added, mechanics and radiation hardness permitting. This would allow a track veto close to the IP to be implemented, and extend the LLP sensitivity to even smaller displacements. Moreover, if such a layer can be designed with double-sided modules, similar to the CMS outer tracker approach for the

HL-LHC, hit pairs (stubs) from this layer can be used in a L1 track trigger for displaced tracks or DTs. The feasibility of such an approach would depend on the ability to store and process data at a rate not allowed by current technology. On the other hand, it is helpful to consider more innovative data-scouting methods at trigger level to store and select information, or introduce additional discriminating factors to reduce the rate for particular data streams, for the potential of exploring such signatures.

5.2. LHCb upgrade

The LHCb experiment is designed to detect decays of LLPs in the SM, namely bottom and charmed hadrons. As such, it is naturally suited for the search of BSM LLPs in a mass and lifetime range comparable to these hadrons. It is the only LHC experiment to be fully instrumented in the forward region $2 < \eta < 5$, where b - and c -hadrons are abundantly produced and their decay length is enhanced due to the large longitudinal boost. In this region, detector occupancy is extremely high and thus the LHCb experiment has been run at reduced luminosity compared to ATLAS and CMS during Runs 1 and 2. However, an upgrade of the detector is planned to allow running at a luminosity of $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ in LHC Run 3 (starting in 2020) while maintaining or improving the current physics performance [373]. This is five times larger than the luminosity during Runs 1 and 2. This first upgrade phase (Phase 1a) will entail a novel trigger paradigm where all sub-detectors are fast enough to be read out in real time and the first trigger decisions are done in software. This trigger scheme is flexible and offers a great opportunity for searches of striking signatures like those of BSM LLPs. This upgrade comes earlier than the planned ATLAS and CMS upgrades for the HL-LHC phase which are planned to be installed during LHC long shutdown 3 (by 2025). In this shutdown, LHCb plans to consolidate and modestly enhance the Phase 1a upgrade detector (Phase 1b), while a Phase 2 upgrade to run at an even higher luminosity up to $\sim 2 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ is planned to be installed later, during long shutdown 4 (by 2030) [374].

Section 5.2.1 gives a brief overview of the Phase 1 upgraded-LHCb detector design and the expected performance of the LHCb sub-detectors. An overview of the upgraded LHCb capabilities in the context of LLP searches is given in section 5.2.2 with a few example signatures. Finally, an overview of the plans for the Phase 2 upgrade and some thoughts on the opportunities given by putative additional detector features are reported in section 5.2.3.

5.2.1. LHCb detector and trigger upgrade for run 3 (Phase 1a). In LHC Run 3, LHCb plans to take data at an instantaneous luminosity of $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$, a factor of five larger than the current luminosity. The LHCb detector needs to be upgraded to cope with the higher radiation dose and, most importantly, to avoid the saturation of the trigger rate and exploit the higher luminosity. The main bottleneck in the current trigger is in the first stage, which reduces the accepted rate from 30 to 1 MHz at hardware level. For the upgrade, the hardware trigger will be removed and the full event will be read out at the bunch crossing rate of the LHC (40 MHz), with a flexible software-based trigger.

In table 4 the current and upgraded conditions of the detector are summarised. To cope with the larger occupancy and higher rate of the upgraded detector, the electronics of all of the sub-detectors must be upgraded, and some sub-detectors must be fully replaced. For example, the tracking system, which plays a crucial role in LLP searches, must be replaced.

The upgraded tracking system consists of the VELO, surrounding the IP, the Upstream Tracker, a TT placed before the magnet, and the scintillating fibers tracker (SciFi), three

Table 4. LHCb current and upgraded operating conditions [374]. Instantaneous luminosity \mathcal{L} , integrated luminosity $\int \mathcal{L}$ (including previous runs), pp collision energy \sqrt{s} and average number of visible proton interactions μ are listed.

	Current	Upgrade 1a	Upgrade 1b	Upgrade 2
$\mathcal{L}/(\text{cm}^{-2} \text{s}^{-1})$	4×10^{32}	2×10^{33}	2×10^{33}	2×10^{34}
$\int \mathcal{L}$	8 fb ⁻¹	23 fb ⁻¹	50 fb ⁻¹	300 fb ⁻¹
\sqrt{s}	7, 8, 13 TeV	14 TeV	14 TeV	14 TeV
μ	~ 1	~ 5	~ 5	~ 50

stations after the magnet. In the VELO [375], the current strips will be replaced by pixel detectors, with a custom developed ASIC (VeloPix) able to cope with a maximum hit rate of 900 Mhits/s/ASIC. The Upstream Tracker [376] is composed of four silicon micro-strip planes, with finer granularity and larger acceptance compared to the current tracker. Each station of the SciFi has four planes of 2.5 m long scintillating fibres read out by silicon photo-multipliers.

The upgrade components most important for LLP searches are the VELO, the tracking and the software trigger. In the following subsections a brief description of the design and capabilities is given for each.

5.2.1.1. VELO upgrade. The VELO plays a fundamental role in LLP searches at LHCb: due to the large boost particles typically experience in the forward direction, a precise measurement of the LLP vertex position allows LHCb to efficiently reject tracks that belong to a different b or c vertex (see section 4.2).

In upgrade conditions, the number of tracks and primary vertices will increase by about a factor of five, making it much more difficult to identify DV close to the beam-line; it is an additional challenge to accomplish this in real time. The VELO was thus completely redesigned [375] to cope with the new expected high-luminosity conditions, maintaining high physics performance and allowing real-time readout for the software trigger. The new VELO has a pixel rather than strip geometry and its distance from the LHC beams is reduced from 8 to 5 mm. This leads to an improvement in the vertex resolution (see figure 47) and reduces the rate of unphysical (ghost) tracks.

The pattern recognition efficiency for track reconstruction is superior to the one of the current VELO when evaluated in high-luminosity conditions. Particularly important for LLP searches is the efficiency of track reconstruction as a function of the displacement from the origin along the beam axis. As shown in figure 48, for the upgraded VELO the efficiency approaches 100% and is uniform in a window of 20 cm around the IP, thanks to the new configuration of the modules in the z direction and the shorter distance from the beam. The VELO acceptance degrades quickly after 20 cm in z , giving an upper limit for LLP decay lengths with vertices reconstructible in the VELO. A display of the upgraded VELO geometry and its acceptance in both the forward and backward directions is shown in figure 49.

Another important metric of detector performance is impact parameter resolution, especially in LLP searches where it can be exploited to reduce the background due to fake tracks. With the upgrade, the impact parameter resolution significantly improves for low- p_T tracks. For example, the impact parameter resolution along x for tracks with p_T of 0.5 GeV is 40 μm in the upgrade versus 70 μm in the current VELO. The replacement of strips with pixel sensors also makes the pattern recognition faster for the same multiplicity. This can be used in

Figure 47. Left: the impact parameter resolution (in the x direction) as a function of the inverse p_T . Right: the resolution on a vertex as a function of number of tracks. The current LHCb VELO performance is shown in black points while the one of the upgraded VELO in red points [375].

Figure 48. Left: a comparison of the current and upgrade VELO z -layouts for LHCb. The top layout (black) is the current VELO while the bottom layout (red) is the upgrade VELO. Right: the track reconstruction efficiency as a function of the origin in z for the current (black) and upgrade (black) VELO in upgrade conditions [375].

the trigger to find tracks and identify DV in the trigger, making it possible to soften or remove inefficient p_T requirements.

Real displaced tracks created by interactions in the VELO material can be a significant background to LLP searches (further details are discussed in chapter 4). The total material budget of the upgraded VELO is similar to that of the current detector (with a radiation length of about 20%) and is dominated by interactions in the radio-frequency foil separating the beam vacuum from the vacuum of the sensors. However, the average percentage of radiation length before the first measured point is significantly reduced in the upgrade VELO, passing

Figure 49. Left: a display of the upgrade VELO geometry and a comparison with the LHCb spectrometer acceptance which is shaded in yellow. Right: the η acceptance of the upgrade VELO geometry both for forward and backward tracks. The fraction of tracks crossing three and four modules is given in red and black, respectively [375].

from $4.6\%X_0$ in the current design to $1.7\%X_0$ in the upgraded VELO (where X_0 is the radiation length).

5.2.1.2. Upgraded trigger. The online event selection in the LHCb experiment during the 2010–2018 running period has been performed by a trigger composed of a hardware level (L0), and two software levels: High Level Trigger 1 (HLT1) and High Level Trigger 2 (HLT2). The L0 reduces the rate from 40 MHz (the LHC bunch-crossing rate) to 1 MHz using information from the calorimeter and MSs. Typical requirements in the L0 are $p_T > 1.4$ GeV for muons and $E > 2.5$ GeV for electrons. The software trigger performs a partial event reconstruction at HLT1, reconstructing tracks and primary vertices for any particle down to $p_T = 500$ MeV, followed by a complete event reconstruction at HLT2, reducing further the rate to 12.5 kHz (in LHC Run 2).

In the Phase 1 upgrade, LHCb foresees to run at a luminosity of $2 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$, about a factor of five larger than that experienced during LHC Run 2. For this reason, a new trigger system, able to fully exploit the LHC potential, has been designed [377, 378]. The upgraded LHCb trigger is based on two paradigms: a triggerless readout and a full software trigger. In addition, as already tested in Run 2, a real-time alignment and calibration will achieve offline-quality reconstruction already in the trigger, allowing a higher signal purity of interesting decay channels. Figure 50 shows the current and the upgraded trigger schemes.

Triggerless readout and full-software trigger. With the LHCb trigger upgrade, the 1 MHz readout limitation will be removed, allowing the full event rate to be processed in software. This will increase the efficiency for several channels which otherwise would not benefit from the higher luminosity because they would saturate the L0 trigger rate. Figure 51 shows how the rate for non-muonic B decays saturates the L0 trigger with increasing luminosity. Most of these channels saturate the L0 trigger already at the Run 2 luminosity ($4 \times 10^{32} \text{ cm}^{-2} \text{ s}^{-1}$). Moreover, a purely software trigger will not be subject to the p_T requirements currently applied at the hardware trigger level. Several physics programs involving low- p_T particles, currently prohibited by of the low L0 efficiency, will therefore become possible.

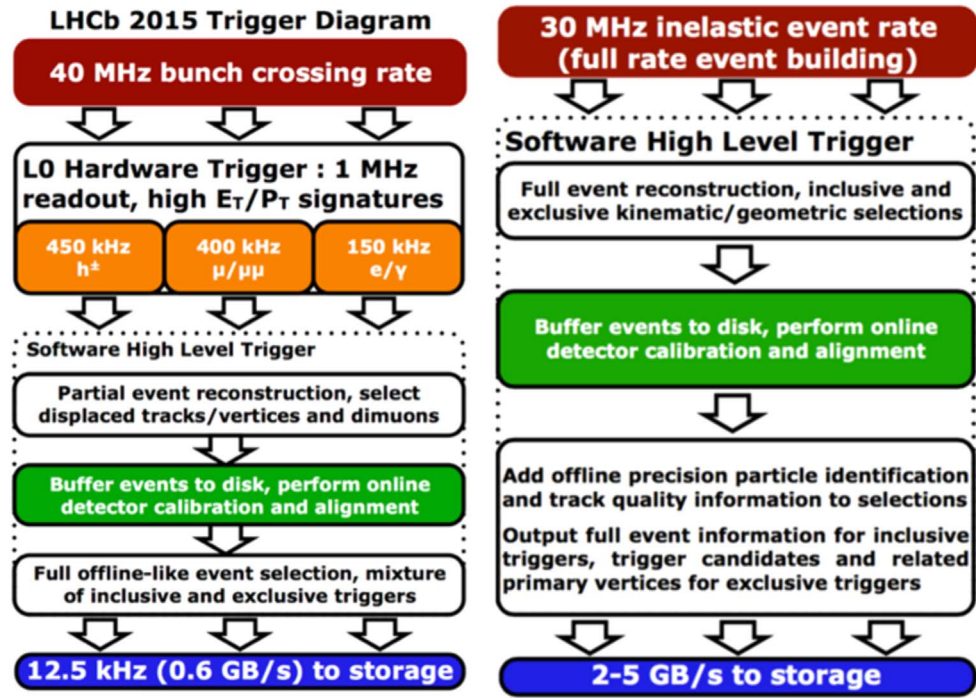

Figure 50. Scheme of the current LHCb trigger (left), and of the upgraded trigger (right) [379].

Figure 51. Trigger yields for $B \rightarrow \pi^+\pi^-$, $B_s \rightarrow \phi(K^+K^-)\gamma$, $B_s \rightarrow J/\psi(\mu^+\mu^-)\phi(K^+K^-)$ and $B_s \rightarrow D_s^-(K^+K^-\pi^-)K^+$ as a function of the luminosity with the current LHCb trigger scheme. For non-muonic channels, the saturation effect due to the L0 trigger can be observed [380].

Turbo stream. Starting from Run 2, offline-quality alignment and calibration has been applied between the HLT1 and the HLT2 levels. This was made possible by the design of a new dedicated trigger output called Turbo Stream. The event record is written directly from

the trigger and processed so that it can be used for physics analysis without the need for offline reconstruction [277]. Several variations of Turbo have been introduced in the last several years. For 2015 data taking, the first version of Turbo allowed only the triggered signal candidate objects to be saved, without keeping the rest of the event and thereby discarding all sub-detector information. While the event size was an order of magnitude smaller than for full stream data, any analysis relying on additional information from the surrounding event could not use Turbo Stream data.

For this reason, full event reconstruction was implemented as Turbo++ in 2016. Finally, a new intermediate solution between Turbo and Turbo++ called Turbo SP (Selective Persistence) was implemented in 2017. With Turbo SP, both the trigger candidate objects and a subset of the other objects in the event are saved. This flexible solution allows the analyzer to choose which objects to save, minimizing the size of the stored event. Once the trigger is upgraded to run purely at the software level, the large majority of LHCb analyses will be moved to Turbo. The reduced event size allows the storage of particle candidates at a high rate, fully exploiting the reduction in p_T thresholds due to the removal of the LO hardware trigger.

Triggers on downstream tracks. Most of the LLP searches at the LHCb experiment use so-called ‘long tracks’ to reconstruct the candidates, which are tracks where inputs from both the VELO and the TTs are considered. These tracks have an excellent spatial and momentum resolution, and result from an LLP decaying within the VELO region. This is the reason why most of the LLP searches done by LHCb correspond to long-lived candidates with displacements typically up to $\mathcal{O}(10)$ cm, with the VELO tracking algorithm optimized for displacements of up to 20 cm. However, for long-lived candidates with displacements larger than 2 cm, a different type of track which considers information only from the TTs, ‘downstream tracks’, has to be used instead of the ‘long track’ type. Unfortunately, these tracks have worse vertex and momentum resolution, limiting the capabilities of LHCb for this displacement range. In order to improve the detector sensitivity in the displacement ranges between 20 and 200 cm, a proposal to develop new trigger lines to select ‘downstream tracks’ is being studied [378]. An interesting idea which can help to achieve this task and to significantly reduce the CPU computing time is the implementation of a system of specialized processors used to rapidly find the downstream tracks through look-up tables, and present these tracks to the software trigger in parallel with all the raw detector information in the event. This system, named ‘retina’, is being studied and has its own R&D programme [381].

The much higher luminosity and improved capabilities of the upgraded LHCb detector are expected to significantly improve the capabilities for LLP searches in LHC Run 3. In the following sections, the projected sensitivities to several benchmark LLP signatures are shown to illustrate the potential of the upgraded detector. However, the potential of the upgraded triggerless readout has not been completely explored yet and its great flexibility could be exploited in several ways beyond those shown here.

5.2.2. LHCb upgrade phase 1a projections for LLP signatures

5.2.2.1. Displaced di-leptons. The upgraded LHCb experiment is expected to have exceptional sensitivity to low-mass, displaced dilepton signatures thanks to the mass resolution, excellent vertexing, and the online selection allowed by the triggerless readout.

The upgrade LHCb sensitivity to dileptons has been explored in the literature in the context of dark photon searches. Two complementary signatures have been considered: an inclusive search for BSM gauge bosons (dark photons) in $A' \rightarrow \mu^+\mu^-$, and a search for A' using radiative charm decays $D^{*0} \rightarrow D^0A'$, $A' \rightarrow e^+e^-$. The inclusive search [341] scans a

Figure 52. Current and expected limits in the dark photon parameter space mixing ϵ^2 versus A' mass [374]. The black line represents current LHCb limits from [269], while grey-shaded regions are existing limits from other experiments. Expected limits from the proposed inclusive search with 50 and 300 fb^{-1} are shown in shades of blue. The expected sensitivity of $D^{*0} \rightarrow D^0 A'(ee)$ at low mass is shown in shades of green. The arrows indicate the available mass range from light meson decays into $e^+e^-\gamma$.

large region from the dimuon threshold $2m_\mu$ all the way up to the Z pole. The second proposed signature [382] exploits a tag of the radiative decay of the D^{*0} using its reconstructed invariant mass and a di-electron dark photon final state to probe a much lower mass range allowed by the decay kinematics, $[2m_e, 142 \text{ MeV}]$. For both signatures, searches for both a prompt and a displaced dark photon vertex are carried out. The prompt search is expected to probe mixing parameters ϵ^2 below 10^{-7} despite the large irreducible background from Drell–Yan and QCD¹⁸⁰. Since the dark photons with masses above the η mass decay promptly for couplings that are accessible within LHCb, no attempt is made to probe displaced dark photons in that region.

An inclusive search for dark photons has already been performed with LHCb data collected in 2016 [269]. This was possible due to the high reconstruction and identification efficiency of soft di-muons at LHCb. These results demonstrated the unique sensitivity that can be reached at LHCb. The planned increase in luminosity and removal of the hardware-trigger stage in Run 3 should increase the number of expected $A' \rightarrow \mu\mu$ decays in the low-mass region by a factor of $\mathcal{O}(100\text{--}1000)$ compared to the 2016 data sample. The limits placed by the current data and the sensitivity expected with future LHC runs is shown in figure 52.

The exclusive search for $D^{*0} \rightarrow D^0 A', A' \rightarrow e^+e^-$ is much more challenging and not feasible prior to the upgrade, since the hardware trigger and the higher material budget degrade the sensitivity. This search highly relies on the online identification of e^+e^- pairs, since over 5 trillion of these D^{*0} decays are expected in Run 3. The expected sensitivity probes unexplored regions of phase space at low A' mass and mixing ϵ^2 that is usually in the realm of beam-dump experiments.

A displaced di-muon signature also appears in some HV scenarios [66], in which a hidden sector with strong dynamics showers and hadronizes into dark mesons that can have an appreciable decay rate to leptons. (For more information on dark showers, see chapter 7.) The upgraded LHCb prospects for this type of signature have been explored in [383] and are very promising. In the scenario explored therein, dark mesons are produced with large multiplicities of between 10 and 30. Selection criteria inspired by the proposed dark photon search [341] in the region after the first VELO module are applied. The expected reach for the

¹⁸⁰ In the limit $m_{A'} \ll m_Z$, the coupling of the dark photon to SM particles with charge Q is approximately $Qe\epsilon$.

Figure 53. Projected bounds from various ATLAS/CMS searches and the LHCb search for hidden valley-like models with a Z_p decaying to a $q_{HV} q_{HV}$ pair which then undergo hadronization in the dark sector, eventually leading to dark meson decays to di-muon final states [383].

proposed searches using Run 3 data from LHCb (15 fb^{-1}) and from ATLAS/CMS (300 fb^{-1}) are shown in figure 53. The model studied involves a 200 GeV $U(1)'$ gauge boson Z_p decaying to a HV quark pair; showering and hadronization in the dark sector leads to a large multiplicity of hidden hadrons ω_V (with $m_{\omega_V} = 0.3 \text{ GeV}/c^2$) that can decay to di-muons. In this context, the upgraded LHCb detector could have better sensitivity than other proposed searches at ATLAS and CMS.

5.2.2.2. Displaced jets. Signatures with displaced jets are common in the context of LLP searches. As summarised in section 3.1.3, LHCb has started to explore its sensitivity to displaced jets by using the data collected during Run 1. In LHCb Upgrade Ia, the background rejection for displaced jet searches is expected to improve thanks to the improved VELO resolution. The selection efficiency should also be significantly higher due to the prospects for online DV identification. The main focus of LHCb will be to probe the region at small lifetime where it has already proven to be the most competitive (see discussion in section 3). The background from QCD and material interactions is the main limiting factor, and the improved vertex resolution of the upgraded VELO together with the lower material budget and the use of a detailed material map are expected to bring large improvements in the upgraded detector.

In some dark sector models, the number of hadronic DV can be large, even in the limited LHCb acceptance (see, for example, [331] and the discussion in chapter 7). An inclusive DV search would likely include a requirement on the isolation of the DV from other tracks in the event (such as the one used for the dark photon analysis [269]). This requirement could be very inefficient in the context of a dark shower and so a dedicated search strategy would be needed. Furthermore, a dedicated software trigger looking for a large number of DV in the VELO and soft p_T requirements could in principle improve the sensitivity to this kind of models, but studies are needed to fully understand its potential and compare LHCb to other experiments.

Figure 54. Projected bounds from various proposed searches for confining hidden valley models exploiting $c\bar{c}$ decays of hidden valley mesons ω_v (taken from [383]). The sensitivities with various signatures at LHCb are shown: two displaced vertices (green), one reconstructed D meson and one DV (blue) and two reconstructed D mesons (red). Searches for this same particular model at ATLAS/CMS are shown not to be competitive (more details can be found in [383]).

5.2.2.3. Displaced mesons. Quark–antiquark pairs from the decay of a low mass particle in the SM often hadronize into SM mesons that subsequently decay with known branching ratios. For example, a dark sector meson with a displaced decay to $c\bar{c}$ often produces two D mesons which in turn have non-negligible lifetimes. In this scenario, the authors of [383] have investigated the prospects of using more or less inclusive reconstruction of the two D meson decays at the upgraded LHCb. A similar approach could be used to target decays to $b\bar{b}$ that hadronize to B mesons since the latter is likely to produce D mesons in its decay. Since LHCb is designed to reconstruct heavy flavor decays, it can be competitive in this kind of search [383] (see figure 54). Furthermore, searches for displaced mesons will greatly profit from the software trigger, which is mainly designed to improve the efficiency of similar-looking hadronic decays of heavy flavor mesons.

5.2.3. After phase 1a upgrade: phase 1b and phase 2. After a consolidation phase (Phase 1b) during long shutdown (LS) 3 aiming to run in the same conditions as in Phase 1a, the LHCb detector plans a Phase 2 upgrade during LS 4 (by 2030). The Phase 2 upgrade is needed to face even more challenging conditions than during previous runs. For example, particle multiplicity, PU, and radiation damage are expected to be ten times higher than those experienced in Phase 1. The LHCb experiment expects to collect at least 300 fb^{-1} by the end of Upgrade 2 [374].

Major improvements to the LHCb detector during Phases 1b and 2 that are relevant for LLP searches are described in the following, as well as some naïve projections of Run 1 results to an an integrated luminosity of 300 fb^{-1} .

Magnet stations. Along with the ‘long’ and ‘downstream’ track types, ‘upstream’ tracks are also considered useful for LLP searches. These tracks correspond to soft charged particles bending out of the detector acceptance, produced from LLP candidates which decay within the VELO region. Aside from the installation of a new tracker during LS2, the Upstream Tracker, a proposal to add magnet stations inside the LHCb magnet to improve low

Figure 55. Impact parameter resolution estimations from simulation using the Phase 1 VELO model for the LHCb experiment: (left) a comparison if considering Phase 1 or Phase 2 conditions; (right) the effect of the RF-foil removal under Phase 2 conditions [384].

momentum resolution is considered [384]. These magnet stations have been proposed to be installed for Phase 1b, and are foreseen to highly improve the tracking of low momentum particles produced from certain kind of LLP candidates, such as for example soft pions from ‘disappearing’ chargino tracks.

Material interactions. The presence of a VELO envelope at approximately 5 mm from the beam line in order to separate the VELO and the LHC vacuums, named ‘RF-foil’, strongly affects the background composition of LLP searches in the LHCb experiment. Namely, for LLP candidates decaying below 5 mm from the beam line, the main source of background is due to heavy flavour decays, while material interactions with the RF-foil compose the main background contribution for LLPs decaying above 5 mm from the beam line. While the former is purely due to QCD processes and hence not reducible, the latter is kept under control by the use of a detailed veto map (see [269]). However, the ideal case would be to completely remove the RF-foil during the Phase 2 upgrade [384], which would result in a large reduction of the background component due to material interactions. The improvements foreseen to the Phase 2 VELO (probably based on an updated version of the Phase 1 VELO), are expected to increase the sensitivity to shorter lifetimes and better PV and impact parameter resolution (see figure 55). Unfortunately, the removal of the RF-foil requires the development of new techniques to isolate the sensors from the beam radio frequency and is not necessarily seen as a viable option. Therefore, improving the material veto maps as much as possible by accurately modeling the material interactions would be desirable as a more realistic option for the HL-LHC era.

Naïve Projections of Run 1 Results to the HL-LHC Era. By taking the published Run 1 results from the single displaced dijet search [253] at LHCb, a naïve extrapolation to the integrated luminosity foreseen to be recorded by LHCb during Phase 2, 300 fb^{-1} , is presented in figure 56. These numbers have been obtained by simply scaling signal and background with the expected increase in cross section and luminosity, neglecting PU effects and expected detector improvements. The removal of neutral objects from jet reconstruction, and the use of machine-learning techniques are expected to assist in the required suppression of

Figure 56. Naive sensitivity projections for searches of displaced dijet vertices at LHCb for the expected luminosity to be collected with the Phase 2 upgraded detector (300 fb^{-1}) [385]. The projected limit is on Higgs boson decays to dark pions π_V with branching fraction \mathcal{B} , and the dark pions each in turn decay to a pair of jets.

PU. Furthermore, jet substructure techniques are foreseen to improve the quality of di-jet object with lower mass.

5.3. Dedicated detectors for LLPs

5.3.1. Introduction. Despite a wide and seemingly comprehensive research program—both existing and, in this document, proposed to be expanded—for LLPs at the LHC, in cases of ultra-low-mass particles, ultra-long lifetimes, or unusual LLP charges, it is hard or impossible to trigger on and/or reconstruct such events in the main ATLAS, CMS, and LHCb detectors. This has led to new proposals for dedicated experiments to look for LLPs in new regimes that are otherwise inaccessible at the LHC. These experiments provide the best sensitivity to new millicharged LLPs, magnetic monopoles, and other LLPs arising from models such as those containing Higgs-portal hidden sectors, dark photons, and Majorana neutrinos.

As discussed in section 2.2, LLPs BSM are theoretically well motivated and come in wide range of masses and lifetimes. ATLAS and CMS have excellent sensitivity for fairly high mass LLPs, regardless of their lifetime (see, e.g. [4, 246, 386, 249]). Low mass and/or softer final states are more challenging due to both background and triggering limitations. In the short-lifetime regime, for $c\tau$ of the scale of the VELO, LHCb has sensitivity to somewhat lower masses and can trigger on softer muonic final states, generating complementary reach provided the LLP has a significant branching ratio to muons [253, 254, 279, 309, 387]. Finally, the low-mass/soft final states with rather long lifetimes are challenging for all three experiments. These signatures can be covered partially by NA62 [388] operating in beam dump mode, or by SHiP [389], or by dedicated LHC experiments like CODEX-b [104] (see section 5.3.5), FASER [105] (see section 5.3.6), or MATHUSLA [103] (see section 5.3.4). Each of these dedicated experiments is sensitive to different LLP lifetimes, masses, and production modes based on their position and orientation and thus each can be considered a necessary component of a comprehensive, coordinated search program for very long-lived particles at the LHC.

Figure 57. A three-dimensional schematic view of the MoEDAL detector (in the yellow circle) around the LHCb VELO region at Point 8 of the LHC.

5.3.2. MoEDAL experiment and future developments. Monopole and exotics detector at the LHCb (MoEDAL) [101]¹⁸⁰ is designed to search for manifestations of new physics through highly-ionising (HI) particles in a manner complementary to ATLAS and CMS [310]. The main motivation for the MoEDAL experiment is to pursue the quest for magnetic monopoles at LHC energies. Nonetheless the detector is also designed to search for any massive, long-lived, slow-moving particle [390, 391] with single or multiple electric charges arising in many scenarios of physics BSM [392].

The MoEDAL detector [311] is deployed around the intersection region at LHC Point 8 (IP8) in the LHCb VELO cavern. A schematic view of the MoEDAL experiment is shown in figure 57. It is a unique and largely passive detector comprising different detector technologies.

The main sub-detector system is made of a large array of CR-39, Makrofol® and Lexan™ nuclear track detector (NTD) stacks surrounding the intersection area. The passage of a HI particle through the plastic detector is marked by an invisible damage zone along the trajectory. The damage zone is revealed as a cone-shaped etch-pit when the plastic detector is chemically etched. Then the sheets of plastics are scanned looking for aligned etch pits in multiple sheets. The MoEDAL NTDs have a threshold of $z/\beta \sim 5$, where z is the charge and $\beta = v/c$ the velocity of the incident particle.

Another type of NTD installed is the very high charge catcher ($z/\beta \sim 50$). It consists of two flexible low-mass stacks of Makrofol®, deployed in the LHCb acceptance between RICH1 and the Trigger Tracker. It is the only NTD (partly) covering the forward region, adding only $\sim 0.5\%$ to the LHCb material budget while enhancing considerably the overall geometrical coverage of MoEDAL.

A unique feature of the MoEDAL detector is the use of paramagnetic magnetic-monopole trappers (MMTs) to capture magnetically-charged HI particles. The high magnetic charge of a monopole—being at least one Dirac charge $g_D = 68.5e$ —implies a strong magnetic dipole moment, which may result in strong binding of the monopole with the nuclei of the aluminium MMTs. In such a case, the presence of a trapped monopole would be detected through the induction technique by measuring the *persistent current*, defined as the

¹⁸⁰ For general information on the MoEDAL experiment, see: <http://moedal.web.cern.ch/>.

difference between the superconducting magnetometer currents before and after the passage of the MMT bar through the sensing coil [393, 394].

The only non-passive MoEDAL sub-detector is an array of TimePix pixel devices distributed throughout the MoEDAL cavern, forming a real-time radiation monitoring system of HI beam-related backgrounds. The operation in time-over-threshold mode allows a 3D mapping of the charge spreading in the volume of the silicon sensor, thus differentiating between various particles species from mixed radiation fields and measuring their energy deposition.

The MoEDAL detector is designed to fully exploit the energy-loss mechanisms of magnetically charged particles [395–398] in order to optimise its potential to discover these messengers of new physics. Multiple theoretical scenarios have been proposed over the years in which magnetic charge would be produced at the LHC [392], resulting in such possible new particles as light γ Hooft–Polyakov monopoles [397–399], electroweak monopoles [400–404], global monopoles [405–410], and monopolium [396, 411–413]. Magnetic monopoles that carry a non-zero magnetic charge and dyons possessing both magnetic and electric charge are predicted by many theories including grand-unified and superstring theories [414–416].

A possible explanation for the non-observation of monopoles so far is Dirac’s proposal [395, 396, 411] that monopoles are not seen freely because they form a bound state called *monopolium* [412, 413, 417, 418] being confined by strong magnetic forces. Monopolium is a neutral state, difficult to detect directly at a collider detector, although its decay into two photons would give a rather clear signal for ATLAS and CMS [419]. Nevertheless the LHC radiation detector systems can be used to detect final-state protons $pp \rightarrow pXp$ exiting the LHC beam vacuum chamber at locations determined by their fractional momentum losses [420]. Such a technique would be appealing for detecting monopolia.

The MoEDAL detector is also designed to search for any massive, long-lived, slow-moving particles [390, 391] with single or multiple electric charges arising in many scenarios of physics BSM. Supersymmetric LLPs [421], quirks, strangelets, Q-balls, and many others fall into this category [392]. A generic search for high-electric-charge objects is currently underway.

For the 2016 run at 13 TeV, the MMT included 672 aluminium rods (for a total mass of 222 kg) that were placed 1.62 m from the IP8 LHC IP under the beam pipe on the side opposite to the LHCb detector. The MMT bars were analysed and no magnetic charge $> 0.5g_D$ was detected in any of the exposed samples when passed through the ETH Zurich SQUID, which is a DC SQUID long-core magnetometer [422]. Hence cross section limits are obtained for Drell–Yan pair production of spin-1, spin-1/2 and spin-0 monopoles for $1g_D \leq |g| \leq 5g_D$ at 13 TeV [422] improving previous bounds set by MoEDAL at 8 TeV [311] and 13 TeV [423]. Monopole production via photon fusion is also now considered in MoEDAL monopole search analyses [424] following recent studies [425]. However, the large monopole-photon coupling invalidates any perturbative treatment of the cross section calculation and hence any result based on the latter is only indicative. This situation may be resolved if thermal production in heavy-ion collisions—that does not rely on perturbation theory—is considered [426], or by including a magnetic-moment term in monopoles with spin [425].

To recapitulate, under the assumption of Drell–Yan cross sections, MoEDAL has derived mass limits for $1g_D \leq |g| \leq 5g_D$, complementing ATLAS results [215, 427], which placed limits for monopoles with magnetic charge $|g| \leq 1.5g_D$, as shown in figure 58. The ATLAS bounds are better than the MoEDAL ones for $|g| = 1g_D$ due to the higher luminosity delivered in ATLAS and the loss of acceptance in MoEDAL for small magnetic charges. On the other

Figure 58. Magnetic monopole mass limits from CDF [429], ATLAS [215] and MoEDAL searches [311, 422] as a function of magnetic charge for various spins, assuming a Drell–Yan pair-production mechanism.

hand, higher charges are difficult to be probed in ATLAS due to the limitations of the level-1 trigger deployed for such searches. Limits on production cross sections of singly-charged magnetic monopoles set by various colliders are presented in [414, 415], while general limits including searches in cosmic radiation are reviewed in [428].

MoEDAL is proposing to deploy the MoEDAL apparatus for detecting penetrating particles (MAPP) in a tunnel shielded by some 30–50 m of rock and concrete from the IP8 [430, 431]. A prototype of the MAPP detector was installed in 2017. It is envisaged that the full detector will be installed in LS2 to take data in LHC Run 3. The purpose of the detector is to search for particles with fractional charge as small as one-thousandth the charge of an electron. This detector would also be sensitive to neutral particles from new physics scenarios via their interaction or decay in flight in the ~ 10 m decay zone in front of the detector or in the detector itself. The isolation of the detector means that the huge background from SM processes in the main detectors is largely absent. Also, the detector can be placed at various angles to the beam axis (from 5° to 25°). The ability to vary depth and angle enhances MoEDAL to be able to distinguish between theoretical scenarios in the event a signal is observed.

The first apparatus specifically designed to detect mini-charged particles was the Stanford Linear Accelerator Centre (SLAC) ‘beam dump’-type detector, comprising scintillator bars read out by photomultiplier tubes [432]. MoEDAL’s new detector, shown in figure 59, and milliQan (discussed above in section 5.3.3) proposed for deployment near to the CMS detector [102] also designed to search for mCPs, both have a design that harks back to the original SLAC detector. In order to reduce backgrounds from natural radiation the photomultiplier tubes and scintillator detectors of the MoEDAL apparatus will be constructed from materials with low natural backgrounds currently utilised in the astroparticle-physics arena. Its calibration system utilises neutral density filters to reduce the received light of high incident muons that manage to penetrate to the sheltered detector from the IP, in order to mimic the much lower light levels expected from particles with fractional charges.

Figure 59. A depiction of the MoEDAL’s MAPP sub-detector [431].

Figure 60. The MALL sub-detector designed to monitor MoEDAL trapping volumes for the decays of trapped electrically charged particles with lifetimes as long as 10 years [431].

MoEDAL is also planning another new sub-detector called MALL (MoEDAL apparatus for detecting extremely long lived particles) [431]. In this case MoEDAL trapping volumes, after they have been scanned through the ETH Zurich SQUID facility to identify any trapped monopole will be shipped to a remote underground facility to be monitored for the decay of pseudo-stable massive charged particles that may also have become trapped. MALL is the detector that monitors MoEDAL trapping volumes for decays of captured particles. It is envisaged that MALL will be installed deep underground at SNOLAB in Canada where cosmic backgrounds are minimised to one muon per $0.27 \text{ m}^2 \text{ d}^{-1}$. Background is further reduced by the ability to determine if a detected track originated within the monitored volume and also by energy cuts on deposited signals. A schematic view of the detector is shown in figure 60. Initial estimates indicate that lifetimes up to around 10 years can be probed. The MALL detector is designed to be sensitive to charged particles and to photons, with energy as small as 1 GeV. It is envisaged that construction of the detector will begin after the MAPP detector is full deployed.

The possibility of analysing decommissioned parts of the LHC beam-pipe system at the ATLAS, CMS and LHCb/MoEDAL sites with a SQUID to search for trapped magnetic monopoles has been proposed [433]. In this context the MoEDAL experiment may serve as a formal platform for coordinating machining, scanning and analysis work, in collaboration with interested ATLAS, CMS and LHCb members.

The induction technique has been successfully employed at the LHC with the dedicated MoEDAL trapping detector. Additional searches for trapped monopoles in beam pipe material would access wide windows of magnetic charges and production cross sections to which other LHC experiments are insensitive. The decommissioned central beryllium beam pipe sections of ATLAS and CMS, with a 4π coverage and exposure to the highest rates of 7 and 8 TeV pp collisions, are by far the most attractive samples to be analysed. The analysis on the CMS beam pipe is expected to be carried out in 2019.

5.3.3. The milliQan experiment. MilliQan is a dedicated experiment at the LHC to search for mCP [102, 434]. The milliQan experiment is part of a general program to search for hidden sectors [435] and other BSM scenarios [436]. As an illustrative example, we show the sensitivity of milliQan to an extra Abelian gauge field coupled to a massive Dirac fermion ('dark QED') that mixes with hypercharge through the kinetic term [122]. The result is that the new matter field is charged under hypercharge with a fractional electric charge of ϵ , where $\epsilon \ll 1$. The milliQan experiment targets an unexplored part of the parameter space, namely mCP masses $0.1 \leq M_{\text{mCP}} \leq 100$ GeV, for charges Q at the $10^{-3} e - 10^{-1} e$ level.

The experimental apparatus consists of three scintillator detector layers of roughly 1 m^3 each, positioned near one of the high-luminosity IPs of the LHC. The experimental signature consists of a few photo-electrons (PE) arising from the small ionization produced by the mCPs that travel unimpeded through material after escaping the LHC detectors.

The milliQan experiment is planned to be sited in the PX56 Observation and Drainage gallery above the CMS underground experimental cavern. The proposed gallery is limited in space. The detector will be located in this tunnel at an optimized location that is 33 m from the CMS IP, behind 17 m of rock, and at an angle of 43.1 degrees from the horizontal plane. The selected location in a 3D model is shown in figure 61.

The milliQan detector is a $1 \text{ m} \times 1 \text{ m} \times 3 \text{ m}$ plastic scintillator array. The array will be oriented such that the long axis points at the nominal CMS IP. The array is subdivided into 3 sections each containing $400 \text{ cm} \times 5 \text{ cm} \times 80 \text{ cm}$ scintillator bars optically coupled to high-gain photomultiplier tubes (PMTs). The detector will be shielded from other background sources such as activity in the scintillator and environmental radiation. With an estimated detection efficiency of about 10%, milliQan expects an average of $\mathcal{O}(1)$ PE from each attached phototube for each mCP with $Q = \mathcal{O}(10^{-3}) e$ that traverses 80 cm of plastic scintillator. The signal is a longitudinal triple-incidence of hits with one or more PEs; a triple-incidence within a 15 ns time window along longitudinally contiguous bars in each of the three sections is required to reduce the background from dark-current noise. Requiring triple-incidence is expected to control background to $\mathcal{O}(10)$ events per year with $N_{\text{PE}} \geq 1$. The milliQan detector will self-trigger to a dedicated readout with no dead time from readout, up to rates of ~ 1 kHz. Energy calibration will be done *in situ* using an ^{241}Am source.

The dominant background is expected to come from dark-current pulses in the PMTs. Pulses from background radiation, including cosmic muons, will consist of 1000s of PEs that can be easily vetoed offline. Assuming a total background rate per PMT of $\nu_B = 500$ Hz, with a time window of $(\Delta t)_{\text{online}} = 100$ ns, milliQan expects a double coincident trigger rate per board of 1.5 Hz. The entire detector will be read out if one board triggers and there will be 50 such boards in total. Therefore, the full background trigger rate is expected to be 75 Hz.

Figure 61. A 3D model showing the optimal position of milliQan within the PX56 Drainage and Observation gallery located above CMS UXC.

Offline, the time window will be tightened to $(\Delta t)_{\text{offline}} = 15$ ns, yielding an offline background rate for a triple coincidence of 2.8×10^{-8} Hz. Since there are 400 such sets, the total offline background rate is estimated to be 1.1×10^{-5} Hz. With these background rates, milliQan estimates a total of 165 (330) background events in 300 (3000) fb^{-1} of integrated luminosity.

The milliQan collaboration has performed a full simulation of the experiment to evaluate the projected sensitivity to various mCP electric charges and masses. The simulation is performed in two stages. In the first, the production of mCP particles via Drell–Yan, J/Ψ , Υ (1S), Υ (2S), and Υ (3S) channels at a center-of-mass energy of 14 TeV is performed. Particles produced at the IP are propagated to the proposed experimental site described above using a map of the CMS magnetic field. The effects of multiple scattering and energy loss are included using a simplified model of the CMS detector material budget and a region of rock spanning 17 m between the CMS experimental cavern and the proposed experimental site. The number of expected mCP particles per fb^{-1} of integrated luminosity incident at the detector is computed as a function of the mass of the mCP. The signal efficiency is then estimated after processing the calculated particles as they would emerge from the IP through a full GEANT4 simulation of the detector; this is necessary because the small charge regime is sensitive to details such as the reflectivity, the light attenuation length, and the shape of the scintillator. These details, as well as the quantum efficiency, light-emission spectrum and the fast-time constants were modeled in GEANT4 using the specifications provided by the manufacturers for the scintillator and PMTs. Combining the estimated background rates discussed above with the cross sections, acceptances and efficiencies calculated for all masses and electric charges, the sensitivity projections of the milliQan experiment for LHC and HL-LHC are shown in figure 62.

A 1/100 scale ‘demonstrator’ of milliQan to validate the detector concept was installed in the PX56 location at CERN during Technical Stop 2 of 2017 and was upgraded during the 2017–2018 year-end technical stop. This demonstrator, shown in figure 63, has been recording data since its installation, and expects to have first results later this year. If funding

Figure 62. The expected sensitivity of the milliQan experiment for different LHC luminosity scenarios. The black line shows the expected 95% C.L. exclusion (solid) and 3σ sensitivity (dashed), assuming 300 fb^{-1} of integrated luminosity. In blue is shown the corresponding expectations for 3000 fb^{-1} .

Figure 63. The 1/100 scale ‘demonstrator’ of milliQan installed in the PX56 drainage gallery 33 m from the CMS IP.

is secured, construction of the full milliQan apparatus is planned for 2019, with installation in the tunnel in 2020.

5.3.4. The MATHUSLA experiment. The basic motivation for the MASSive Timing Hodoscope for Ultra-Stable neutral pArticles (MATHUSLA) detector [103] is the search

Figure 64. Simplified MATHUSLA detector layout showing the position of the $200\text{ m} \times 200\text{ m} \times 20\text{ m}$ LLP decay volume.

for LLPs with lifetimes much greater than the size of the LHC main detectors, $c\tau \gg 100\text{ m}$. Any detector that can be reasonably constructed could only catch a small fraction of such LLPs decaying inside of its volume. Even with potentially large LLP production rates at the LHC, suppression of backgrounds is therefore crucial for discovery.

For LLP searches with high-energy or lepton-containing final states, the spectacular nature of displaced-vertex (DV) signals leads to very low backgrounds in searches at LHC detectors such as ATLAS or CMS. Any other class of LLP signature suffers from backgrounds and triggering limitations that can be significant. This greatly curtails the main detectors' ability to discover LLPs with very long lifetimes.

To address this broad blind spot of existing detectors, MATHUSLA is proposed to be a large, relatively simple surface detector that can robustly reconstruct DVs with good timing resolution. This gives MATHUSLA a similar geometric acceptance to LLP decays in the long-lifetime limit as the main detectors, while providing shielding from QCD backgrounds and sufficient tracking to reject ubiquitous CRs. As a result, MATHUSLA is able to detect LLPs produced with $\sim 1\text{ pb}$ cross sections at the HL-LHC with lifetimes near lifetimes of $\sim 0.1\text{ s}$, which is generally the limit imposed by big-bang nucleosynthesis (BBN).

The simplified detector design for MATHUSLA is shown in figure 64. The main component of the detector is a tracker array situated above an air-filled decay volume that is 20 m tall and $200\text{ m} \times 200\text{ m}$ in area. The tracker should have on the order of five planes to provide robust tracking with $\sim\text{ns}$ timing and $\sim\text{cm}$ spatial resolution. The current MATHUSLA design employs proven and relatively cheap technologies to allow for MATHUSLA's construction in time for the HL-LHC upgrade. Therefore, the trackers are envisioned to be implemented with resistive plate chambers (RPCs), which have been used for very large area experiments in the past [437, 438], while plastic scintillators provide the surrounding veto.

This minimal design has been shown to be capable of measuring the LLP boost on an event-by-event basis [439] using the geometry of the LLP visible decay products. Final-state multiplicity provides a straightforward discriminant between hadronic and electromagnetic decays. Additional particle identification capability, as well as detection of final-state photons, might be possible by inserting an additional material layer between tracking layers to induce an electromagnetic shower that can be used to distinguish electrons, photons and muons.

As argued in [103], MATHUSLA could search for LLPs decaying into charged particles with little or no backgrounds. In figure 64 is shown, schematically, the two main MATHUSLA signals, LLPs decaying into at least two charged leptons, or into jets that

Figure 65. Sensitivity of MATHUSLA to hadronically decaying LLPs produced in exotic Higgs decays, where the solid lines correspond to four decays in the detector [103]. The dotted lines are the most optimistic ATLAS projection, using a very inclusive search for a single DV in the muon chamber [262].

contain $\mathcal{O}(10)$ charged hadrons [439]. In 50%–90% of leptonic decays and practically 100% of hadronic decays [439], two or more charged particles hit the ceiling due to the LLP boost and are recorded by the tracker. The charged particle trajectories can be fitted to reconstruct a DV. Unlike most analyses in the main detectors, these DVs must satisfy the additional stringent requirement that all trajectories coincide in time at the DV. The scintillator is used as a veto to ensure that the charged particles originate at the DV: there can be no hits along the line between the vertex and the LHC main IP, nor along the lines obtained by extrapolating the individual charged particle trajectories backwards. These exhaustive geometric and timing requirements make it extremely difficult for backgrounds to fake the LLP signal. Cosmic rays can be rejected since they travel in the wrong direction (as well as occurring mostly in CR showers with extremely highly correlated particle multiplicity in the detector). Muons from the LHC collision do not satisfy the DV signal requirement. The rare occasions in which muons scatter inside the decay volume can be vetoed with the scintillators. Finally, neutrinos from CRs and LHC collisions can scatter in the decay volume and produce DV, but those can also be rejected with geometric and timing requirements. We refer the reader to [103] for more details. More comprehensive studies of these backgrounds and their rejection strategies, including full simulations, are currently in progress.

An important general class of signals are LLPs with masses ~ 100 GeV that decay hadronically and are produced without other highly visible signals like high MET or high-energy leptons. MATHUSLA can improve the sensitivity to these LLP production cross sections by a factor of $\sim 10^3$ compared to searches with the main detectors alone. This is illustrated in figure 65, which shows MATHUSLA’s sensitivity to hadronically decaying LLPs produced in exotic Higgs decays [103] compared to an optimistic projection for searches for a single DV in the ATLAS MS [262]. For branching ratios of $\sim 10\%$, the BBN lifetime limit [440] can be probed.

Apart from reaching the BBN upper limit or ceiling of LLP parameter space, MATHUSLA extends the power of other LHC measurements. If a $\sim 10\%$ invisible branching ratio for the Higgs was detected via coupling measurements at the HL-LHC, the absence of a MATHUSLA signal would lend strong support to the interpretation that the Higgs decayed to a stable component of DM.

Beyond LLPs produced in rare Higgs decays, MATHUSLA is a general-purpose LLP detector that is sensitive to a wide range of other models. Its reach for other BSM scenarios has been explored in [172, 174, 198, 441–447]. The general physics case for MATHUSLA’s construction is made systematically in the recently released whitepaper [2].

It is important to point out that MATHUSLA is a very flexible detector concept that is completely scalable. The sensitivity of MATHUSLA is roughly proportional to the decay volume (which scales with surface area) and roughly independent of the precise geometry or location of the detector, as long as it is $\mathcal{O}(100\text{ m})$ horizontally displaced from the IP. Therefore, a detector with smaller or larger volume than the benchmark in figure 64 may be implemented, depending on available space and budget. Furthermore, the detector volume can be divided into smaller, independent modules (which cooperate for triggering purposes). These can be mass-produced economically and arranged according to the requirements of the experimental site. Such a modular construction also allows for a natural way to improve or extend the physics program of the experiment in an efficient way, by eventually upgrading, for example, one or a few modules with additional capabilities, such as higher tracking resolution for reconstruction of very low-mass LLPs below 10 MeV, or an additional material layer between the trackers for particle ID.

The MATHUSLA collaboration is currently studying such a modular design with the aim of producing a Letter-of-Intent in 2018. Crucial to this endeavor is the data from the MATHUSLA test stand, a $\sim 3 \times 3 \times 5\text{ m}$ MATHUSLA-type detector that took a few days of data in the ATLAS instrument hall in 2017 and will take data for a few months in 2018. This allows local CR backgrounds to be measured, background rejection and signal reconstruction strategies to be tested, and simulation frameworks to be calibrated.

In conclusion, the MATHUSLA detector concept calls for a dedicated LLP surface detector above ATLAS or CMS. A detector volume of $\sim 10^6\text{ m}^3$ gives sensitivity to LLPs near the BBN lifetime limit if they are produced with $\sim\text{pb}$ cross section. This improves LLP sensitivity, compared to the main detectors alone, by several orders of magnitude for many LLP scenarios. The detector is simple and relies on proven technology, making its construction in time for the HL-LHC upgrade feasible. Once constructed, MATHUSLA could function without modification as a detector for the HE-LHC (with increased sensitivity). A small-scale test stand detector is already taking data at CERN, and studies are underway to finalize a detailed design for the full-scale detector.

5.3.5. A COmpact Detector for EXotics at LHCb (CODEX-b). The CODEX-b proposal involves housing a small detector in the LHCb cavern—external to the LHCb detector itself—in a space approximately 25 m from the interaction point (IP8), behind the 3 m thick concrete UXA shield wall. This space is presently occupied by the LHCb data acquisition (DAQ) system, but will become available before Run 3 once the DAQ system is relocated to the surface. The layout of the cavern is shown in figure 66, with the location of CODEX-b overlaid. The nominal CODEX-b configuration features a $10 \times 10 \times 10\text{ m}$ volume instrumented with RPC tracking layers or other off-the-shelf tracking technology, as well as roughly 25 interaction lengths of shielding near IP8—e.g. 4.5 m of Pb—to suppress primary and secondary K_L , neutron, and other hadronic backgrounds. This shield requires an active muon veto with an efficiency of $\mathcal{O}(10^{-5})$, in order to reject backgrounds induced by muons or other charged particles in the downstream parts of the shield. The veto is located several metres within the shield such that backgrounds induced by neutral particles remain suppressed. See [104] for a study of a proof-of-concept example detector layout and corresponding tracking efficiency, as well as a detailed study of the backgrounds. More

Figure 66. Layout of the LHCb experimental cavern UX85 at point 8 of the LHC [448], overlaid with the proposed CODEX-b location. From [104].

ambitious technologies, including calorimetry, precision TOF measurements, or integration into the LHCb readout may also be feasible.

For the current discussion, the reach of CODEX-b for two benchmark models is quantified: first, a light scalar field, φ , that mixes with the SM Higgs boson is considered. If $m_\varphi \lesssim 5$ GeV, the production mode is primarily through inclusive $b \rightarrow s\varphi$ decays [449–451]. The LLP φ subsequently decays back to SM fermions through the same Higgs portal. The reach in terms of m_φ and the mixing angle s_θ is shown in the left-hand panel of figure 67. CODEX-b significantly extends the projected reach of LHCb using only VELO-based DV reconstruction, and covers part of the parameter space to which SHiP [452] and MATHUSLA [443] are projected to be sensitive. Studies of the potential LHCb reach to longer lifetimes using downstream tracking are ongoing [378, 453]. The right-hand panel of figure 67 indicates the reach for more general models, where the lifetime and production rate of φ are unrelated.

For the second benchmark, a dark boson, γ_d , produced through the exotic Higgs decay $h \rightarrow \gamma_d \gamma_d$ is considered. For concreteness the γ_d is taken to be a spin-1 field which can decay through mixing with the SM photon [70, 230, 456, 457]. In this benchmark, the production and decay are therefore controlled by different portals. The projected reach is shown in figure 68, overlaid with the reach of ATLAS [262, 273] and MATHUSLA [103]. In particular, at low γ_d masses, CODEX-b complements and significantly extends the reach of ATLAS and CMS.

Finally, it might be possible to install a larger version of the CODEX-b detector at IP2, after the ALICE collaboration concludes its heavy ion program. This option is named ‘A Laboratory for Long-Lived eXotics’ (AL3X) [459], and can make use of the existing ALICE TPC, supplemented with a thick hadron absorber. The B-field from the L3 magnet would provide a good momentum measurement of the tracks, something which is absent in MATHUSLA and CODEX-b. The feasibility of this proposal is however contingent upon a luminosity upgrade of IP2, as well as the possible continuation of the ALICE physics during Run 5.

5.3.6. The forward search experiment (FASER). If new LLPs are light compared to the weak scale and very weakly coupled, the focus at the LHC on searches for new particles at high p_T

Figure 67. Top: CODEX-b reach for $B \rightarrow X_s \varphi$ in the $s_\theta^2 - m_\varphi$ plane. Solid (dotted-dashed) line assumes $\mathcal{L} = 300 \text{ fb}^{-1}$ ($\mathcal{L} = 1 \text{ ab}^{-1}$). Bottom: inclusive CODEX-b $B \rightarrow X_s \varphi$ reach (solid lines). The shaded regions (dashed lines) indicate current LHCb limits (300 fb^{-1} projection) from $B \rightarrow K(\varphi \rightarrow \mu\mu)$, rescaled to the inclusive process and assuming $\text{Br}[\varphi \rightarrow \mu\mu] \simeq 30\%$ and 10% for $m_\varphi = 0.5 \text{ GeV}$ and 1 GeV , respectively. The gray shaded area and the dashed line indicate the approximate current [454] and projected [455] limits, respectively, for Belle II, from $B \rightarrow K^{(*)} \nu \bar{\nu}$ precision measurements. From [104].

may be completely misguided. In contrast to TeV-scale particles, which are produced more or less isotropically, light particles with masses in the MeV–GeV range are dominantly produced at low p_T . In addition, because the new particles are extremely weakly coupled, very large SM event rates are required to discover the rare new physics events. These rates are not available at high p_T , but they are available at low p_T : at the 13 TeV LHC, the total inelastic pp scattering cross section is $\sigma_{\text{inel}}(13 \text{ TeV}) \approx 75 \text{ mb}$ [460, 461], with most of it in the very forward direction. This implies

Figure 68. Comparison of experimental sensitivity to the BSM decay of an SM-like Higgs to dark photons with and without the muon shadow (μSh) for a few different existing and proposed detectors. The $\gamma_d \rightarrow \mu\mu$ branching ratio is taken from e^+e^- data [458]. The CODEX-b sensitivity here is the so-called ‘optimistic’ reach, with $\mathcal{L} = 1 \text{ ab}^{-1}$ and a larger volume, assuming DELPHI is removed. From [104].

$$N_{\text{inel}} \approx 2.3 \times 10^{16} (2.3 \times 10^{17}) \tag{5.5}$$

inelastic pp scattering events for an integrated luminosity of 300 fb^{-1} at the LHC (3 ab^{-1} at the HL-LHC). Even extremely weakly-coupled new particles may therefore be produced in sufficient numbers in the very forward region. Due to their weak coupling to the SM, such particles are typically long lived and travel a macroscopic distance before decaying back into SM particles. Moreover, such particles may be highly collimated. For example, new particles that are produced in pion (B -meson) decays are typically produced within angles of $\theta \sim \Lambda_{\text{QCD}}/E$ (m_B/E) off the beam-collision axis, where E is the energy of the particle. For $E \sim \text{TeV}$, this implies that even $\sim 500 \text{ m}$ downstream, such particles will have only spread out $\sim 10 \text{ cm} - 1 \text{ m}$ in the transverse plane. A small and inexpensive detector placed in the very forward region may therefore be capable of extremely sensitive searches to LLPs, provided a suitable location can be found and the signal can be differentiated from the SM background.

Forward search experiment (FASER) [105, 462–465], the is an experiment designed to take advantage of this opportunity. It is a small detector, with volume $\sim 1 \text{ m}^3$, that is proposed to be placed along the beam-collision axis, several hundreds of meters downstream from the ATLAS or CMS IP. In the following, we present a promising location of FASER, discuss the properties of the signal and the required detector design, and present the new physics reach for representative models.

As shown in figure 69, FASER will be placed along the beam collision axis, several hundreds of meters downstream from the ATLAS or CMS IP after the LHC tunnel starts to curve. A particularly promising location is a few meters outside the main LHC tunnel, 480 m downstream from the ATLAS IP, in service tunnel TI12, as shown in the bottom panels of figure 69. (A symmetric location on the other side of ATLAS in tunnel TI18 is also possible.) This tunnel was formerly used to connect the SPS to the LEP tunnel, but is currently empty and unused. As shown on the tunnel map in the lower left panel of figure 69, the beam collision axis passes through TI12 close to where it merges with the main LHC tunnel. A

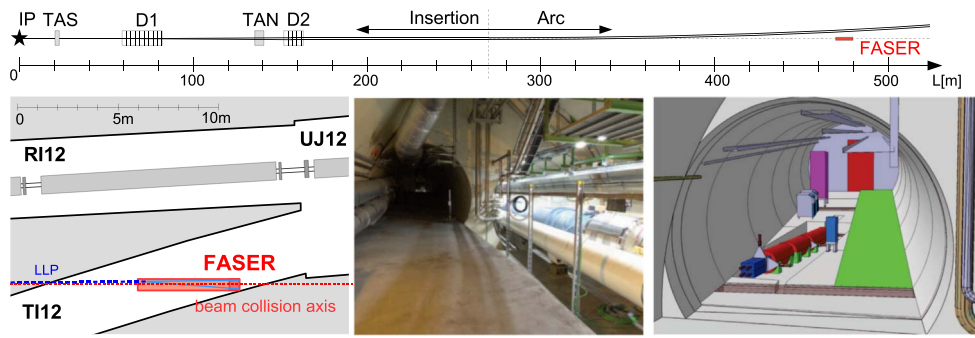

Figure 69. Proposed location for FASER in TI12. Top panel: a schematic drawing of the LHC and the very forward infrastructure downstream from the ATLAS and CMS interaction points; FASER is to be located 480 m from the IP, after the LHC ring starts to curve. Bottom panels: a map of the tunnel TI12 including the beam collision axis (left), a photo of this location (center), and a model of the experiment integrated in the TI12 tunnel (right).

more detailed study of the intersection between the beam collision axis and TI12 verifies that there exists space for FASER in the tunnel, as shown in the lower-right panel of figure 69.

In this location, FASER harnesses the enormous, previously completely unused and unexamined cross section for very forward physics ($\sigma \sim 100$ mb). This cross section implies that even very weakly coupled new particles can be produced in large numbers at the LHC. In addition, the production of LLPs at high center-of-mass energy results in long average propagation distances ($\bar{d} \sim \mathcal{O}(100)$ m) and decays that are far beyond the main LHC infrastructure in regions where the backgrounds are expected to be negligible.

FASER will search for LLPs that are produced at or close to the ATLAS IP in the very-forward direction, travel approximately 480 m, and then decay via $\text{LLP} \rightarrow \text{charged tracks} + X$. When LLPs are produced in the very-forward region of the beam collision axis, they typically have very high energies $E \sim \text{TeV}$. Although the identity of the LLP decay products depends on the mass of the LLP and the concrete new-physics model, some of the standard, characteristic LLP decay signatures are generically expected, such as two or more stable charged particles, such as electrons, muons or pions. This leads to a striking signature at FASER: two oppositely charged tracks with very high energy that emanate from a vertex inside the detector and which have a combined momentum that points back to the IP. A measurement of individual tracks with sufficient resolution and an identification of their charges is therefore imperative if the apparatus is to make use of kinematic features to distinguish signal from background. A tracking-based technology, supplemented by a magnet and a calorimeter to allow for energy measurements, will be the key components of FASER. Details of the detector design can be found in the Letter of Intent [462] and Technical Proposal [464].

The FASER signals consist of two extremely energetic ($\sim \text{TeV}$) coincident tracks or photons starting at a common vertex and pointing back to the ATLAS IP. Muons and neutrinos are the only known particles that can transport such energies through 100 m of rock and concrete between the IP and FASER. The CERN Sources, Targets, and Interactions group has computed the fluxes of muons and neutrinos at the FASER location using a FLUKA simulation [466–468]. These muon fluxes then allow one to estimate the rate and energy spectrum of muon-associated radiative processes near the detector. Preliminary estimates

show that muon-associated radiative processes and neutrino-induced backgrounds may be reduced to negligible levels [464, 464].

Emulsion detectors and battery-operated radiation monitors were installed in both TI12 and TI18 during Technical Stops in 2018. The results from these *in situ* measurements have validated the estimates of the FLUKA simulation, confirming that the high-energy particle background is highly suppressed and radiation levels are also very low and not expected to be problematic for detector electronics. Additional work is ongoing to refine background estimates, evaluate signal efficiencies, and optimize the detector.

In its first stage, FASER is an extremely compact detector, sensitive to decays in a cylindrical region of radius $R = 10$ cm and length $L = 1.5$ m. FASER is planned to be constructed and installed in LS 2 and will collect data during Run 3 of the 14 TeV LHC (2021–23). After FASER’s successful operation, FASER 2, a much larger successor with roughly $R \sim 1$ m and $L \sim 5$ m, could be constructed in LS 3 and collect data during the HL-LHC era (2026–35). More details on the FASER timeline can be found in the Letter of Intent [462] and Technical Proposal [464].

The sensitivity of FASER to detect LLPs has been studied in a plethora of new physics models, including dark photons [105], dark Higgs bosons [469], HNLs [297], axion-like particles (ALPs) [470], iDM [471], flavor-specific scalar mediators [472], $U(1)_{B-L}$ -gauge bosons [473], R -parity violating supersymmetry [60, 174] and SIMPs [474]. A summary on FASER’s physics reach for LLP can be found in [463]. Combined, these studies establish FASER’s significant impact on the LHC’s discovery reach for LLPs. The physics reach at FASER and FASER 2 for these models is shown in figure 70. Here we assume that backgrounds can be reduced to negligible levels. The gray-shaded regions of parameter space have already been excluded by previous experiments. For comparison we also show the projected reaches of other proposed experiments that search for LLPs.

Dark photons and ALPs (upper panels) are mainly produced in the decay of light mesons, via dark bremsstrahlung, or through the Primakoff process, and they are therefore very collimated around the beam collision axis. Already a very small detector is able to probe large and unconstrained regions of parameter space, making dark photons an ideal short-term goal for FASER. In contrast, dark Higgs bosons and HNLs (lower panels) define good long-term physics goals. They are both mainly produced in heavy meson decays, leading to a larger spread around the beam collision axis. A larger, but still relatively small, detector with $R \sim 1$ m is then required to exploit the full potential of FASER.

6. Reinterpretation and recommendations for the presentation of search results

Chapter editors: Giovanna Cottin, Nishita Desai, Sabine Kraml, Andre Lessa, Zhen Liu

6.1. Introduction

Models and scenarios with LLPs have seen an enormous rise in interest in recent years. They include supersymmetric scenarios with almost mass-degenerate lightest states [63, 65], highly split spectra [113, 475], very weakly interacting LSPs like gravitinos or axinos [476, 477], or R -parity violation [55, 110, 111], as well as equivalent scenarios in other SM extensions (e.g. extra-dimensional models) with new SM gauge-charged particles. More recent ideas include models with feebly interacting DM [146] (supersymmetric or not), asymmetric DM [478],

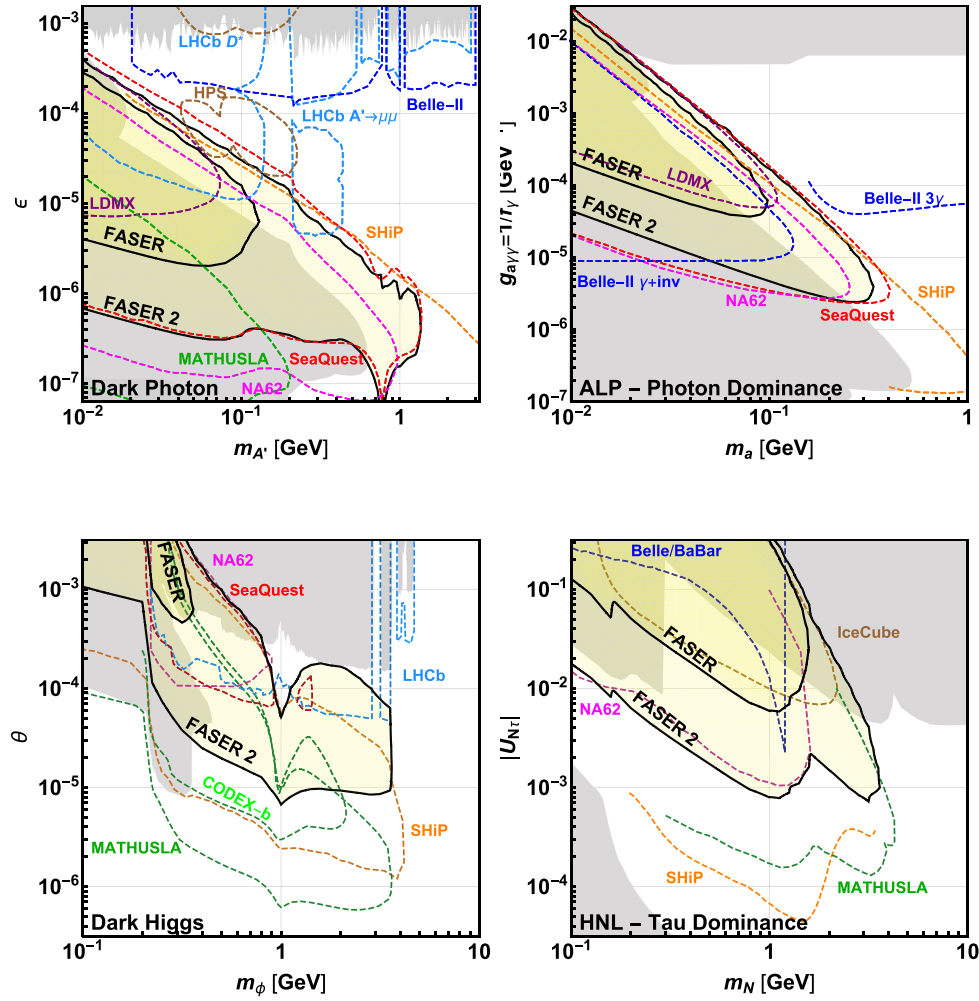

Figure 70. Projected FASER exclusion reach for benchmark new-physics scenarios containing dark photons (top left), ALPs with dominantly photon couplings (top right), dark Higgs bosons (bottom left), and HNLs with dominantly τ -mixing (bottom right) in the corresponding coupling versus mass planes. The gray shaded regions are excluded by current experimental bounds, and the colored contours represent projected future sensitivities of other proposed experiments that search for LLPs. See [463] for details.

HV models [66], and other dark-sector models; for a comprehensive discussion, see the classification of existing well-motivated theories with LLPs in chapter 2.

All of these models can feature a large variety of possible LLP signatures. In HV models [66], for instance, new particles can either decay into invisible dark particles or back to the SM, thus possibly leading to a mix of long-lived and prompt signatures, with or without missing transverse energy (\cancel{E}_T). Furthermore, new theoretical frameworks are constantly emerging, often motivated by new approaches to the hierarchy problem or DM. It is therefore

of great interest to our community to be able to reinterpret the LLP experimental results for new models which may be developed in the future¹⁸².

The reinterpretation of experimental results can generically be done in two ways: by applying appropriate simplified-model results to more complete models, or by reproducing the experimental analysis in a MC simulation. Clearly, the former is easier and faster, while the latter is more generally applicable but also more difficult and much more time consuming¹⁸³.

In the context of searches for prompt signatures with \cancel{E}_T , the use of simplified models has been shown to be a fruitful approach for both the experimental and theoretical communities [74, 76, 78, 87, 88, 480, 481]. Dedicated tools, notably SMOBELS [482–484] and FASTLIM [485], are publicly available and allow the user to reinterpret SUSY simplified-model results within the context of a full model. The coverage of a full model can, however, be severely limited by the kind of simplified-model results available, as discussed recently in [106] for the case of the phenomenological MSSM. Indeed, for some models the large number of relevant simplified-model topologies and their complexity can make the simplified-model approach inexpedient. In this case, a more complete and robust recasting procedure is necessary.

Again, for prompt signatures, a general recasting approach is available through several public tools, notably CHECKMATE [486, 487], MADANALYSIS5 [488, 489], RIVET [490] (v2.5 onwards) and Gambit’s COLLIDERBIT [491]. These tools allow the user to reproduce experimental analyses by means of MC event simulation coupled to an approximate emulation of detector effects¹⁸⁴. For the latter, CHECKMATE and MADANALYSIS5 rely on DELPHES [342], in some cases supplemented with appropriate tuning, while RIVET and COLLIDERBIT employ object smearing and analysis-specific reconstruction efficiencies. The ATLAS and CMS collaborations are helping these recasting efforts by providing more and more detailed information about their analyses and results. As an example, covariance matrices for the background correlations in the framework of simplified likelihoods were provided for the analysis of [492].

The situation is, so far, quite different for LLP searches. First, the presentation of results in terms of simplified models is still limited to a few topologies and does not always include all of the parameters required for a general purpose reinterpretation. It is worth noting that, compared with simplified models for prompt searches, simplified models for LLP searches always have at least one additional free model parameter: the lifetime of the LLP. Second, recasting LLP searches outside of the experimental collaborations is a difficult task since the searches are very sensitive to the detector response, which in most cases cannot be easily emulated by a fast detector simulation (and many backgrounds are also challenging to simulate due to their non-standard nature; see chapter 4 for a full discussion of backgrounds to LLP searches). As a result, while first steps towards the treatment of LLPs were achieved in SMOBELS [493] and MADANALYSIS5 [494], the implementation of LLP searches in public recasting tools is still in its infancy, thus limiting the applicability of the experimental results.

¹⁸² In this context we refer the reader also to the activities of the ‘Forum on the Interpretation of the LHC Results for BSM studies’ [479].

¹⁸³ When no new backgrounds need to be considered and the hypothesized signal does not affect control regions, one can simply determine the event counts in the signal regions and compare them to the 95% C.L. observed limits, or take the numbers of observed events and expected backgrounds to compute a likelihood.

¹⁸⁴ For completeness it should be noted that, while all of these tools include a more-or-less extensive set of SUSY searches, many of the searches for other, ‘exotic’ types of new physics cannot yet be reproduced outside the experimental collaborations. This concerns in particular searches relying on multivariate techniques such as boosted decision trees.

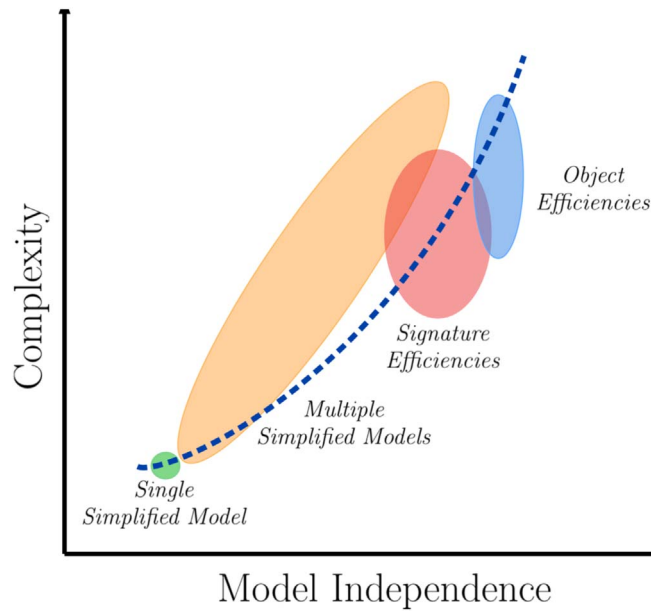

Figure 71. A qualitative overview of the possibilities for the presentation of results discussed in this chapter. The axes represent the complexity of information required by each format and the corresponding level of model independence.

In order to allow for a more extensive reinterpretation or recasting of the experimental analyses, detailed information concerning the detector performance and object reconstruction is needed. These can in principle be provided in the format of efficiencies¹⁸⁵ for selection and reconstruction of relevant objects, as demonstrated already by some pioneering experimental publications [237, 495]. One difficulty in this respect is that the information needed for recasting LLP searches is clearly analysis dependent, which means an additional workload for the analysis groups to provide this information on a case-by-case basis.

The objective of this chapter is to discuss the presentation of LLP search results with the aim that they can be re-used for interpretations beyond the models considered in the experimental publications. To this end, we first discuss in section 6.2 the various options for presenting the LLP results (and for a summary, see figure 71), and compare their advantages and shortcomings. In section 6.3, we discuss in more details how the simplified models defined in section 2 can be used to reinterpret LLP searches. In section 6.4, we present several attempts at recasting LLP searches, according to the LLP signature, focusing on HSCPs and various displaced objects. For each case, we elaborate on the lessons learned from the reinterpretation effort. Section 6.5 presents a first attempt to extend the public detector simulator DELPHES to deal with LLP searches, while section 6.6 focuses on reinterpretations performed within the experiments themselves, including the RECAST framework [496]. In section 6.7, we discuss complementary constraints on LLPs from reinterpreting prompt searches. We conclude in section 6.8 with our recommendations for the presentation of LLP results.

¹⁸⁵ We employ the term ‘efficiency’ in a broad sense. It can refer to reconstruction efficiencies, selection efficiencies, overall signal efficiencies, etc, which will be further specified below.

Figure 72. Possibilities for the presentation of results: simplified-model efficiencies assuming a specific topology of LLP production and decay, signature efficiencies assuming only a specific LLP decay, and final-state object efficiencies which are independent of the specific decay mode.

6.2. Options for presenting experimental results

A qualitative view of the various possibilities for presentation of search results is illustrated in figure 71. We broadly classify these possibilities according to the type of information provided for reinterpretation (in other words, the type of efficiency). Each type refers to distinct signal objects, as illustrated in figure 72. As we can see, each possibility relies on distinct assumptions about the signal, resulting in different levels of model dependence. Below, we provide a brief discussion of the advantages and limitations of the various possibilities of presentation of LLP search results. We gradually progress from the simplest case towards more complexity but also better re-usability.

Simplified models. In most cases, the simplified-model topology corresponds to single or pair production of the LLPs, though in principle simplified models for production through cascade decay of heavier states can also be envisaged. In any case, the simplified model incorporates important assumptions on the LLP production mode, decay mode and quantum numbers. Simplified-model results can be presented at different levels of sophistication and re-usability:

- exclusion curves in, e.g. a mass-versus-mass or mass-versus-lifetime plane, are highly model dependent and can rarely be used for reinterpretation without significant effort;
- cross section upper limits¹⁸⁶ can be applied to a larger variety of models in which the same LLP production and decay mode occurs through a rescaling of the cross section times branching ratio factor;

¹⁸⁶ For the sake of re-usability, cross section upper limits in absolute terms are much preferred over limits on the signal strength.

- simplified-model efficiencies go one step further: they make it possible to combine different topology contributions to the same signal region and compute an approximate likelihood using the number of expected and observed events.

The main advantages of simplified models are a parametrization of the signal sensitivity in terms of few physical parameters and a unified language and format applicable to a wide range of searches. Also, when re-using simplified-model results one avoids detector simulation uncertainties. The disadvantages are that the simplified-model result cannot be applied to other LLP production or decay modes, resulting in overly conservative limits if the LLP signal is composed from multiple topologies. This can be important if the LLP is a color singlet, but there are several heavier color-charged states which can be produced and decay to the LLP. In principle this can be overcome if efficiencies are provided for a sufficiently large number of simplified models (including cascade decays), as a function of the simplified-model parameters, which should include the LLP lifetime. These efficiencies can then be combined in order to compute the corresponding constraints to complex models, where multiple topologies are present¹⁸⁷. We stress, however, that in order for this combination to be possible, signal efficiencies and not cross section upper limits must be provided. The major drawback of this approach is that in order for the results to be applicable to a broad class of models, the number of required simplified models and their complexity can easily become very large. For achieving a high level of model independence, it is therefore desirable that the experimental analysis can be recast with MC event simulation. Two ways of presenting results are useful to this end: *signature efficiencies* and *object efficiencies*.

Signature efficiencies. Signature efficiencies are efficiencies for the reconstruction of the main LLP signature treated as a single ‘object’ (single charged track, DV, DT, etc) as a function of the LLP kinematic parameters and the lifetime. Signal efficiencies require the assumption of a specific LLP decay mode, but are otherwise highly model independent since they make no assumption on the LLP production mode. In addition, they are fully model independent for stable particles (within the detector volume), since in this case no assumptions about the LLP decay mode are required at all. In many cases, however, the reconstruction efficiencies depend on multiple kinematic variables, such as the LLP p_T , its transverse decay position, impact parameter, etc. As illustrated in section 6.4.6, these efficiencies can be very useful for recasting LLP searches, but they are not often provided by the experimental collaborations. Many recasting efforts consist of extracting these efficiencies from the provided information, but this procedure can result in large uncertainties.

Object efficiencies. Object efficiencies are efficiencies for the reconstruction of the physics objects relevant for building the LLP signature; for example, if an analysis reconstructs DV out of tracks, the associated object efficiencies would be the efficiency of reconstructing each displaced track that is later combined to form the vertex. They can clearly be applied to a wide range of LLP decay and production modes, since no specific assumptions about either is required. For instance, a displaced lepton reconstruction efficiency can be provided as a function of the lepton p_T and its transverse impact parameter d_0 . As discussed in section 6.4.2, these efficiencies can be used to recast LLP searches to an acceptable accuracy ($\sim 20\%$). Furthermore, as illustrated in section 6.4.6, knowledge of object efficiencies are essential for a general purpose recasting of the search. Within this approach the model dependence is minimal and can be restricted to a few general assumptions about the nature of the LLP. Also, object efficiencies could be included in fast-detector simulators, thus

¹⁸⁷ These points are illustrated by the reinterpretation of the CMS search for HSCPs [495] discussed in section 6.3: for the specific model considered in [97], constraints obtained using only a single simplified model (direct production of $\tilde{\tau}$ s in this case) can underestimate the bounds on the LLP mass by almost a factor of two.

providing a way of recasting LLP searches on a similar footing as prompt searches. The main difficulty with providing such object efficiencies is the potentially large number of parameters required for their parametrization.

6.3. Reinterpretation using simplified models

One of the possibilities for extending the experimental results from LLP searches to a large variety of scenarios is through the use of simplified-model topologies. Simplified models (or simplified-model spectra, SMS) have been widely used for the interpretation of prompt and LLP searches. As discussed in chapter 2, a large number of SMS topologies are possible for the distinct LLP signatures, which can be grouped by the LLP production mode, decay and lifetime. These SMS topologies aim to capture the main physical properties of the LLP signal and can then be used to constraint other scenarios containing similar topologies. The use of simplified-model results to constrain full models has been shown to be possible [93, 106, 482, 485, 497, 498], even though it has its shortcomings [106]. Also within the context of LLP searches, the use of simplified model results for reinterpretation can be a good alternative, e.g. when a recasting based on a MC simulation is difficult or is too computationally expensive. In this section, we briefly review how SMS results can be used to reinterpret searches for full models as well as the particular challenges presented by LLP searches. A concrete example of reinterpretation using simplified models is given in section 6.3.2, based on the results of [97].

6.3.1. From simplified to full models. The interpretation of experimental results using simplified models typically corresponds to producing upper limits on the production cross section or signal efficiencies for a specific SMS topology (production and decay channel). These results are provided as a function of the simplified model parameters, which have been largely taken to be the masses of the BSM particles appearing in the topology. For LLP topologies, however, a new parameter must be considered: the LLP lifetime (see chapter 2). With the exception of searches for stable particles, the lifetime is one of the main parameters affecting the topology efficiency and upper limit.

Once signal efficiencies¹⁸⁸ (ϵ) are provided for one or more SMS topologies, these can be used, under some approximations, to quickly compute the number of expected signal events (S) for a full model:

$$S = \mathcal{L} \times \left(\sum_{\text{SMS}} \sigma_{\text{SMS}} \times \text{BR}_{\text{SMS}} \times \epsilon_{\text{SMS}} \right), \quad (6.1)$$

where \mathcal{L} is the luminosity for the respective search and the sum runs over simplified model topologies. Since the production cross section (σ_{SMS}) and branching ratios (BR_{SMS}) for each topology can be quickly computed for any full model, the simplified model signal efficiencies (ϵ_{SMS}) can be directly used to obtain the signal yield. This procedure does not rely on any MC simulation or recasting of LLP searches and can be easily applied to a wide variety of models, provided ϵ_{SMS} is known. The main limitation of this approach comes from the limited (although growing) number of SMS results available. Since ϵ_{SMS} is typically known only for very few simplified models, the sum in equation (6.1) is limited to the number of available topologies, resulting in an under-estimation of S .

¹⁸⁸ For simplicity we will refer to the signal acceptance times efficiency as ‘signal efficiency’. This efficiency is a function of the simplified model parameters, including the LLP lifetime.

Figure 73. Region of the CMSSM parameter space with long-lived NLSP staus. The light gray regions are excluded by the requirements $m_{\tilde{\tau}} - m_{\tilde{\chi}_1^0} > m_{\tau}$ and $m_h < 120$ GeV. The top red region is excluded by the upper limit on the neutralino relic density, while the lower blue region is excluded by the CMS constraints on direct production of long-lived staus. For more details see [97].

For prompt SUSY searches, a systematic approach for reinterpreting simplified model results based on the procedure outlined above has been developed in [482, 485]. Furthermore, using the large number of available SUSY SMS results, public tools are available for constraining full models using these results [483, 485]. The same procedure can also be applied to LLP SMS results, as shown in [97] for the case of HSCPs and implemented recently in SMOBELS [493]. In the next section we review some of the results found in [97]. Although these have been obtained within the context of HSCPs, the main results can be generalized to other LLP signatures, and demonstrate some of the advantages and shortcomings of reinterpretations using LLP simplified models.

6.3.2. Reinterpretation using HSCP simplified models. The CMS search for HSCPs in [495] provided signal efficiencies for the simplified model topology $pp \rightarrow \tilde{\tau}\tilde{\tau}$ as a function of the stau mass. In the language of the simplified models of section 2.4.2, this is the direct pair production mode of a charged LLP. The stau is assumed to be stable (at detector scales), thus producing a highly ionizing track, which can be used to search for this scenario (see section 3.5). Since the stau lifetime (τ) is assumed to be $\gg 10$ ns, the signal efficiencies do not depend on τ , thus simplifying the SMS parameter space, which reduces to the stau mass¹⁸⁹. The relevant selection efficiencies required for a general purpose MC recasting of the HSCP search have also been provided by the CMS analysis; see section 6.4.1 for details.

The efficiencies for the stau simplified model can be used to constrain a full BSM scenario which contains HSCPs. In [97], the region of the CMSSM parameter space with $m_{\tilde{\tau}} - m_{\tilde{\chi}_1^0} < m_{\tau}$ has been considered, since it provides a possible solution to the Lithium problem [499, 500]. Due to the small mass difference, the stau is long-lived and decays outside the detector, thus generating a HSCP signal. In figure 73, we show the constraint on

¹⁸⁹ We point out that it is still possible to apply these simplified model results to models with smaller LLP lifetimes if we include the suppression factor from the LLP decay length distribution, as discussed in section 6.4.1.2.

Table 5. Definitions of the HSCP simplified models considered in this section. The symbol X represents the HSCP, Y_i represents intermediate BSM particles, SM represents any Standard Model particle and inv represents an invisible final state, such as the neutralino. The correspondance with the simplified models language of chapter 2 (section 2.3.1) is also given.

SMS topology	Notation in chapter 2
$pp \rightarrow X X$	DPP
$pp \rightarrow Y_1 Y_1, Y_1 \rightarrow SM X$	HP
$pp \rightarrow Y_1 Y_1, Y_1 \rightarrow SM Y_2, Y_2 \rightarrow SM X$	—
$pp \rightarrow Y_1 Y_2, Y_1 \rightarrow SM Y_2, Y_2 \rightarrow SM X$	—
$pp \rightarrow Y Y, Y \rightarrow SM SM X$	HP
$pp \rightarrow inv X$	CC
$pp \rightarrow Y_1 Y_2, Y_1 \rightarrow SM inv, Y_2 \rightarrow SM X$	—
$pp \rightarrow Y_1 Y_2, Y_1 \rightarrow SM inv, Y_2 \rightarrow Y_3 SM, Y_3 \rightarrow SM X$	—

the CMSSM parameter space obtained using only the simplified model provided by CMS (direct stau production). Since the simplified model only contains one parameter, it translates to a limit on the stau mass ($m_{\tilde{\tau}} < 260$ GeV), as shown by the blue region in figure 73. In this CMSSM scenario, however, direct production of staus only contributes to a small fraction of the total HSCP signal, since staus are typically produced from cascade decays of heavier SUSY states, such as charginos, squarks and gluinos. (Note that these correspond to the HP modes of section 2.4.2.) Furthermore, there are several possible topologies which contain a stau and the LSP ($\tilde{\chi}_1^0$) in the final state, thus resulting in a mixed missing energy-HSCP signature. Therefore using only the CMS constraints for the direct stau production simplified model largely underestimates the sensitivity of the CMS search.

In order to improve the constraints shown in figure 73, one must have efficiencies for several SMS topologies. Fortunately, a MC recasting of the 8 TeV CMS search is possible (see section 6.4.1 for details) and can be used to compute simplified model efficiencies. In [97], seven additional simplified models containing cascade decays were considered and their efficiencies computed as a function of the masses appearing in the topology. A summary of the topologies considered are shown in table 5. It is important to point out that it is not necessary to specify the SM final states appearing in the simplified models, since the HSCP search is inclusive and the efficiencies do not depend on the additional event activity. Using this extended database of simplified model efficiencies and equation (6.1), we can compute a more inclusive signal yield for each point of the CMSSM parameter space and improve the constraints on the model. The results are shown in figure 74, where we see a drastic improvement in the region excluded by the constraints on HSCPs, as expected. For this specific scenario (with $\tan \beta = 10$), all the parameter space is excluded either by the CMS or DM constraints [97].

Figure 74 illustrates the feasibility of using simplified model efficiencies to constrain full models. This approach has the advantage of being computationally inexpensive (once the efficiencies are known) and can be used to quickly test a large number of model points. However the approach relies on a few approximations and is never fully inclusive, since the number of SMS topologies with published efficiencies is always limited. Hence, it is important to verify how close the simplified model reinterpretation comes to the full recasting using a MC simulation. In [97] it was shown that, within the CMSSM scenario discussed above and using eight simplified model topologies, the SMS results reproduce the full

Figure 74. Region of the CMSSM parameter space with long-lived NLSP staus, as in figure 73, but here additionally using all the simplified models listed in table 5.

simulation within 20% or better. Since this error is of the order of the uncertainties in recasting, the use of simplified models becomes a viable alternative to full recasting. The SMS reinterpretation is even more relevant for the cases where a straightforward MC recasting is not possible.

Lessons learned. The example discussed in section 6.3.2 illustrates how simplified models for LLPs can be used as a reinterpretation tool. One important point which becomes clear once we compare figures 73 and 74 is the importance of a sufficiently inclusive database of simplified model efficiencies. In particular, depending on the full BSM scenario considered, the minimal set of simplified models proposed in chapter 2 and the appendix may not be sufficient to allow for a reinterpretation based on simplified model results alone. The reason is that this set was derived as the minimal set to generate a collection of relatively inclusive signatures, but may not correctly model the efficiency of every UV theory leading to that signature. In these cases, results for additional simplified model topologies are necessary and can be provided by the experimental collaborations or generated by theory groups if a full recasting is available. Furthermore, since LLP searches can be very inclusive, the simplified models considered can also be defined inclusively, as discussed above. In this way a limited number of simplified models can cover a large number of event topologies, thus increasing the SMS coverage of full models.

6.4. Recasting examples for specific searches

Here we provide examples of recasting specific experimental searches for several LLP signatures: searches for HSCPs, displaced leptons, displaced jets, displaced LJs, non-pointing photons, and DV. These recasting attempts have been made outside the experimental collaborations, making use of the public information provided by the experimental note or publication. The aim here is to highlight the challenges faced when recasting LLP searches and also to highlight the cases where the experimental information provided is straightforward and useful for recasting.

6.4.1. Heavy stable charged particles. Searches for HSCPs are based on the signature of highly ionizing tracks and/or an anomalous TOF between the particle's production at the IP and its arrival in the muon detector [390] (see section 3.5.1.1 for more details). Both signatures are sensitive to the particle's velocity and exploit the production of HSCPs outside of the ultra-relativistic regime, allowing for a powerful discrimination against the highly boosted SM backgrounds. HSCP searches assume particles are sufficiently long-lived to traverse the entire detector. They have been interpreted for HSCPs that are purely electrically charged or carry color charge, the latter of which hadronize to form R -hadrons as they propagate through the detector [10]. Typically, the HSCP signature yields high sensitivities providing a very strong background rejection while still allowing for large signal efficiencies. As a consequence, search strategies for new physics models with HSCPs typically do not benefit from more model-dependent selection criteria, like requiring additional particles in the event [95]. The corresponding searches can, hence, be performed in a mostly inclusive manner concentrating on the HSCP candidate itself. This fact opens up the possibility of providing a widely applicable recasting based on signature efficiencies. This approach has been followed by the CMS Collaboration [495], which has provided probabilities for HSCP candidates to pass the on- and off-line selection criteria for Run 1 as a function of the relevant kinematical parameters.

In this section we describe the recasting of the 8 TeV CMS search for HSCPs and discuss its validation and applicability. Furthermore, we comment on the attempt to extrapolate the 8 TeV signature efficiencies to the corresponding 13 TeV analysis, for which the corresponding efficiencies have not been provided by CMS.

6.4.1.1. Recasting using signature efficiencies. Reference [495] provides efficiencies for the reconstruction and selection of HSCP candidates with $|Q| = 1$ in the form of on- and off-line probabilities, $P_{\text{on}}(\mathbf{k})$ and $P_{\text{off}}(\mathbf{k})$. These are given as a function of the truth-level kinematic variables velocity (β), pseudo-rapidity (η) and transverse momentum (p_{T}) of isolated HSCP candidates, so the vector \mathbf{k} is defined as: $\mathbf{k} = (\beta, \eta, p_{\text{T}})$. The on- and off-line probabilities must be applied to isolated HSCP candidates, which are required to fulfill

$$\left(\sum_i^{\text{charged}} p_{\text{T}}^i \right) < 50 \text{ GeV}, \quad \left(\sum_i^{\text{visible}} \frac{E^i}{|\mathbf{p}|} \right) < 0.3, \quad (6.2)$$

where the sums include all charged and visible particles, respectively, within a radius of $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.3$ around the HSCP candidate track, p_{T}^i denotes their transverse momenta and E^i their energy. Muons are not counted as visible particles and the HSCP itself is not included in either sum.

If an event contains one or more HSCPs satisfying the above isolation criteria, the efficiency for the event to pass the analysis selection is given by:

$$\epsilon = \epsilon_{\text{on}} \times \epsilon_{\text{off}}. \quad (6.3)$$

For an event with one HSCP candidate $\epsilon_{\text{on/off}}$ is directly given by the signature efficiencies $P_{\text{on/off}}(\mathbf{k})$. For an event with two candidates, the efficiency reads [495]

$$\epsilon_{\text{on/off}} = P_{\text{on/off}}(\mathbf{k}^1) + P_{\text{on/off}}(\mathbf{k}^2) - P_{\text{on/off}}(\mathbf{k}^1)P_{\text{on/off}}(\mathbf{k}^2), \quad (6.4)$$

where $\mathbf{k}^{1,2}$ are the kinematical vectors of the two HSCPs in the given event. Therefore the on- and off-line probabilities combined with the isolation criteria allow for the complete recasting of the HSCP search using only truth-level events generated in MC.

Figure 75. Left: signal efficiency ϵ of the HSCP search. Right: 95% C.L. cross section upper limit for the GMSB model as the function of the stau mass. We compare the CMS analysis [495] from the full detector simulation (red solid lines) with the recasting using signature efficiencies (blue dashed lines). In the lower frames we show the respective ratios $\epsilon^{\text{Full}}/\epsilon^{\text{Recast}}$, $\sigma_{\text{limit}}^{\text{Full}}/\sigma_{\text{limit}}^{\text{Recast}}$. Taken from [97].

The recasting of the 8 TeV search was performed in [97] using the procedure described above. Events were simulated using PYTHIA 6 [501] and the total signal efficiency for a given model was then computed using:

$$\epsilon = \frac{1}{N} \sum_{i=1}^N \epsilon_i,$$

where the sum runs over all the (N) generated events and ϵ_i is the efficiency for each event computed using equation (6.3). Since the probabilities $P_{\text{on/off}}(\mathbf{k})$ are given for four distinct cuts on the reconstructed HSCP mass (m_{rec}), these were considered as four different signal regions. The number of observed events and the expected background for which of these cuts are reported in [495].

6.4.1.2. Validation and applicability. A validation of the method described above was done in [97] using the same GMSB model considered by CMS [495]. This supersymmetric model features a gravitino and a long-lived stau as the lightest and NLSP, respectively. Since the stau only decays outside the detector volume, all cascade decays of the produced sparticles terminate in the lightest stau, which provides the HSCP signature. The left pane of figure 75 compares the resulting signal efficiency obtained by the recasting and the full CMS detector simulation. The signal efficiencies agree within 3%, demonstrating that the recast is an excellent approximation to the full CMS simulation. The differences are of the order of the statistical uncertainties from the MC simulation of the signal. In the right pane of figure 75, we show the 95% C.L. upper limits on the inclusive production cross sections, which, again, agree (within $\sim 3\%$) with the ones obtained by the full simulation in [495]. Note that both limits are based on the discrete mass cuts on m_{rec} mentioned above. In the full CMS analysis [306], an event-based mass cut is used, resulting in slightly stronger constraints for some HSCP masses.

Due to the inclusive nature of the search, the above recasting provides a widely applicable and highly reliable way to reinterpret the HSCP search for arbitrary models

containing detector-stable HSCPs. Accordingly it has been used in a variety of phenomenological studies. For instance, it has been used for reinterpretations of supersymmetric models [96, 205, 502, 503] and non-supersymmetric models of very weakly interacting DM [142, 148]. In [96, 142], the recasting has been used to reinterpret the HSCP search for finite lifetimes by convolving the signature efficiency with the fraction of HSCPs that decay after traversing the relevant parts of the detector. The recasting has also been used for a reinterpretation in terms of simplified models, as discussed in section 6.3.2.

6.4.1.3. Extrapolation to 13 TeV. While the CMS search for HSCPs at 8 TeV has provided the signature efficiencies discussed above, the same is not true for the 13 TeV analysis [4]. Therefore a straightforward recasting of the Run 2 search is not possible. Nonetheless, since the 8 TeV CMS search has proven to be extremely useful in constraining models with long-lived charged particles, it would be desirable to recast the 13 TeV analysis as well. In the following we discuss an attempt [504] to obtain a similar recasting for the corresponding HSCP search at 13 TeV. Our aim is to extrapolate the public 8 TeV efficiencies to Run 2 by introducing a correction function F that accounts for the differences between both runs:

$$P_{\text{off}}^{13 \text{ TeV}}(\mathbf{k}) = F(\beta) \times P_{\text{off}}^{8 \text{ TeV}}(\mathbf{k}), \quad (6.5)$$

where we have assumed that the correction function is mainly dependent on the HSCP velocity. If $F(\beta)$ is sufficient to account for the difference between both runs and can be computed, we can directly obtain $P_{\text{off}}^{13 \text{ TeV}}$ and, using the procedure described in section 6.4.1.1, recast the 13 TeV analysis.

In order to compute the correction function $F(\beta)$, we use the total signal efficiencies reported by the 13 TeV CMS analysis [4] for direct production of long-lived staus. Since the signal efficiencies have been provided for six distinct values of the stau mass, we perform a fit of F to the efficiencies reported. We chose to parametrize the correction function $F(\beta)$ by eight parameters (C_i). Using MADGRAPH5_AMC@NLO [226] and PYTHIA 6 [501], we obtain generator-level events for each of the stau mass points at 13 TeV. Then, comparing the total signal efficiencies obtained for a given set C_i to the efficiencies reported in [4], we can determine the best-fit values for the C_i parameters and consequently the best-fit for the correction function ($F_{\text{best-fit}}$). The result of the best-fit function and its 1σ uncertainty is shown in figure 76. The deviation of F from 1 implies a decrease or increase of the respective detector and signal efficiency between the 8 and 13 TeV analyses. Figure 76 also shows that the function is loosely constrained for low values of β .

In order to verify the validity of the extrapolation to 13 TeV, we use $F_{\text{best-fit}}$ and equation (6.5) to compute the total signal efficiencies for the same six benchmark points used in the fit. A comparison between the results obtained through recasting and the efficiencies reported by CMS is shown by the second and third columns in table 6. The results reproduce the CMS values well within the expected uncertainties, thus validating the fitting procedure. Furthermore, the inclusion of the correction function significantly improves the agreement with respect to the direct extrapolation of the 8 TeV efficiencies ($F = 1$), as shown by the fourth column in table 6.

The high level of agreement obtained with $F_{\text{best-fit}}$ for the direct stau benchmark points is expected, since these points were used in order to fit the correction function. Therefore an independent test of the above fit must be performed in order to properly validate the recasting of the 13 TeV analysis. Fortunately CMS has also reported efficiencies for a second scenario, the GMSB model with long lived staus. This scenario not only contains direct stau production, but also includes production through cascade decays of heavier sparticles. Since

Figure 76. Best-fit correction function $F(\beta)$, used for recasting the CMS HSCP search (described in the text), and its $\pm 1\sigma$ band.

Table 6. Efficiencies for the 13 TeV LHC for the six benchmark masses in the direct stau production scenario reported by CMS (second column) and obtained through recasting using $F_{\text{best-fit}}$ and without the inclusion of the correction function ($F = 1$).

m_{HSCP} (GeV)	Direct production		
	$\epsilon(\text{CMS})$	$\epsilon(F_{\text{best-fit}})$	$\epsilon(F = 1)$
200	0.235	0.232	0.259
308	0.294	0.298	0.346
494	0.387	0.384	0.452
651	0.450	0.448	0.503
1029	0.497	0.501	0.466
1599	0.428	0.429	0.225

the GMSB model produces distinct event topologies, it provides a good test for the validity of the recasting procedure.

The results for the six GMSB benchmark points considered in [4] are shown in table 7. As we can see, they deviate from the CMS values by up to 20% for large stau masses, where our estimate undershoots the CMS efficiencies. Although the overall agreement is improved by the correction function, the result is not entirely satisfactory, given that the uncertainties for the 8 TeV recasting were under 5% (see figure 75). The observed difference might arise from several shortcomings in our description.

In particular, we assume F to only depend on β whereas the full probability maps are parametrized in the three kinematic variables β , η and p_T . However, assuming a dependence of all three kinematic variables is clearly not feasible given the very limited amount of information provided by the 13 TeV CMS analysis. Therefore we conclude that it is not possible to extrapolate the 8 TeV efficiencies in a straightforward way without additional information from the experimental collaboration.

Table 7. Efficiencies for the 13 TeV LHC for the six GMSB model benchmark points reported by CMS (second column) and obtained through recasting using $F_{\text{best-fit}}$ and without the inclusion of the correction function ($F = 1$).

m_{HSCP} (GeV)	GMSB		
	$\epsilon(\text{CMS})$	$\epsilon(F_{\text{best-fit}})$	$\epsilon(F = 1)$
200	0.276	0.297	0.279
308	0.429	0.401	0.423
494	0.569	0.494	0.556
651	0.628	0.524	0.580
1029	0.665	0.538	0.493
1599	0.481	0.442	0.228

Lessons learned. The prominent signature of HSCPs allows for a mostly inclusive search strategy concentrating on the HSCP track itself. Hence, searches for HSCPs can be reinterpreted using signature efficiencies in a widely applicable and highly reliable way. This possibility has been followed by the CMS Collaboration providing signature efficiency maps for the 8 TeV LHC. The validation reveals an excellent performance. The recast has been successfully used in the literature.

The signature efficiencies for 8 TeV can also be used to estimate the ones for Run 2 by applying a multiplicative correction function. While such an extrapolation introduces some level of approximation, a better knowledge of the underlying changes between both runs might reduce the uncertainties.

6.4.2. Displaced leptons. Searching for displaced leptons by requiring the leptons to have large impact parameters with respect to the PV is a very clean strategy due to the low backgrounds, and such searches are usually very straightforward to recast. The CMS displaced $e\mu$ search [275] demands two oppositely charged, different flavour (e, μ) leptons with large impact parameters (see also section 3.2). The recast is fairly straightforward to do, and the biggest difficulty in doing so is locating all of the relevant information as it is not all provided within the main document. The ‘standard’ isolation requirements used in the search can be found in an earlier version of the search [505]. The necessary cuts on the displaced decay position (v_T, v_Z) as well as the selection (as a function of p_T), reconstruction (as a function of impact parameter, d_0) and trigger efficiencies can be found on an additional website [506] containing auxiliary information for recasting. Although all of this information is excellent and greatly facilitates recasting the search, it is a challenge to collect the relevant information due to the fact that the additional material is not referenced in the document.

The benchmark model used in this search is the direct pair production of stops that decay through small lepton-flavor-universal RPV $\lambda'_{ijk} L_i Q_j D_k^c$ couplings ($\lambda'_{133} = \lambda'_{233} = \lambda'_{333}$) to yield displaced $\tilde{t} \rightarrow eb, \mu b$, and τb decays. The signal is simple to generate, where the only challenge is in handling the displacement properly. The most identifying pre-selection requirement of this search is that the transverse impact parameter, $|d_0|$, is required to be larger than $100 \mu\text{m}$ for both the electron and muon. The impact parameter is not the point where the parent object (e.g. τ or b) decays, i.e. the v mentioned above, but rather the distance to the point of closest approach of the lepton’s track relative to the center of the beampipe in the transverse plane. Backgrounds in this search from $Z \rightarrow \tau\tau$ or heavy flavor tend to result in leptons that are nearly collinear with the parent due to the small mass-to-momentum ratio, and yield a small impact parameter even for decays well on the lifetime tail of the parent. Events

Table 8. Left: preselection cuts in [275] (see also [506]). Right: the transverse impact parameter bins that define the exclusive signal regions. Table and figure taken from [205].

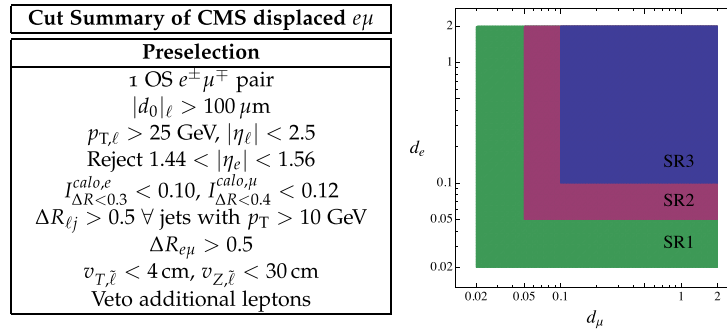

Figure 77. Validation of the CMS displaced $e\mu$ search [275] for the displaced supersymmetry benchmark model [507]. Figure taken from [205].

are binned across three exclusive signal regions: SR3, where both leptons have transverse impact parameters $|d_0|$ between 0.1 and 2.0 cm; SR2, with $|d_0|$ of both leptons between 0.05 and 2.0 cm, but not satisfying the requirement of SR3; and SR1, with $|d_0|$ between 0.02 and 2.0 cm, but not within SR2 or SR3. All selection requirements are summarized in table 8.

Figure 78. Number of expected events in the signal regions defined based on $|d_0|$ for the CMS displaced $e\mu$ search. The green points refer to the expected signal published by the analysis. Left: validation for 8 TeV analysis. Production cross section assumed NLO+NLL value 85.6 fb for $M_{\tilde{t}_1} = 500$ GeV, BR = 0.33 in each ℓ -channel. Right: validation for 13 TeV analysis. Production cross section assumed NLO+NLL value 67.0 fb for $M_{\tilde{t}_1} = 700$ GeV. The 13 TeV numbers are made using efficiency maps published for the 8 TeV search, as the 13 TeV maps are not yet public. Figures taken from [504].

In figure 77, we present the validation of the CMS displaced $e\mu$ search [275] from the study performed in [205]. For this search, we show the recommended 25% modeling uncertainty¹⁹⁰. The recast agrees very well with the results from the CMS displaced $e\mu$ search in the region of highest sensitivity, $300 \mu\text{m} < c\tau < 50$ cm, but exhibits a moderate deviation on the tails. As this extremely low efficiency region is overly sensitive to the tails of kinematic distributions, it may be the case that the sensitivity is slightly under-estimated for lifetimes near 1 m or $100 \mu\text{m}$, but this discrepancy typically has no qualitative impact on any application of the results.

6.4.2.1. Extrapolation to 13 TeV. We now show another reinterpretation example of the CMS displaced $e\mu$ in order to highlight the comparison between 8 TeV [275] and 13 TeV [197] analyses. We compare in figure 78 our reproduction of expected signal events with the published validation material for the 8 TeV version, and the partially-available validation material for the 13 TeV search. Information on efficiency maps from the 8 TeV analysis was needed to obtain an extrapolation to 13 TeV, as the 13 TeV efficiency maps are not yet public. As we can see, the 8 TeV recast for the CMS displaced lepton search [275] agrees very well in the region of highest sensitivity. The 13 TeV recasting, however, under-estimates the CMS values by a factor of two or more. This is likely due to the fact that the lepton efficiencies can not be directly extrapolated from 8 to 13 TeV, as assumed in making figure 78. Also, with the absence of a cut-flow table, it is impossible to verify where the mis-match arises, whether it is due to mis-modeling of the signal region cuts or due to genuine changes in the efficiencies.

Lessons learned. The selection and trigger efficiencies provided by CMS are very useful for recasting the 8 TeV CMS search for displaced leptons [275] and allow for a very good level of agreement. The main challenge, however, consisted in collecting all the available

¹⁹⁰ A similar validation was done in [96] with details provided in its appendix D. After applying a flat 80% efficiency, a 20% modeling uncertainty is found to be appropriate, as shown in figure 14 of the reference.

information, which was not provided by the main document in [275]. Furthermore, the corresponding information for the 13 TeV search is not publicly available and an extrapolation of the 8 TeV efficiencies was shown to be inadequate.

6.4.3. Displaced jets. Searches for displaced jets are less straightforward to reinterpret than displaced leptons. Interest in accurate reinterpretation is increasing, as many new physics models give rise to this particular signature. The CMS search for displaced di-jets [508] was reinterpreted in [26] to explore LLP signatures for certain weak-scale models of baryogenesis [24, 26, 509], as well as a study [96] to understand current limits on long-lived signatures in supersymmetry.

The CMS search [26] uses a multivariate discriminant composed of observables that are challenging to model in MC, such as the track-multiplicity of the vertex and the root mean square of a cluster track-multiplicity variable. The reinterpretation approach in [26, 96] was to construct track information at truth level based on the output of a parton shower program (such as PYTHIA 8), and then use the truth-level information to construct the various vertex, cluster, and track-level observables for each event. As it is difficult to adequately account for inefficiencies of track and vertex reconstruction, the efficiency of passing the cuts with truth-level observables was considered and then it was normalized to the results from CMS. To do so, the authors of [26] simulated identical signal models to those with efficiencies reported by the CMS collaboration, assumed that the MC truth-level reconstruction gave an adequate description of kinematics but *not* track and vertex reconstruction, and so computed a ratio of truth-level efficiencies to those reported by CMS. The resulting efficiency ratios were used to re-scale the truth-level results of other models, leading to a reinterpretation of the CMS search for different models beyond the ones they considered. The details can be found in [26]; a more sophisticated approach in which object efficiencies were estimated and applied to tracks and DV in [96].

To validate this approach, truth-level quantities for the models constrained in [508] were computed and compared to the numbers and distributions reported. For example, comparisons of the distributions of the observables going into the multivariate reinterpretation discriminant, as well as the output of the multivariate discriminant itself, could be performed. While the truth-level distributions disagreed with those of CMS for individual observables, the actual multivariate discriminant output agreed with that of CMS at better than 25%. The ratio of truth-level efficiencies to CMS efficiencies are also compared for different LLP masses and kinematics, and these typically agree with one another at the factor-of-two level [26]. This suggests that this reinterpretation of the CMS results in terms of cross-section limits is likely accurate to the factor-of-two level.

Lessons learned. We find that a rather naïve truth-level reconstruction of the event could give a reinterpretation of cross-section limits to agree within a factor of two, provided the efficiencies were normalized to the experimental values using an overlapping set of signal models. One of the major obstructions to improving the accuracy of the estimate was the model dependence observed among the ratios of efficiencies between truth-level information and CMS. For instance, it was found that highly boosted models showed a much lower relative reconstruction rate in data versus truth-level MC than less-boosted LLPs. Since pair production of LLPs was considered near threshold in [26], this degradation in the performance of highly boosted LLPs does not greatly affect the confidence in the final result. However, it does suggest that characterizing the effects of the particle boost are important for reinterpretation.

In addition, with a larger and more diverse set of signal benchmarks available, the prospects for the reinterpretation of search results are better. The reasons are twofold:

- Increasing the number of presented signal models by the collaboration allows for more cross-checks between MC and the results in data. This allows for more sophisticated tuning of efficiencies as applied to truth-level events.
- Having a more diverse set of benchmark signal models means that it is easier to disentangle various kinematic effects on the efficiency (such as the LLP mass, boost, etc) and find a signal benchmark that most closely matches the model for which one wants to derive sensitivity.

6.4.4. Displaced LJs. A variety of scenarios predict the existence of LLPs decaying to a pair of highly collimated leptons, also known as LJs [127]. Models giving rise to LJ signatures include heavy RHNs, exotic Higgs decays, and dark gauge bosons. The relevant signature is one or more LJs emerging from a DV. In many cases, there can also be associated prompt objects, such as a prompt lepton produced in conjunction with the RHN (corresponding to CC production in the simplified model framework of section 2.4).

Existing searches. Current search results are outlined in section 3.2. The search in [273] was interpreted in the framework of the Falkowski–Ruderman–Volanksy–Zupan (FRVZ) model [155] for the Higgs boson interacting with a hidden sector containing a massive dark photon (γ_d), massive neutralinos, and three hidden scalars. Displaced LJs are produced at the end of Higgs cascade decay that also yields two hidden light stable particles (HLSPs). Depending on the hidden-sector spectrum, the cascade decay may yield two or more γ_d that each decay to pairs of SM charged particles via kinetic mixing with the hypercharge gauge boson. The γ_d decay products are highly collimated. For $m_{\gamma_d} < 500$ MeV, LJs are the dominant decay mode, while for larger dark photon masses, displaced hadronic jets can also be significant.

Results are presented as limits on $\sigma \times \text{BR}(H \rightarrow n\gamma_d + X)$ ($n = 2, 4$) as a function of the $\gamma_d c\tau$. The strongest limits from the 8 TeV dataset arise from events that require at least one LJ with muons. For $n = 2$, $a\sigma \times \text{BR}(H \rightarrow 2\gamma_d + X)$ of 1 pb is excluded for $c\tau \sim 50$ mm.

Recast: dark photon with non-abelian kinetic mixing. The FRVZ model on which the ATLAS analysis was based implies the presence of at least two displaced LJs in the final state as well as two additional unobserved HLSPs that correspond to missing energy. The ATLAS analysis did not impose any \cancel{E}_T cuts. The presence of the two HLSPs affects the kinematics and topology of the signal event but does not explicitly enter the event selection or reconstruction. Thus, one should be able to reinterpret the ATLAS analysis in terms of any other model containing two or more displaced LJ, along with potentially additional, unobserved objects.

We consider a scenario for a dark photon X_μ that mixes with the neutral SM $SU(2)_L$ gauge boson W_μ^3 via a higher dimensional operator. Two possibilities have recently been considered: a dimension six operator involving the SM Higgs doublet, the $SU(2)_L$ field strength $W_{\mu\nu}^a$ and the corresponding $U(1)'$ field strength $X_{\mu\nu}$ [511]; and a dimension five operator involving $W_{\mu\nu}^a$, $X_{\mu\nu}$, and a real scalar triplet $\Sigma \sim (1, 3, 0)$ [512]. We consider the latter since it can yield an event topology similar to that of the FRVZ model and since it is the leading operator that may generate non-abelian kinetic mixing (NAKM) of the $U(1)'$ gauge boson with the SM. We will henceforth refer to this model as the NAKM5 scenario. The corresponding operator is

$$\mathcal{O}_{WX}^{(5)} = -\frac{\beta}{\Lambda} \text{Tr}(W_{\mu\nu}\Sigma)X^{\mu\nu}, \quad (6.6)$$

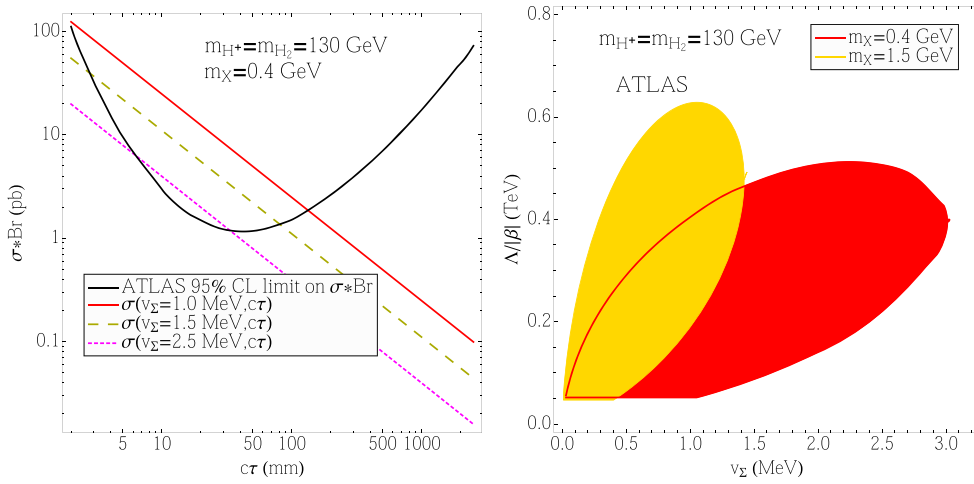

Figure 79. Constraints on the NAKM5 scenario, recast from the ATLAS search reported in [272]. The left panel gives the exclusion in the $(c\tau, \sigma \times \text{BR})$ plane, where the region above the parabola is excluded. The diagonal lines indicate the dependence of $\sigma \times \text{BR}$ on $c\tau$ for different representative choices of v_Σ . The right panel gives the exclusion region in the $(v_\Sigma, \Lambda/\beta)$ plane for $m_X = 0.4$ GeV (red region) and $m_X = 1.5$ GeV (yellow region).

where Λ is the associated effective field theory mass scale and β is a dimensionless coupling that is nominally $\mathcal{O}(1)$. When the neutral component of the Σ obtains a vacuum expectation value (vev) v_Σ , one has the ratio of the dark photon and SM photon couplings

$$\epsilon = \beta \sin \theta_W \left(\frac{v_\Sigma}{\Lambda} \right). \tag{6.7}$$

Note that the ρ -parameter constrains v_Σ to be smaller than about 4 GeV. Consequently, for Λ of order one TeV, ϵ is small (and consistent with present experimental constraints) without requiring the presence of a suppressed coupling in the Lagrangian. This feature distinguishes the dimension-five non-abelian kinetic mixing from the dimension-four kinetic mixing between X_μ and the SM hypercharge gauge boson.

The final state with two γ_d (resulting from the $X_\mu - W_\mu^3$ mixing) can be produced in one of two ways: (a) electroweak Drell–Yan pair production of triplet scalars that subsequently decay to a γ_d and SM gauge boson via the operator in equation (6.6); (b) production of the γ_d and a triplet scalar via $\mathcal{O}_{WX}^{(5)}$ with a subsequent decay of the triplet to a second γ_d plus a SM gauge boson via the same operator. In each case, one would expect the presence of two γ_d plus one or more unobserved massive prompt bosons in the final state. The ATLAS DV plus LJ analysis can be recast in a straightforward way for these event topologies, as no information about the unobserved prompt object has been used. It is worth emphasizing that both the production processes as well as the Σ decay rate are independent of the triplet vev, v_Σ . The latter only enters ϵ and, thus, only affects the dark photon $c\tau$.

The corresponding implications of the ATLAS 8 TeV results are indicated in figure 79. The first panel shows the limits on the $\sigma \times \text{BR}$ as a function of $c\tau$. The corresponding model sensitivity is shown for different choices of v_Σ by the diagonal lines. Note that for fixed v_Σ both the $\sigma \times \text{BR}$ and $c\tau$ depend on the operator coefficient β/Λ , leading to a non-trivial relationship between the two experimental quantities. This situation differs from the FRVZ

model, where $\sigma \times \text{Br}$ is independent of $c\tau$ since the mixing parameter ϵ does not depend on the parameters governing production of the hidden sector particles or their cascade decays. The intersections of the model lines with the ATLAS limits can then be translated into bounds on Λ/β as a function of v_Σ for different choices of the dark photon mass (denoted here as m_χ), as shown in the second panel of figure 79. For a 1.5 GeV dark photon, the excluded region reaches 600 GeV for $v_\Sigma = 1$ MeV.

The aforementioned recast does not require detailed information on event topology, other than the dark photon decay length. Consequently, the 13 TeV limits [273] translate rather straightforwardly into stronger bounds on the model parameter space, reaching to somewhat larger Λ/β .

Lessons learned. The triggering requirements used in the ATLAS analysis thus far limit the reach of displaced LJ searches. For models having a signal with only the displaced LJ and no other observable objects, such as the FRVZ model, triggering solely on MS tracks not associated with ID tracks is appropriate, though even here the 3mu6 trigger may not be sufficiently inclusive, as it requires at least three ROIs in the MS (see section 3.2.1). Events with LJ pairs for which neither LJ can be resolved into two separate ROIs will be missed.

It is clear that triggering on associated prompt objects, such as the lepton from one of the final state vector bosons in the NAKM5 scenario or from the W boson in heavy RHN models (CC LLP production), could significantly enhance the triggering efficiency and extend the reach of displaced LJ searches to a wider class of models and to a broader range of model parameter space. Inclusion of an associated prompt object in triggering may also enhance background rejection and relax the requirement on $\Delta\phi$ between LJs.

In addition, the implications of the mass scale of the intermediate BSM particles and the number of final state prompt objects remains to be investigated. The ATLAS 8 TeV search assumed the hidden sector particles are light compared to the mass of the SM Higgs boson, whose decay chain leads to the final states involving multiple γ_d and HLSPs. For the NAKM5 scenario and models with heavy RHNs, these assumptions about mass hierarchy may not apply. It is also not clear what impact the DV LJ isolation requirements have when there is an associated prompt lepton in the signal event.

6.4.5. Non-pointing photons. The search for non-pointing photons produced in association with missing transverse energy (\cancel{E}_T) [301] plays an important role in probing BSM particles that decay to a SM photon and an invisible particle through a highly suppressed coupling. Besides the GMSB models [513], which were the main motivation for the non-pointing photon search, this type of signal can also appear in many hidden-sector models. For example, in the dipole-mediated DM model (the ‘Dark Penguin’) [156], the production of two heavier dark fermions $pp \rightarrow Z^*/\gamma^* \rightarrow \chi_h \bar{\chi}_h$ is followed by the decays $\chi_h \rightarrow \chi_l + \gamma$. If the flavor structures of the DM mass and coupling are aligned, χ_h can be long-lived and give rise to non-pointing photons. Another example is provided by the dark-shower scenario [514, 515] that explains the galactic center gamma-ray excess. In this model, many hidden pions can be produced in the same LHC event. Some of these have displaced decays to a pair of SM photons, while others decay outside of the detector, yielding \cancel{E}_T . Notice that in this case the topology of the events is different from the previous examples, as the non-pointing photons and \cancel{E}_T originate from separate particles (and for more discussion on dark showers, see chapter 7).

Here, we describe a method used to recast the bounds of [301] to a BSM scenario that is different from the GMSB model, using the Dark Penguin signal [156] as an example.

Figure 80. Left: the Δz_γ distribution of the non-pointing photon signals measured by ATLAS. The background reported by ATLAS (blue histogram) was obtained from a data-driven analysis, using diphoton events with $E_T < 20$ GeV. Also shown, stacked on top of the background (red histogram), is the signal distribution from the dipole-mediated DM scenario with $(m_{\chi_h}, m_{\chi_l}, M) = (300, 10, 300)$ GeV, $\lambda\sqrt{NY} = 6$, and $\varepsilon = 10^{-7}$. See [156] for more details. Right: the geometry of the displaced signals.

6.4.5.1. Calculation of the signal efficiency for the non-pointing photon search. We follow the non-pointing photon analysis in [301], performed by the ATLAS collaboration on about 20 fb^{-1} of 8 TeV data. In [301] delayed photons were also considered, but here we focus only on the measurement of the Δz_γ of non-pointing photons (see figure 80). For DM signals given by the long-lived $\chi_h \rightarrow \chi_l \gamma$ decay, Δz_γ can be related to the χ_h decay length ℓ_d in the lab frame:

$$\begin{aligned} \Delta z_\gamma &= \ell_d \left(\hat{f}_{\chi_h, z} - \frac{\hat{f}_{\chi_h, T} \cdot \hat{f}_{\gamma, T}}{1 - (\hat{f}_{\gamma, z})^2} \hat{f}_{\gamma, z} \right) \\ &= \ell_d [\cos \theta_{\chi_h} - \cos(\phi_{\chi_h} - \phi_\gamma) \cot \theta_\gamma \sin \theta_{\chi_h}], \end{aligned} \quad (6.8)$$

where $\hat{f}_{T, z}$ represent the transverse and longitudinal components of the unit vector \hat{f} , respectively, as shown in the right panel of figure 80. To obtain the Δz_γ distribution of the DM decay, we first simulate the prompt process, $p p \rightarrow \chi_h \bar{\chi}_h$, $\chi_h \rightarrow \chi_l \gamma$, $\bar{\chi}_h \rightarrow \bar{\chi}_l \gamma$ in MadGraph5, then we apply the cuts performed in the ATLAS analysis, and finally reweight the events using the dark penguin form factors. Then we calculate the proper lifetime of χ_h and boost it to the lab frame using the momenta of each parton-level event. The angular information of the photon and χ_h allow us to calculate Δz_γ in equation (6.8) as a function of the decay length. Using this, each simulated MC event contributes to the differential cross section in Δz_γ as

$$\frac{d\sigma_{\text{displaced}}}{d\Delta z_\gamma} = \sigma_{\text{prompt}} \frac{dP}{d\Delta z_\gamma} = \sigma_{\text{prompt}} \frac{|\mu|}{2} e^{-\mu \Delta z_\gamma}, \quad (6.9)$$

where the μ characterizing the probability distribution $dP/d\Delta z_\gamma$ of the decay is defined as

$$\mu \equiv \frac{\Gamma_{\chi_h} m_{\chi_h}}{P_{\chi_h}} \left(\hat{f}_{\chi_h, z} - \frac{\hat{f}_{\chi_h, T} \cdot \hat{f}_{\gamma, T}}{1 - (\hat{f}_{\gamma, z})^2} \hat{f}_{\gamma, z} \right)^{-1}. \quad (6.10)$$

Summing the distributions derived from all the simulated events we obtain the differential cross section in Δz_γ shown in figure 80.

The ATLAS search requires at least two loose photons with $|\eta| < 2.37$ and $E_T > 50$ GeV. At least one photon is required to be in the barrel region $|\eta| < 1.37$. To

avoid collisions due to satellite bunches, both photons are required to have an arrival time at the ECAL t_γ smaller than 4 ns, with zero defined as the expected time of arrival for a prompt photon from the PV. We approximate t_γ with the TOF of the χ_h , requiring it to be smaller than 4 ns. In our sensitivity estimate, we do not include the detailed isolation cuts on the photon. We also neglect the effect of the displaced decay on the angular acceptance of the photons, simply imposing the requirements on $|\eta|$ at the level of the prompt event. The signal region also requires $\cancel{E}_T > 75$ GeV.

Finally, to simplify the discussion we assume that every event has a reconstructed PV in the geometrical center of the detector.

For events where only one photon satisfies $|\eta| < 1.37$ (i.e. it is in the barrel calorimeter), this photon is used for the measurement of Δz_γ . For events where both photons are in the barrel, the photon with larger t_γ is used. We approximate this timing condition by taking the photon emitted by the more boosted χ_h , in which case the average decay is more delayed. In figure 80 the generated Δz_γ signal distribution is shown on top of the expected background. The latter is taken from figure 4 of the ATLAS paper [301]. Because we are focusing on the non-pointing photon signals, to set constraints on the DM couplings in [156] we remove events with $|\Delta z_\gamma| < 30$ mm. In our exploratory analysis we only consider the statistical uncertainty on the background, neglecting the effect of systematics.

Lessons learned. The ATLAS paper gives detailed descriptions of the cuts and background analysis, which makes an approximate estimation of the signal efficiency quite straightforward.

The background analysis in [301] is based on a data-driven study, for which events passing the diphoton selection with $\cancel{E}_T < 20$ GeV are used as control region sample. It is challenging for theorists to simulate the background for different energy cuts. This is particularly true for the \cancel{E}_T cut that plays a vital role in the DM and HV searches.

To obtain a more precise result, it would be useful if the ATLAS collaboration could provide the reconstruction efficiency of non-pointing photons as function of Δz_γ , or of the angle between the photon and the surface of the ECAL, a variable that may be relevant to the efficiency. The paper does provide a table of signal acceptance times efficiency for the GMSB model used therein. However, the numbers depend on details of the particular model used, and it is hard to extract the efficiency that is associated to the non-pointing photon reconstruction. Therefore, when estimating the signal efficiency, we only consider efficiency from the selection cuts and do not include possible suppressions from photon reconstruction.

It would also be very useful to have a table of background events for different cuts on \cancel{E}_T . For instance, the Dark Penguin signature has \cancel{E}_T from the decay of $\chi_h \bar{\chi}_h$ with electroweak-scale m_{χ_h} , and \cancel{E}_T can easily be higher than 100 GeV. By contrast, in the dark shower scenario where soft hidden pions decay to two SM photons, the \cancel{E}_T originating from additional late-decaying pions can be much lower than the 75 GeV cut used in the ATLAS analysis. Knowing the background and systematic uncertainty for different \cancel{E}_T cuts would be very important to constrain different models with potentially very different kinematics.

6.4.6. Displaced vertices. Displaced-vertex searches differ from displaced jets and displaced leptons due to the requirement of an actual secondary vertex from the displaced objects. These searches are sensitive to LLP lifetimes that allow it to decay in the inner trackers or MS of the LHC detectors, where vertexing is possible [196, 237, 248, 251, 253, 265, 279]. These searches have extremely low backgrounds as there are no irreducible contributions from the SM, making them sensitive to very small signals of new physics (for more information, see

chapter 4). Moreover, the identification of displaced decays can be used to extract kinematical information in a decay, such as (invisible) particle masses [516, 517].

In this section we review some reinterpretations of DV searches, differentiating between reinterpretations making use of only truth-level information to identify displaced decays and reinterpretations in which an attempt is made to reconstruct DV from displaced tracks (with an approximate detector response).

6.4.6.1. Truth level DV. The work in [26] reinterpreted the 8 TeV ATLAS search for a displaced muon and a multi-track vertex (DV+ μ) [518], where LLP signatures for certain weak-scale models of baryogenesis [24, 26, 509] were explored. For reinterpreting this search, a similar procedure described in section 6.4.3, on displaced jets, of constructing ratios of truth-level versus ATLAS efficiencies for the ATLAS multi-track vertex analysis [518] was performed, with similar results for the validation being correct within approximately a factor of two.

This DV+ μ analysis has since been superseded by [196], in which a DV is searched for at 8 TeV in association with either a muon, electrons, jets, or missing transverse momenta. Recently, an updated ATLAS analysis [237], which looks for multi-track DV at 13 TeV in association with large \cancel{E}_T , was made public. This search now includes a prescription using parametrized efficiencies as a function of vertex radial distance, number of tracks and mass. Their prescription can be applied to vertices and events passing certain particle level acceptance requirements using the truth MC event record.

Here we validate the prescription with parametrized selection efficiencies in [237]¹⁹¹. The results of this search are interpreted by ATLAS in a split-SUSY simplified model with a long-lived gluino that hadronizes, forming an R -hadron before decaying as $\tilde{g} \rightarrow q\bar{q}\tilde{\chi}_1^0$. Event samples are generated with PYTHIA 8.2 [220]. We use truth-level \cancel{E}_T and we identify the truth R -hadron decay position and decay products, as the ATLAS collaboration provides selection efficiencies that can be directly applied to these truth-level quantities. These efficiencies can be found in the auxiliary material in [519], and are given at the event-level as a function of the truth \cancel{E}_T and DV radial distance, and at the vertex level parametrized as functions of vertex invariant mass and number of tracks. The efficiencies are given for different detector regions, encapsulating also the effect of the material veto cut.

The selection of events used for the signal region requires:

- truth level $\cancel{E}_T > 200$ GeV;
- one trackless jet with $p_T > 70$ GeV, or two trackless jets with $p_T > 25$ GeV. A trackless jet is defined as a jet with $\sum_{\text{tracks}} p_T < 5$ GeV.

In addition, events must have at least one DV with:

- transverse distance between the IP and the decay position > 4 mm;
- the decay position must lie in the fiducial region $r_{\text{DV}} < 300$ mm and $|z_{\text{DV}}| < 300$ mm;
- the number of selected decay products must be at least 5, where selected decay products are charged and stable, with $p_T > 1$ GeV and $|d_0| > 2$ mm;
- the invariant mass of the truth vertex must be larger than 10 GeV, and is constructed assuming all decay products have the mass of the pion.

Applying these cuts and efficiencies, we get event-level efficiencies for two of the benchmarks (with gluino masses of 1400 GeV or 2000 TeV, and the neutralino mass is fixed to 100 GeV). Based on the efficiencies obtained and the estimated number of background

¹⁹¹ This prescription is also validated in [504].

Figure 81. Comparison of our recast and ATLAS [237] on the upper limit on the gluino production cross section versus its proper lifetime [504].

vertices, we can extract 95% C.L. upper limits on the total visible cross section for the two gluino masses. For reference, assuming 100% efficiency, we get an upper limit of 0.091 fb. The curves in figure 81 show our recasting results compared to ATLAS. The level of agreement is very good, within 20% for most of the lifetime values. We also point out that the recasting limits agree well even for regions where the efficiency is very low ($\tau > 10$ ns and $\tau < 10^{-2}$ ns). This 13 TeV ATLAS multitrack analysis [237] has also been reinterpreted in the context of long-lived sterile neutrinos [48, 264].

6.4.6.2. Displaced-vertex reconstruction. Before parametrized efficiencies applicable for truth-level DV were made public, attempts to recast DV searches were made by performing their reconstruction from charged tracks only, with an approximate detector response. In [206] the ATLAS DV+jets multitrack analysis [196] was recast. Reinterpretation was performed using generator-level events and the detector fiducial region was reproduced as well as possible. A description of the criteria from the ATLAS analysis that were implemented in the recast is shown in table 9. The jets are clustered according to the anti- k_T prescription [366] in the analysis with momentum smearing, validated by reproducing the jets+ \cancel{E}_T exclusion curve of prompt searches. The selection of events used for the signal region (and the approximations to real detector simulation) were as follows:

A tracking efficiency of the form

$$\begin{aligned} \varepsilon_{\text{trk}} = & 0.5 \times \left(1 - \exp\left(\frac{-p_T}{4.0 \text{ GeV}}\right) \right) \times \exp\left(\frac{-z_{\text{DV}}}{270 \text{ mm}}\right) \\ & \times \max\left(-0.0022 \times \frac{r_{\text{DV}}}{1 \text{ mm}} + 0.8, 0\right), \end{aligned} \quad (6.11)$$

is used, where r_{DV} and z_{DV} are the transverse and longitudinal distance of the track’s production vertex (which is the same as the DV origin when using truth-level generator information). This functional form is designed to take into account the size of the detector (i.e. it imposes a linear dependence on r_{DV} , and an exponential dependence on z_{DV}), as well as a turn-on like feature dependent on the p_T of the track. It reproduces the overall behavior of efficiency falling off with vertex displacement. The parameters were determined by fitting the

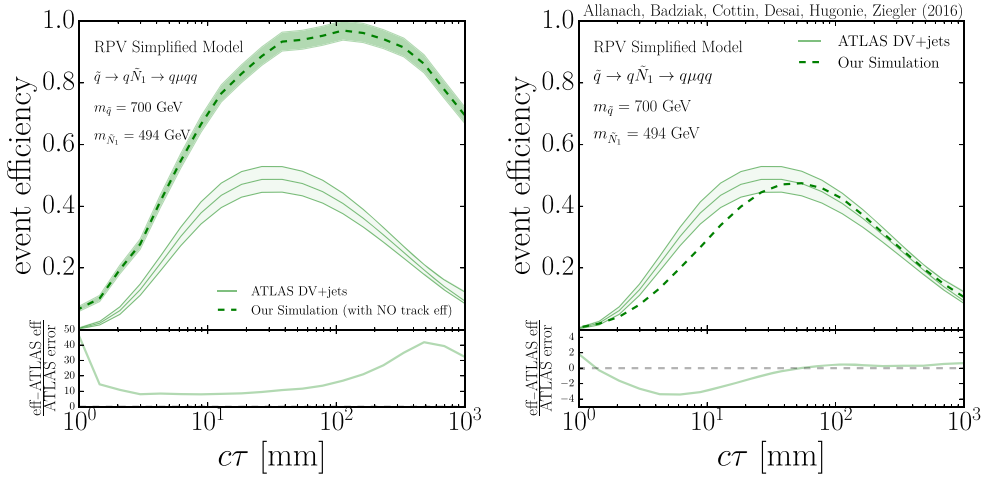

Figure 82. Validation of the DV + jets search for the ATLAS benchmark of a simplified RPV model with a 700 GeV squark decaying to a neutralino, $\tilde{q} \rightarrow q\tilde{N}_1 \rightarrow q\mu qq$. Left: without any tracking efficiency. Right: with a tracking efficiency function given by equation (6.11), taken from [206].

Table 9. Implementation of cuts applied in the ATLAS multitrack DV + jets search, from [196]. Cuts denoted by an asterisk (*) are approximations to the experimental analysis in the absence of the full detector simulation.

DV jets	4 or 5 or 6 jets with $ \eta < 2.8$ and $p_T > 90, 65, 55$ GeV, each
DV reconstruction*	DV made from tracks with $p_T > 1$ GeV, $ \eta < 2.5$ and $ d_0 > 2$ mm. Vertices within 1 mm are merged. Note: a tracking efficiency needed here; we assume a functional form given by equation (6.11)
DV fiducial	DV within 4 mm $< r_{DV} < 300$ mm and $ z_{DV} < 300$ mm
DV material*	No DV in regions near beampipe or within pixel layers. Discard tracks with $r_{DV}/\text{mm} \in \{[25, 38], [45, 60], [85, 95], [120, 130]\}$.
N_{trk}	DV track multiplicity 5
m_{DV}	DV mass > 10 GeV

efficiency curve (with lifetime dependence), for three benchmarks in the analyses. We find that fitting only one benchmark does not correctly reproduce the efficiency curve for any of the others. This is most likely due to insufficient dimensionality of the efficiency map. We expect that a full tracking-efficiency parametrization depends not only on r_{DV} , z_{DV} and p_T , but also on transverse and longitudinal impact parameters (d_0 , z_0), and on the charge and pseudorapidity of the track. Furthermore, we expect a vertex efficiency that depends on the topology of the event and the nature of the particles forming the vertex. The fit for the event efficiencies from this tracking function can be seen in figure 82.

Lessons learned. With a larger and more diverse set of signal benchmarks, the prospects for reinterpretation are better. For example, the ATLAS analysis examined in [518] only showed limits for three signal model benchmark points for which efficiencies were shown,

making it challenging to find a benchmark whose kinematics matched the desired signal models for the reinterpretations of other models (for example, in [26]). Because the efficiencies and limits were shown for either a high-mass, low-boost LLP or a low-mass, high-boost LLP, this made it more challenging to reinterpret the results for other types of kinematics.

The new parametrized efficiencies presented by ATLAS in [519] are extremely useful. They constitute an optimal efficiency map for recasting these type of analyses, as they can be applied in a straightforward way to truth-level quantities. Before this information was made public, efficiency tables (for vertex-level efficiency) in terms of r_{DV} were only available for few channels and for a single benchmark. It was not clear how to translate this information to other channels, or to parent particles of a different mass. In this case, a functional parametrization for track efficiency was needed (as derived in [206]) to be able to reproduce the experimental results. Finding this kind of parametrization is not easy, as it needs to be validated across different benchmarks. For example, [206] found that fitting only one benchmark did not correctly reproduce the event-level efficiency curve for any of the others.

6.5. Handling LLPs in DELPHES-based detector simulations

6.5.1. Long-lived particle simulation in DELPHES 3.4.1. The DELPHES package [342] allows for the generic simulation of the response of a typical detector used in high-energy physics experiments. It is widely used for simulating the effects of the ATLAS and CMS detectors or the hypothetical detectors that could be used for the future FCC and CLIC projects. The architecture of DELPHES is composed of distinct and specialized modules that interact with each other. The detector is described by the user through an input card, where the modules to be used in the simulation are sequentially enumerated and their input parameters are specified.

The detector simulation relies on a mix of parametric and algorithmic modules. More precisely, tracking is simulated through efficiency and smearing functions that are applied to the properties of the electrically-charged stable particles. The particles are then propagated to the calorimeters and dedicated modules simulate the energy deposits in the electromagnetic and HCALs. The output of such a step consists of a list of calorimetric towers. Moreover, DELPHES includes a particle-flow-like algorithm that combines tracking and calorimetric data in order to improve the identification of the final-state objects and the resolution on their reconstructed momenta.

Jet clustering is performed via an internal call to the FASTJET package [367], which takes as input the list of calorimeter towers or, alternatively, the particle-flow candidates, and outputs jet objects. Lepton and photon isolation is then handled through a specific isolation module. Finally, DELPHES takes care of removing the double-counting of objects that could be simultaneously identified as elements of different collections. The final output is stored in a ROOT file.

In addition, DELPHES allows for the simulation of PU effects by superimposing minimum-bias events attached to displaced interaction vertices along the beam direction to the hard scattering event. Procedures mimicking PU removal can then be configured in the input card. The subtraction of the charged particles belonging to PU vertices is performed at the tracker level. Neutral particles are removed by applying the jet area method [520] supplied within the FASTJET package. More advanced methods are also available in DELPHES, such as the PUPPI [521] or SOFTKILLER [522] techniques, and they can easily be added to the input card. The loss of performance originating from PU, in particular relative to the isolation, is automatically accounted for.

The official DELPHES package (version 3.4.1) with the default detector cards needs to be adapted for the proper handling of LLPs. By default, the decay products of a LLP enter the simulation as if the corresponding decay would have occurred within the tracker volume. However, the user has the possibility to define a volume in which the particle can decay and still be detected outside the tracker volume. This is achieved in practice by making use of the `RadiusMax` parameter of the `ParticlePropagator` module, that is by default set to the tracker radius stored in the `Radius` parameter. When setting the `Radius` and `RadiusMax` parameters to different values, the particles decaying outside the tracker volume, but inside the ‘decay volume’ of radius `RadiusMax`, are included in the collection of stable particles stored in the output ROOT file. They can in this way be used for an offline, more correct, treatment.

Moreover, several modules that are not used in the default ATLAS and CMS cards could serve for a better simulation of the LLPs in DELPHES. For instance, the `TrackSmearing` module allows the user to smear the track momentum according to the impact parameter in the transverse plane (i.e. the d_0 parameter) and in the longitudinal plane (i.e. the d_z parameter).

By default, the detector simulation in DELPHES totally ignores the presence of any LLP. While this is convenient for neutral particles like a neutralino which could be considered as invisible from the detector standpoint, a charged particle leaves tracks in the tracker and would interact with the calorimeters if its lifetime is large enough. In this case, if the LLP decays inside the tracker, its trajectory is properly propagated to the calorimeters and the DV is correctly accounted for. However, if the LLP decays outside the tracker, its decay products are ignored in DELPHES, unless the `RadiusMax` parameter has been specified to be larger than the tracker `Radius` parameter. In this case the decay products can be found in the `Delphes/stableParticles` output collection and treated with adequate smearing functions and efficiency directly from the DELPHES output.

Finally, DTs are simply treated as missing energy in DELPHES. Emerging tracks or tracks containing kinks are not treated appropriately, in the sense that the parameterizations required for a proper description of such signatures has not been implemented yet. Also, DELPHES does not include any trigger simulation, and the latter is in general complex in the case of LLPs.

6.5.2. Displaced tracks with the MADANALYSIS 5 tune of DELPHES. The DELPHES-LLP package can be installed from the version v1.6 of MADANALYSIS 5 [488, 523] and contains improvements of DELPHES specific to LLPs. It leads to new possibilities for phenomenological investigations of LLPs and the recasting of related LHC analyses¹⁹².

This new package was designed to handle neutral LLPs that decay into leptons within the tracker volume. Realistic efficiencies are applied to the displaced tracks and several parameters specific to this kind of analysis have been made available within MADANALYSIS 5. An extension to the case of neutral LLPs decaying into muons outside the tracker volume can be easily implemented, the muons being thus reconstructed only through their hits in the muon chambers. The simulation of the displaced leptons is performed through efficiencies and resolution functions to be specified by the user. Furthermore, another extension allowing the user to handle long-lived charged particles that decay into leptons could be implemented. A similar dedicated tune of DELPHES and MADANALYSIS was devised for the studies of neutral particles decaying to displaced leptons and jets in [44, 49, 169]¹⁹³.

¹⁹² More information is available at the following website: <https://madanalysis.irmp.ucl.ac.be/wiki/MA5LongLivedParticle>.

¹⁹³ The code is available to download at <https://sites.google.com/site/leftrighthep/>.

The DELPHES-LLP package contains a new module called `MA5EfficiencyD0` that allows for the definition of a track reconstruction efficiency parameterized as a function of the $|d_0|$ and d_z parameters (named `d0` and `dz` in the DELPHES input card). The default efficiency function, specified via a `DelphesFormula` is taken from the 8 TeV tracking performance of CMS [275]¹⁹⁴,

```
setEfficiencyFormula
{ (d0 <= 20) * (-5.061 07e - 7 * d0**6
+ 0.000 027 275 6 * d0**5 - 0.000 493 21 * d0**4
+ 0.002 871 89 * d0**3 + 0.005 220 07 * d0**2
- 0.091 795 7 * d0 + 0.924 921)
+(d0 > 20) * (0.00)}
```

In addition, the data-format of DELPHES has been extended so that the `Muon` and `Electron` classes now include the transverse ($|d_0|$) and longitudinal (d_z) impact parameters relative to the closest approach point (encoded in the `d0` and `dz` variables), the coordinates of the closest approach point (x_d, y_d, z_d) (encoded in the `xd`, `yd` and `zd` variables), and the four-vector of the vertex from which the lepton is originating from (t_p, x_p, y_p, z_p) (encoded within the `tp`, `xp`, `yp` and `zp` variables), the latter quantity being evaluated from MC information.

Consequently, the data-format of MADANALYSIS 5 has been extended, so that the `Muon` and `Electron` classes now contain the `d0()` and `dz()` methods allowing to access the value of the $|d_0|$ and d_z parameters, the `closestPoint()` method that returns the coordinates of the closest approach point (through the `X()`, `Y()` and `Z()` daughter methods) and the `vertexProd()` method that returns coordinates of the DV from which the lepton originates (through the `X()`, `Y()` and `Z()` daughter methods). An analysis example [494] can be found in the public analysis database of MADANALYSIS 5¹⁹⁵, where information about the re-implementation in MADANALYSIS 5 of [197], an analysis of 2.6 fb^{-1} of 13 TeV LHC data, is available. This is a search for LLPs decaying into electrons and muons, where signal events are selected by requiring the presence of either an electron or a muon whose transverse impact parameter lies between $200 \mu\text{m}$ and 10 cm . For a given benchmark signal where a pair of long-lived stops is produced through QCD interactions and where each stop further decays into a displaced b -jet and a displaced lepton. In table 10, we present the number of events surviving the selection of the three different signal regions of the CMS analysis. Our event generation has been performed with PYTHIA 8 [219] and for the benchmark scenario used. We observe that a good agreement is obtained, except in the case of long stop lifetimes, $c\tau = 1 \text{ m}$. This is however the region in which no public information on the CMS reconstruction efficiencies is available.

The MADANALYSIS 5 tune of DELPHES has neither been designed for disappearing (or appearing) tracks nor for track kinks. Concerning the disappearing (or appearing) tracks, the only missing experimental ingredients are the track reconstruction efficiency and resolution as a function of the number of missing hits in the (inner) outer layers of the tracker. There is to this date no public material on the tracking performance description related to track kinks.

6.5.3. What about other LLP signatures? In this section, we briefly discuss how DELPHES could be improved for a better handling of LLP signatures.

¹⁹⁴ <https://twiki.cern.ch/twiki/bin/view/CMSPublic/DisplacedSusyParametrisationStudyForUser>

¹⁹⁵ <http://madanalysis.irmp.ucl.ac.be/wiki/PublicAnalysisDatabase>

Table 10. Number of events populating the three signal regions (SR-1, SR-2 and SR-3) of [197] for different stop decay lengths ($c\tau_{\bar{t}}$). We compare the CMS and MADANALYSIS 5 (MA5) results in the second and third column of the table, respectively, and the difference taken relatively to CMS is shown in the last column.

Region	$c\tau_{\bar{t}}$ (cm)	MA5	CMS	Difference (%)
SR-1	0.1	3.89	3.8	2
	1	4.44	5.2	15
	10	0.697	0.8	15
	100	0.0610	0.009	>100%
SR-2	0.1	0.924	0.94	2
	1	3.87	4.1	5
	10	0.854	1.0	15
	100	0.0662	0.03	~100%
SR-3	0.1	0.139	0.16	15
	1	6.19	7.0	10
	10	4.45	5.8	25
	100	0.497	0.27	85

6.5.3.1. Displaced jets. Displaced jets are jets that are reconstructed either from SA calorimeter information, or from the particle-flow input with a minimum requirement on the multiplicity of tracks with high transverse displacement (see [251]). Conceptually, such jets can be handled in DELPHES provided that the displaced tracks are properly parametrized. As described above, a module designed to smear the full set of track properties, including their transverse and longitudinal displacement, exists (i.e. the `TrackSmearing` module). In addition, efficiencies based on displacement parameters have already been implemented in MADANALYSIS 5 (see above) and a module that performs the matching of an existing jet collection with a track collection based on track displacements is very similar to the already existing `TrackCountingBTagging` module. Minor modifications to this module are hence needed to be able to select tracks based on an absolute displacement instead of the impact parameter significance. Finally, in order to be able to perform a displaced jet selection, one would need a (not yet existing) module that performs jet clustering on the basis of the secondary vertices and the displaced tracks matched with these jets. Alternatively, a module that includes a vertex reconstruction efficiency and a module including a vertex position smearing could be implemented.

6.5.3.2. Displaced vertices. The missing modules described in section 6.5.3.1 could perfectly serve the purpose of a DV analysis. Provided that tracking efficiencies and resolutions are available as a function of the full set of tracking parameters (d_0 , d_z , p_T , ϕ , and θ) and, eventually, of the MC truth vertex position, a simple vertexing algorithm can be implemented in DELPHES.

6.5.3.3. Discussion: DELPHES versus a specific parametric simulation. In a fully parametric simulation of the detector, the detector effects are encoded in terms of efficiencies and resolution functions. Such a simulation is typically very fast, but is likely to suffer from a lack of accuracy in the modeling of complex observables such as jet properties and missing energy. The DELPHES simulation is an admixture of such a parametric simulation and of an algorithmic one. This is slower, but has the clear advantage of correctly treating in particular the reconstruction of the jets and the missing energy.

In order to be able to answer whether DELPHES should be used in place of a fully parametric simulation in recasting LLP analyses, further studies are needed. In the meantime, the following guidelines could be used. If the signal selection is based only on displaced tracks, a simple parametric simulation should in principle be sufficient. This simulation could encapsulate the track reconstruction efficiency and resolution, including PU effects. DELPHES could then optionally be used to mix the resulting ‘reconstructed’ tracks with the additional tracks originating from the PU vertices. On the other hand, if the analysis under consideration additionally uses calorimetric information (i.e. jets or missing energy), DELPHES should be preferred to a fully parametric framework. However, a precise quantification of these effects cannot be assessed without detailed comparative studies between the two approaches. Finally, it should be pointed out that neither of these techniques can be used to correctly simulate the instrumental background, which is challenging to simulate and is discussed in chapter 4.

6.6. Recasting inside the experimental collaborations

Reinterpretations performed within the experiments themselves present unique advantages and disadvantages. They allow for thorough and consistent treatment of detector effects and geometry, object reconstruction, and systematic uncertainties in a way which is impossible through external recasting. Groups can share resources and easily communicate all necessary details. On the other hand, they are of course limited to the model(s) chosen for reinterpretation. In the ideal situation, reinterpretations which provide meaningful results can be performed with minimal overhead to a given analysis.

As the LHC enters an era of decelerating luminosity growth and analysis techniques are becoming more sophisticated, the LHC analyses become harder to re-implement with sufficient accuracy outside of the experiments compared to cut-based analyses. Analyses increasingly utilize machine-learning algorithms that transform a large number of event-level and particle-level observables into higher-level discriminants which are not easily characterized by low-dimensional efficiency tables and may require inputs that third-party detector simulations are not able to reproduce. In particular non-prompt searches may depend on non-traditional reconstruction objects and details of the detector simulation and geometry in ways that require a more detailed simulation than is achievable by, e.g. third-party simulators. Hence, experiments are investigating approaches that enable internal reinterpretation using the full set of available information.

Full-fidelity reinterpretations are especially relevant for LLPs, since the signal simulation may depend more heavily on details not well captured by third-party simulation tools. For example, for sufficiently high lifetime, the decays must be handled by a full detector simulation such as GEANT (or some complex interaction between GEANT and MC packages such as Pythia). Such decays are not well-covered by tools like Delphes as the response of such in-detector decays may require access to a more detailed geometry description.

6.6.1. The RECAST framework. The RECAST Framework [496] is a developing platform for experiments as well as researchers external to the collaborations who wish to reinterpret LHC analyses. RECAST enables cloud-based analysis execution and common presentation of reinterpretation results. The framework consists of two components:

The RECAST front end. This is a web-based service in which reinterpretation of analyses can be suggested by interested authors that provide necessary inputs such as UFO model files [225], process and parameter card templates, or suggested scan grids. Responses to such requests, possibly by more than one analysis implementation, can then be uploaded. Such a

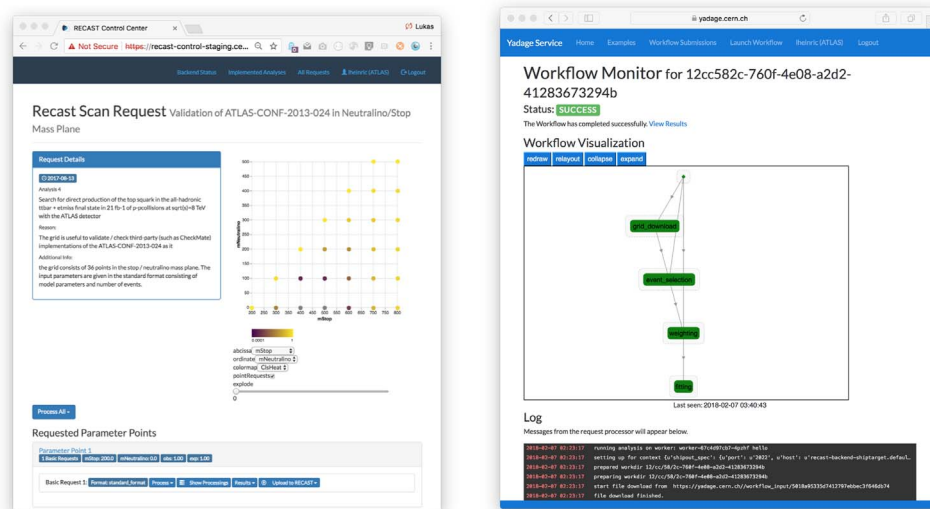

Figure 83. Left: web-based interface for the RECAST back end for an experiment that presents the requested parameter points and color-coded results. Right: an experiment-internal reinterperation executing on the distributed infrastructure built by CAP and RECAST.

web service, interfaced with services such as HepData, may then serve as a resource for the LHC community to organize and share reinterperation results obtained by the various analysis implementations.

The RECAST back end. An important objective of the framework is to enable a full-fidelity reinterperation of an LHC analysis using the original analysis code developed within the experiment that can be approved by the collaboration and be placed on an equal footing with the original publication. In contrast to third-party recasting tools, in which multiple analyses are implemented using a single, common framework that is executed on a single computing element, such an exact analysis re-execution often necessitates a distributed data analysis using a number of different frameworks in use within the experiments. Therefore, RECAST has developed a flexible graph-based analysis description and execution back end [524] that enables a faithful re-execution of nearly arbitrary analysis code on cloud platforms such as those offered by CERN¹⁹⁶. The back-end provides experiments with an access-controlled interface to view reinterperation requests, retrieve the necessary analysis description from repositories such as the CERN analysis preservation portal (CAP) [525], execute the analysis on datasets for the new model and—if approved—upload the results to the public front-end. Figure 84 shows a screenshot of the current prototype user interface, giving collaboration members an overview over requested points as well as controls to steer processing and submission.

These services are being developed in close collaboration with the CERN Analysis Preservation project, which is a common project supported by the four major LHC experiments. While this integration work is on-going, the computing back end for RECAST

¹⁹⁶ Thanks to this flexibility, the popular third-party recasting tools can be easily integrated into this back-end as well, with current integrations being available for CheckMate and Rivet.

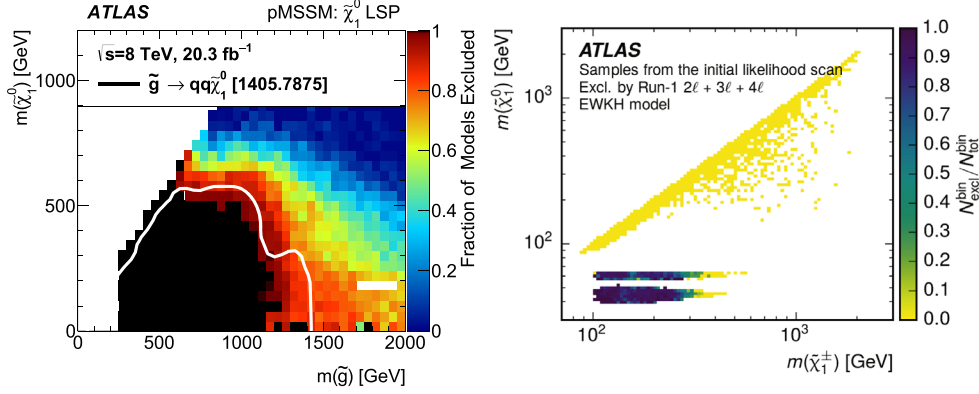

Figure 84. Left: pMSSM exclusion in the gluino-neutralino mass-plane. Results partially provided by RECAST. From [528]. Right: follow-up dark-matter reinterpretation. Exclusions presented in chargino-neutralino mass-plane. From [530].

has been successfully used for a number of Runs 1 and 2 reinterpretations published by the ATLAS Experiment.

6.6.2. Analysis preservation as a driver for reinterpretation. Within the LHC experiments, the ability to reinterpret analyses is, perhaps unintuitively, mostly limited by the internal availability of the analysis routines to the wider collaboration as opposed to, e.g. availability of computing resource constraints. The large number of measurements and searches, the heterogeneity and complexity of the analysis software, as well the size of the collaboration, all lead to a situation in which very often only a small number of analyzers of the original analysis team is able to execute any given analysis. Furthermore, due to the collaborative development model, analyzers are typically responsible for only a subset of the analysis, which results in knowledge fragmentation. Therefore, both ATLAS and CMS are now designing an interface to store analysis-relevant information (the CAP [525]) to mitigate this problem. In the context of RECAST, the software and analysis-workflow preservation aspects of this effort are most relevant. The former is mainly implemented through archiving of source-code repositories and the archival Linux Containers, which now enjoy wide-spread industry support, while internal structure of the analysis workflow is archived in CAP in the form of declarative workflow specifications such as yadage [526], which has been developed for RECAST, and the common workflow language [527]. It is planned that CAP and RECAST will utilize a common computing back-end in order to re-execute the analyses that have been preserved in the portal. As the preservation is enabled by recent technological advances and the process of archival is increasingly streamlined, it is expected that a higher number of experiment-internal analysis codes will be available for RECAST.

6.6.3. RECAST examples. ATLAS-internal analysis examples and results: A number of reinterpretation publications have been supported by the back end underpinning RECAST. After Run 1, ATLAS has conducted a thorough reinterpretation of the SUSY landscape in the context of the phenomenological pMSSM [528], a study involving 20 SUSY analyses and 50 000 fully simulated pMSSM parameter points. While at that time, most analyses had to be reinterpreted manually, the 2L electroweak analysis [529] included in that paper served as a prototype analysis and provided results using the highly automated RECAST back-ends.

Figure 85. Exclusion limits as a function of λ''_{323} and $m(\tilde{g})$ as a result of an internal reinterpretation of several ATLAS SUSY results. Expected limits are shown with dashed lines, and observed as solid. Taken from [243].

The analysis was then later re-used with minimal additional effort in two further publications that focused on more domain-specific SUSY realizations: a five-dimensional DM reinterpretation of electroweak seaches [530], as well as a reinterpretations in the context of general gauge-mediated models [531].

Recently ATLAS has reinterpreted ten analyses [243] in terms of models of supersymmetry with non-vanishing baryon number-violating coupling strength λ'' partly through the use of the new analysis preservation infrastructure. In such models the lightest neutralino is unstable with a decay length of

$$L(\text{cm}) = \frac{0.9\beta\gamma}{\lambda''^2} \left(\frac{m(\tilde{q})}{100 \text{ GeV}} \right)^4 \left(\frac{1 \text{ GeV}}{m(\tilde{\chi}_1^0)} \right)^5. \quad (6.12)$$

This reinterpretation required a joint re-execution of a mix of analyses originally designed for R -parity-conserving and RPV models and special systematics have been added into the statistical analyses to account for the detector response and flavor-tagging rate of displaced jets. Results were presented in a two-dimensional parameter space of gluino mass and neutralino lifetime (or analogously the λ'' coupling) as shown in figure 85. Such reinterpretations are difficult to perform outside of the experiments, as the publicly available information lack details of the detector and analyses.

Third-party tool integration. Both the CheckMate [486, 487] and the Rivet [490] analysis catalogues have been implemented in the analysis execution framework. Both are configured to analyze events that are provided in the HepMC format [532]. Due to the modular approach of the analysis back end, a number of MC generation workflows, such as Herwig [533], SHERPA [534] or MadGraph [238], can be used depending on their ability to correctly model the desired signal.

For analyses where multiple implementations exists, e.g. from multiple third-party tools such as Rivet BSM, CheckMate or MadAnalysis [488, 489] as well as from multiple

experiment-internal configurations (fast simulation, full simulation), RECAST will allow the community to compare and contrast reinterpretation results.

6.6.4. Outlook. Thanks to industry-backed technological advances, a realistic technical solution to the problem of analysis preservation for the LHC experiments and the original RECAST proposal has come into view. The initial use of such infrastructure for the reinterpretation for prompt SUSY searches is generalized easily for LLP searches as the tools used for signal simulation, analysis preservation, and execution do not make simplifying assumptions on the nature of the BSM signal or analysis structure. As such, RECAST may cover reinterpretation use cases, where either third-party reinterpretations are impossible due to missing public information or limitations of third-party tools or accurate, experiment-approved results are desired.

6.7. Reinterpretation with prompt analyses

Since the decay time probability of an unstable particle follows an exponential decay law (dependent upon the mean lifetime), some percentage of the decays of the LLP will occur outside the detector, leading to an \cancel{E}_T signature if the LLP is electrically and color neutral. Likewise, some part of the LLP decays can appear ‘promptly’. Prompt searches with and without \cancel{E}_T can therefore provide additional, corroborating constraints on models with LLPs, especially for short lifetimes. Therefore, it is important to understand the sensitivity of prompt searches to displaced objects.

Reinterpreting prompt searches in the context of LLPs is, however, quite nontrivial, because (a) prompt searches may or may not make explicit requirements on the PV and (b) it is currently not documented how reconstruction efficiencies drop as a function of small displacement. Thus, the reinterpretation of prompt searches in the context of LLPs is currently best done within the collaborations themselves.

An example of such an experiment-internal reinterpretation can be found in a CMS search for an RPV SUSY model where pair-production of stops each proceed through an RPV decay to a b quark and a lepton. A dedicated long-lived search for this model exists in the $e\mu$ channel [197]. This search includes selection criteria which require the transverse impact parameter to the IP be greater than $10 \mu\text{m}$. This maximizes sensitivity to the long-lived model and greatly reduces SM backgrounds. It also necessarily highly reduces the sensitivity of the search at low stop lifetime. The exclusion curve in the stop lifetime ($c\tau$) versus top squark mass is shown in the left frame of figure 86.

A reinterpretation was performed of a search for pair-production of second generation LQs [535, 536]. In this model, massive LQs are pair-produced. Each of these bosons then decays to a muon and c quark, leading to a final state with two muons and two jets from c quarks. In the prompt limit of the RPV SUSY model with a final state of two muons and two jets from b quarks, the kinematics of the LQs are nearly identical. In the LQ search, no selection is made on jet flavor. The LQ search uses final selections which are optimized to the event kinematics for each LQ mass hypothesis, but the search in general strives to remain as model-independent as possible. In this case, the reinterpretation was simply performed using the original LQ analysis, and replacing the signal samples with the long-lived RPV samples, only taking into account the reduced branching fraction to the final state with two muons and two jets. The expected and observed exclusion curves of the reinterpretation are shown in the right frame of figure 86.

The reinterpretation gives large improvements for lifetimes $\sim 1 \text{ mm}$, and as expected, contributes little in the large lifetime limit. This type of reinterpretation is valuable not only

Figure 86. Left: expected and observed 95% confidence level limits in the $c\tau$ - $M_{\tilde{t}}$ plane from the displaced lepton search [197] for pair-production of long-lived stops decaying to b quarks and leptons. Right: exclusion on the pair-production of long-lived stops decaying to b quarks and leptons in the $c\tau$ - $M_{\tilde{t}}$ plane, from the prompt reinterpretation of the second generation LQ search [536].

because it extends coverage of a given model, but also because it helps guide the analysts performing the dedicated search to focus their efforts in areas which are truly uncovered.

Reinterpretations like this one, which provide meaningful results without placing a large burden on analysis teams, should be highly encouraged. Other reinterpretations along these lines can be found in [537–539]. Another relatively simple reinterpretation is [243], although in this case, it should be noted that the original analysis was modified in a simple way, that is, the reliance on tracking information to identify jets and suppress non-collision background was removed, in order to be sensitive to long-lived gluinos.

6.8. Our proposals for the presentation of results

Here we summarize the recommendations for the presentation of searches involving LLPs. These recommendations follow from the detailed examples presented in sections 6.3 and 6.4.

Our primary recommendation is that the experiments provide as detailed information as possible to make a general recasting feasible. We therefore encourage the experiments to:

- A.1. Provide LLP reconstruction and selection efficiencies at the signature or object level. Although the parametrization of efficiencies is strongly analysis dependent, it is advantageous if they are given as a function of model-independent variables (such as functions of DV d_0 , p_T , η , etc), so they do not rely on a specific LLP decay or production mode.
- A.2. Present results for at least two distinct benchmark models, with different event topologies, since it greatly helps to validate the recasting. For clarity, the input cards for the benchmark points should also be provided.
- A.3. Present cut-flow tables, for both the signal benchmarks and the background, since these are very useful for validating the recasting.

- A.4. When an analysis is superseded, differences and commonalities with previous versions of the same analysis should be made clear, especially if the amount of information presented in both analyses differs. The understanding as the extent to which the information presented in an old version can be used directly in a later version greatly helps the recasting procedure, and also highlights ways in which the new search gains or loses sensitivity relative to the superseded analysis.
- A.5. Provide all this material in numerical form, preferably on HEPdata, or on the collaboration wiki page. A very useful resource we also highly encourage is a truth-code snippet illustrating the event and object selections, such as the one from the ATLAS disappearing-track search [218] provided in HEPdata under ‘Common Resources’.

We realize that implementing the above recommendations requires an enormous amount of time and effort by the collaborations and may not always be feasible to the full extent. However, good examples of presentations are already available, such as the parametrized efficiencies provided by the ATLAS 13 TeV DV [237] (see the auxiliary material to [519]) and the CMS 8 TeV HSCP [495] analyses.

When the object- or signature-level efficiency maps are not feasible, providing efficiencies for an extensive, diverse array of simplified models can be useful for reinterpretation. Concerning simplified-model results, we recommend that the experiments:

- B.1. Provide signal efficiencies (acceptance times efficiency) for simplified models and not only upper limits or exclusion curves. Note that efficiencies for *all signal regions*, not only the best one, are necessary for reinterpretation.
- B.2. Present efficiency maps as a function of the relevant simplified-model parameters, such as the LLP mass and lifetime, with sufficient coverage of the simplified-model parameter space. While for direct production of LLPs the parameter space is two-dimensional (LLP mass and lifetime), simplified models with cascade decays have a higher-dimensional parameter space. In these cases we strongly recommend efficiencies to be provided for a significant range of *all* the parameters.
- B.3. Release the efficiencies in digital format (on HEPdata or the collaboration wiki page), going beyond the two-dimensional parameterization suitable for paper plots whenever necessary. In particular, for auxiliary material, we recommend multidimensional data tables instead of a proliferation of two-dimensional projections of the parameter space;
- B.4. Consider in each analysis a range of simplified models which aim to encompass:
 - (a) Different decay modes, including distinct final-state particles and multiplicities.
 - (b) Different LLP boosts (for example, provide efficiencies and limits for distinct parent particle masses, which decay to the LLP).

Although extensive, the above recommendations for the choice of simplified models allow for a thorough comparison between the range of validity of the LLP analyses and a detailed test of recasting methods. Furthermore, when an MC-based recasting is not available, one can use the ‘nearest’ simplified model or a combination of them to estimate the constraints on a theory of interest. Finally, if a sufficiently broad spectrum of simplified models is covered, this can be useful for quickly testing complex models which feature a large variety of signatures, and rapidly finding the interesting region in a model scan before going to more precise but computationally more expensive MC simulation.

We hope that our recommendations, in particular, points A.1–A.5, will serve as a guide for best practices and help establish a reliable and robust reinterpretation of LLP searches. The added value for the experiments and the whole HEP community will be the immediate

and more precise feedback on the implications of the LLP results for a broad range of theoretical scenarios, including gaps in coverage.

7. New frontiers: dark showers

Chapter editors: Simon Knapen, Jessie Shelton

7.1. Introduction: the anatomy of a dark shower

Hidden sectors are increasingly common features in many models that address mysteries of particle physics such as the hierarchy problem, the origins of DM, baryogenesis, and neutrino masses, in addition to being a generic possibility for physics BSM; ‘hidden valleys’ are one such broad class of hidden-sector scenarios [66, 69]. Given the complexity of the SM, such hidden sectors may very well have rich dynamics of their own, with numerous far-reaching implications for their phenomenology [67, 68, 70, 71, 540]. The main LHC signatures predicted by such hidden valley models are characterized by an injection of a large amount of energy into a hidden sector, which is then shared among a large number of relatively soft particles [70]. We will refer to this class of signatures, where rich dynamics internal to the hidden sector yields a high multiplicity of dark states, as ‘dark showers’. Given that the particles emerging at the end of this process are necessarily both comparatively light and secluded from the SM, their lifetimes can easily become long, thus giving rise to displaced signatures at the LHC.

Long-lived particles are especially generic predictions of hidden valleys with confining gauge groups, similar to QCD in the SM [66]. It is worth noting that QCD already provides many familiar examples of LLPs, realizing macroscopic lifetimes through a hierarchy of scales (Λ_{QCD}/m_W) combined with approximately preserved symmetries (K_L , B and D hadrons) or restricted phase space (n). Also provided by QCD are numerous examples of particles that have a hierarchy of lifetimes. For instance, charged pions experience a slow decay through a very off-shell W boson, while neutral pions can decay much faster through their anomalous coupling to photons. The neutral pion lifetime is thus orders of magnitude shorter than the lifetime for charged pions. Both long-lived species and a hierarchy of lifetimes between species are generic predictions and nearly unavoidable consequences of confining theories which produce dark showers. However, LLPs with a hierarchy of lifetimes also arise naturally in non-confining hidden sectors, especially in theories with multiple species. A familiar example from the literature is theories with dark photons. Here, a small kinetic mixing can make the dark photon long-lived, but a simple, well-motivated extension of the model by a dark Higgs boson introduces additional dark species and production mechanisms for dark states that are independent of the small coupling controlling the macroscopic lifetime. This naturally yields high-multiplicity events featuring particles with a hierarchy of lifetimes [32, 230, 456].

More generally, a dark shower topology can be broken down in three components (see figure 87), each of which allows for a large degree of variation between models:

1. *Production.* A dark shower event begins with the production of one or more heavy states which decay into the dark sector. These heavy states could be part of the SM, most

Figure 87. Schematic representation of a dark shower event, in this case from hidden valley model with a Z' production portal. Figure adapted from [71].

notably the Higgs boson, or could be a new particle from the menu of BSM states we have become accustomed to (Z' s, color triplets/octets, electroweak doublets/triplets, etc). In some cases the production mechanism provides an important trigger handle (e.g. VH production for the Higgs), but this is not universal (e.g. Z' production). The options for production are laid out in section 7.2.

2. *Showering and hadronization.* If the dark sector contains an asymptotically free gauge group, the originally produced particles will shower and possibly hadronize within the dark sector. This yields a final state with a potentially large number of dark states, similarly to how quarks and gluons undergo showering and hadronization to yield a jet of hadrons. The shape of the shower and the p_T spectrum depends on the coupling of the dark gauge group: the shower may be pencil-like, as in QCD, completely spherically symmetric, or something in between. Alternatively, it is possible that the hidden sector does not contain a gauge sector but instead features a perturbative cascade decay over a large number of states. Indeed, in certain cases the perturbative picture is dual to the strongly coupled showers. In general, showering and hadronization are the sources of greatest uncertainty from a theory perspective; the current status and some new results are discussed in section 7.3.
3. *Decay.* After the dark degrees of freedom hadronize (or reach the bottom of the cascade in perturbative models), they can decay back to the SM. The decay may occur through the same (off-shell) portal as the production, but this is not essential, and one may expect multiple species with a range of lifetimes. The specifics of the decay step (e.g. muon multiplicity) are particularly important if there is no good trigger handle from the production topology. Decays are frequently interconnected with showering and especially hadronization, however, and it is not tractable to enumerate all possibilities without making simplifying assumptions and/or inserting additional theory prejudice. For this reason it is often useful to focus on the species with the largest multiplicity and/or shortest (macroscopic) lifetime; this frequently provides a reasonable guide to the overall signatures, just as one may obtain a reasonable $O(1)$ picture of QCD jets by considering only their pions. We survey a (non-exhaustive) list of popular decay portals in section 7.4.

A priori it is typically possible to construct a model by choosing an ingredient from the menu of options for each of the three components outlined above. This is an enormous model space, and it may appear daunting to construct searches capable of capturing all possibilities.

On the other hand, the signatures of these models are often so striking that they enable powerful, inclusive searches, sensitive to a very large portion of this overall model space, provided that triggers allow the event to be recorded. Toward this end, it is useful to observe that dark shower events have the following generic features:

1. Events have a *variable and potentially large multiplicity of LLPs*. The number of produced particles of various dark species depends on the details of the parton shower and/or hadronization, as in QCD, and varies from event to event. Typically there are more than two LLPs per event.
2. The BSM species produced in dark showers exhibit a *hierarchy of proper lifetimes*. This could result in production of, e.g. mostly prompt particles with a few displaced decays; mostly invisible detector-stable particles with a few displaced decays within the detector; or anything in between.
3. *LLPs are not generically isolated*, i.e. they often appear within $\Delta R \sim 0.4$ of other LLPs and/or prompt objects (such as the decay products of short-lived species originating from the same shower).
4. The *energy flow in the event reflects the evolution of the BSM parton shower and hadronization*, and thus looks non-SM-like. For instance, hidden sector jets may be either narrower or broader than QCD jets, depending on the hidden sector gauge group, gauge coupling, and particle spectrum. Additionally, SM particle multiplicity—i.e. the relative fractions of pions, kaons, etc, produced in a jet—differs from QCD. While energy flow can be a powerful discriminant to separate dark showers from the SM at any stage from the trigger level forward, it is model dependent and must be assessed on a case-by-case basis. Note that this also implies that traditional (displaced) jet triggers do not suffice to cover the general model space, and alternative trigger strategies (e.g. track or muon multiplicity) are needed as well.

The existence of ~ 2 LLPs per event, and indeed frequently $N_{\text{LLP}} \gg 2$, generally ensures that these events can be easily distinguished from background if they can be recorded on tape and subsequently reconstructed. However, the unique features of events with dark showers require new strategies to ensure that this class of theories is actually captured by the trigger. In particular, non-isolation and the hierarchy of proper lifetimes can result in qualitatively novel collider signatures that require new triggering approaches. Meanwhile, event-level observables such as non-SM-like energy flow or particle multiplicity are potentially powerful but highly model-dependent discriminants, and must be considered on a case-by-case basis. We discuss the strengths and shortcomings of existing triggers and off-line strategies in sections 7.5 and 7.6, as well as a number of new ideas. An executive summary of our main points and recommendations is provided in section 7.7. The chapter concludes with a collection of example models for which MC event samples are currently available (see section 7.8).

7.2. Production

Events with dark showers generically begin with the pair production of dark partons Q_D . In most cases the two produced partons are of the same species, but this does not necessarily need to be true. For clarity and simplicity, we confine ourselves to the case where Q_D is a SM singlet. Then the production modes for Q_D can be simply related to the production modes discussed for neutral LLPs in section 2.4, in the chapter on Simplified Models. In particular, the most relevant production modes are:

- *Heavy parent*: Pair production of a SM-charged HP X_D , which subsequently decays via $X_D \rightarrow Q_D + (\text{SM})$. The SM quantum numbers of the parent X_D , together with its mass, control both the overall production cross section and the typical prompt AOs in the event. Depending on the lifetime of X_D , showering can begin before or after its decay. The model of [331] features this production mechanism, where the parent X_D is a heavy scalar carrying both color and dark color charges. After QCD pair-production, the mediators each decay into a visible jet and a dark shower.
- *Higgs (HIG)*: Production in exotic Higgs decays, $h \rightarrow Q_D \bar{Q}_D$. As the Higgs boson provides an especially sensitive window into low-mass dark sectors, this production mechanism is one of the best-motivated at the LHC [67, 117]. In particular, Higgs portal production is the dominant production mechanism in many Twin Higgs and related models of neutral naturalness [118, 263, 541]. The Higgs boson determines the overall mass scale of the event, often awkwardly low for LHC triggers, while the branching fraction remains a free parameter. As discussed in section 2.3.1, the SM Higgs has a characteristic set of accompanying prompt objects, which can extend trigger options. As also emphasized in section 2.3.1, this category additionally encompasses production through parent Higgs-portal scalars, which may be either heavier or lighter than the SM Higgs.
- *Z' (ZP)*: Here a new Z' boson couples to both SM and hidden sector states, allowing for production through $q\bar{q} \rightarrow Z' \rightarrow Q_D \bar{Q}_D$. This scenario was developed in the original hidden valley models [66, 69], and considered again recently in [372]. The Z' mass determines the overall mass scale, while production cross sections depend on its couplings to both SM and hidden sector states. The only typical AOs are ISR radiation.
- *Charged current*: Here the parent dark states couple to the SM through the neutrino portal, $\mathcal{O}_{\text{int}} = HL\mathcal{O}_{\text{dark}}$. When the dark states carry charge under a dark gauge group, this coupling requires (at least) two dark states, one fermionic and one bosonic. For instance, if the dark sector contains both scalar and fermionic fundamentals, ϕ and ψ , respectively, then one can construct the dimension five interaction $\mathcal{O}_{\text{int}} = HL\phi^*\psi$. This production mode has not been well studied in the literature. It is worth noting that given this dark field content, it is generically possible to also construct Higgs portal couplings, $\mathcal{O}_H = |H|^2|\phi|^2$, $|H|^2\bar{\psi}\psi$, which can generally include lower dimensional operators.

As we have taken Q_D to be SM singlets, the first process discussed in section 2.4, direct pair production, is typically negligible. Of course, if BSM mediators connecting the dark sector to the SM, like the X_D and Z' in the examples discussed above, are heavy enough to be integrated out at LHC scales, then the resulting higher-dimension operators can mediate direct pair production of Q_D . Single production of Q_D is generally suppressed, and in many cases impossible, in particular when Q_D transforms nontrivially under an unbroken gauge group. In Abelian theories, single production of a dark gauge boson is possible, e.g. through a loop of heavy bi-charged matter; this gauge boson can then subsequently shower. In perturbative cascades, a single BSM state Q_D may certainly be produced, but whether Q_D goes on to produce one or more ‘showers’ is highly dependent on the detailed kinematics of the event.

In contrast with most of the simplified models in section 2.4, after a parton Q_D is produced it undergoes extensive evolution in the hidden sector, so that there is no one-to-one connection between the initial Q_D and relevant detector objects. Thus, an event that begins with two partons may result in a final state that contains two pencil-like jets, each containing more than one displaced object; a spherical distribution of displaced objects; or anything in between.

The most important consequences of production modes for our purposes are twofold. First and most importantly, the production mode informs the types of prompt AOs in an event, as well as determining overall event rate and energy scale. These AOs can be useful levers to distinguish signals from SM background, beginning at the trigger level. Secondly, production modes rely on a mediator that couples the dark sector to the SM, which may be a BSM particle like a bifundamental X_D or a Z' , or a SM particle like the Higgs boson. In many models, this mediator-SM coupling also ultimately governs the decay of the dark sector states back into the SM. This is the case for the examples of [66, 67, 69, 118, 263, 331, 372, 541, 542], and is certainly the minimal possibility. It is worth mentioning, however, that decays may be governed by a different interaction than production. As a simple perturbative example, consider the hidden abelian Higgs model. This theory can realize dark showers in a variety of ways; consider for concreteness the perturbative cascade decay chain $h \rightarrow ss, s \rightarrow Z_D Z_D$, which can yield collimated pairs of dark photons when $m_s \ll m_h$ (see, e.g. [543]). In this case a Higgs portal interaction governs production, but the long-lived Z_D decays back to the SM through a separate vector portal interaction.

7.3. Shower

7.3.1. Motivation. A familiar feature of QCD is the formation of jets, sprays of approximately collinear hadrons arising from a parton emitted in a hard scattering process. The physics of jet formation is independent of hadronization or confinement, originating in the singularities of the weakly coupled theory at short distances [544], where the 't Hooft coupling is $\lambda \equiv g_s^2 N_c \ll 1$. In perturbation theory, the differential probability for a quark to radiate a gluon carrying a small energy fraction z at small angle θ is

$$P(z, \theta) dz d\theta \sim \frac{\lambda}{4\pi^2} \frac{dz d\theta}{z \theta}, \tag{7.1}$$

independent of the underlying hard process. The logarithmic divergences at $z, \theta \rightarrow 0$ indicate that perturbative theories favor radiation that is *soft* (low energy) and *collinear*. This enhanced emission of collinear radiation is the source of jets, even in theories that do not confine at all, such as the perturbative, conformal Banks–Zaks gauge theories [545]¹⁹⁷. The large logarithms appearing in these calculations can be numerically resummed through Markov Chain algorithms, leading to the *parton showers* widely used to model jets in MC simulations.

In the limit of strong 't Hooft coupling¹⁹⁸ ($\lambda \gg 1$) perturbation theory breaks down; soft and collinear radiation are no longer enhanced over more general radiation at wide angles. In QCD, the coupling gradually runs strong in the infrared, but other gauge theories (which could be realized in nature as hidden valleys [66]) exist that have an intrinsically large 't Hooft coupling persisting over a wide energy range. Such theories can be understood with the use of gauge/gravity duality. Examples may be conformal, e.g. strongly coupled $\mathcal{N} = 4$ super-Yang–Mills, or confining, e.g. those detailed in [547, 548]. Such large- λ theories were conjectured to lead to spherical event shapes [70], a result that has been directly proven for strongly-coupled large- N_c CFTs [549]. At colliders, these spherical events would lead to

¹⁹⁷ See [546] for a brief and clear recent introduction to jet physics emphasizing the role of scale invariance.

¹⁹⁸ When making this and similar statements below, we always implicitly mean the coupling at the energy scales being probed by a given measurement. For example, while QCD does become strongly coupled near its confinement scale, treating the theory as weakly coupled is justified provided one only ever talks about jet masses and energies at much larger scales.

Figure 88. Illustrations of event shapes, from jetty (left) to spherical (right) with an intermediate event in the middle. The values of Sphericity and Thrust are: (left) Sphericity = 0.006 36, Thrust = 0.991; (center) Sphericity = 0.530, Thrust = 0.706; (right) Sphericity = 0.940, Thrust = 0.521.

characteristic soft unclustered energy patterns (SUEPs) [182, 242, 550]. An illustration of the range of event shapes from jets to SUEPs is shown in figure 88.

Thus we have two well-understood regimes, jets at $\lambda \ll 1$ and SUEPs at $\lambda \gg 1$. There is a gap in the middle when $\lambda \sim 1$ over a wide range of energies. Both perturbative QCD and gravitational duals approach strong coupling in this regime (from different sides) and cannot be trusted to give accurate predictions; for some questions, the predictions may not even be qualitatively accurate.

This regime is of interest because we want to ensure that LHC experiments do not miss a hidden valley signal simply because it looks different than expected. We should aim to be able to trigger on and analyze these events. While sufficiently long lifetimes may provide useful trigger handles, theories at intermediate 't Hooft coupling could also occur with prompt decays while still failing to provide the types of trigger handles typically associated with prompt hard production and decay. Given our inability to reliably calculate the predictions of this scenario, in this section we will take a pragmatic approach: we push the two tools we have, perturbation theory and gauge/gravity duality, into a regime where we do not fully trust them. To the extent that their predictions overlap, one could gain confidence in the qualitative picture we obtain. Where they differ, one would hope that experimental strategies broad enough to encompass the range of possibilities would also be sensitive to poorly modeled scenarios. In the following we present some initial results, which we aim to improve and expand upon in future published work.

7.3.2. Phenomenological models

7.3.2.1. Parton showers and their limits. One can approach the intermediate regime from the direction of weak 't Hooft coupling using parton shower methods. The coupling is then a direct parameter of the model whose value is easy to vary. However, naïvely setting the coupling to large values would quickly lead to unphysical results. The reason is that the simplest derivation of parton shower evolution equations assume that the final state can be organized as a series of splittings where $z, \theta \ll 1$ at each iteration. Since the full matrix element for a given final state has no uniquely-defined splitting history associated with it, this soft, collinear condition needs to hold as a function of the final-state kinematics alone. As the

Figure 89. Schematic view of a $2 \rightarrow 3$ branching process, with the initial two-particle state approximated as a localized dipole. For more details and further discussion see [551].

coupling is increased, the increased showering probability means that there is an increased chance of populating the phase space while violating these conditions. Regions of phase space without nominal soft-collinear enhancements (but in truth populated with comparable probability) will end up under-populated, leading to more jet-like events than the underlying theory actually predicts.

Things can be somewhat improved by a more careful consideration of parton-shower methods. It is currently known how to implement iterated corrections allowing one to relax one, but not both, of the inequalities given above. Implementations which allow for the correct inclusion of finite- z (but small- θ) effects can be accomplished by extending the approximation of equation (7.1) with terms non-singular in z .

If we have reason to believe that the wide-angle structure of dark showers will be more critical to detecting models in the transition region, sacrificing finite- z corrections for a better understanding of the finite- θ region is preferable. This requires going beyond the $1 \rightarrow 2$ splitting picture of equation (7.1) as information about multiple particles in the event must be encoded. A known solution is to phrase the shower in the language of $2 \rightarrow 3$ evolution kernels [552], where radiation is treated as coming from dipoles rather than individual charges, as in figure 89. Necessarily more complicated, in this approach the splitting function describing the emission of a gluon with momentum p^μ is then expressed as

$$P(p_r^\mu) d\Phi_r \sim \frac{\lambda}{s_{ij}} \left[\left(1 - \frac{s_{ir}}{s_{ij}} - \frac{s_{rj}}{s_{ij}} \right) \left(\frac{2s_{ij}^2}{s_{ir}s_{rj}} + \frac{s_{ir}}{s_{rj}} + \frac{s_{rj}}{s_{ir}} \right) \right] \quad (7.2)$$

$$+ \text{non-singular}] d\Phi_r, \quad (7.3)$$

$$s_{ij} = (p_i + p_j)^2. \quad (7.4)$$

for the process $a + b \rightarrow a + r + b$. Features related to the expected broadening of jets at larger coupling will be well-modeled deeper into the transition region with a dipole shower. Angular structure will be correctly reproduced even at larger couplings while final-state energy sharing of collinear particles becomes increasingly untrustworthy. When some sort of angular localization of energy flow can be expected (i.e. soft-collinear enhancements are still present) the corrections at finite splitting angle may still provide a good approximation.

7.3.2.2. Gauge/gravity duality: spheres to jets. Gauge/gravity duality allows calculation in $\lambda \gg 1$ theories with spherical events, from which we extrapolate toward the $\lambda \sim 1$ regime. The

simplest case is Anti-de Sitter (AdS)/CFT duality, where events are perfectly spherical [549]. AdS space is a warped product of a $(3 + 1)$ D Minkowski space with an infinite fifth dimension. To obtain a theory with a discrete spectrum, we cut off the fifth dimension of AdS space at a hard wall or *IR brane* as in Randall–Sundrum (RS) models [553]. 5D fields then decompose into a tower of 4D Kaluza–Klein (KK) modes (dual to hadrons in the gauge theory), each with an associated wave function in the fifth dimension. This wave function, as well as the 4D mass, is calculated by solving the equations of motion up to quadratic order. The couplings between 4D mass eigenstates are proportional to the overlap of their wave functions in the fifth dimension.

Heavy KK modes decay to lighter modes, which decay to still lighter modes, populating a cascade of particles. The case of a flat (unwarped) extra dimension yields sinusoidal wave functions and modes with linearly spaced masses. In this case, the *KK number* is a conserved discrete momentum in the fifth dimension, and KK modes decay only to daughters at threshold. The RS model breaks translation invariance in the fifth dimension, so KK number is no longer exactly conserved and a variety of decays are possible. Nonetheless, for the simple model of a bulk cubic coupling, KK number is still approximately conserved, as illustrated in figure 90, top panel, and the sum of the two daughter modes is approximately equal to the KK mode of the parent. At each step of the cascade, daughter particles have small momentum. This results in spherical event shapes, with no highly boosted daughters [554]. Here we have studied a scalar field with a Φ^3 interaction for simplicity, with the expectation that qualitative features of the event shapes persist in more realistic models.

To push our toy model into the jetty regime, we introduce interactions that explicitly break KK number themselves. We continue to study the simple case of a scalar field, but now, to move toward jettier events, we include the Φ^3 interaction as a boundary term, restricted to the IR brane. As shown in figure 90, right panel, this opens up a much wider range of possible decays with greater phase space, which lead to more variety in the resulting event shapes. We emphasize that moving the Φ^3 term to the boundary is a simple toy model for the purpose of this section that accomplishes the goal of altering event shapes. However, it is not expected to be a good approximation of the dual of an actual confining gauge theory with smaller λ .

Although the IR brane interaction is used here as an ad hoc tool for generating less spherical events, we expect that similar results can be achieved in a more principled way. As λ decreases toward $O(1)$ values, the expectation from gauge/gravity duality is that more bulk fields, dual to the many single-trace operators in the gauge theory, become light. This suggests that models with several interacting bulk fields are a more faithful toy model of the physics of the dual gauge theories at intermediate λ . Such models could be of interest for a wider set of questions than event shapes, as they move the AdS/QCD toolkit—always a toy model at best—somewhat qualitatively closer to QCD. Such models and their consequences will be studied in a forthcoming publication.

7.3.3. Results. We wish to characterize to what extent our available methods allow us to model the range of behaviors we might expect from new showering sectors. Since we do not expect collimated sprays of final-state particles to be a sensible way of organizing information in the event in all cases, for our purposes here we focus on observables that can be defined globally. In particular, we study a pair of event-shape variables that have proven useful to both establish and provide precision data on the non-abelian nature of QCD.

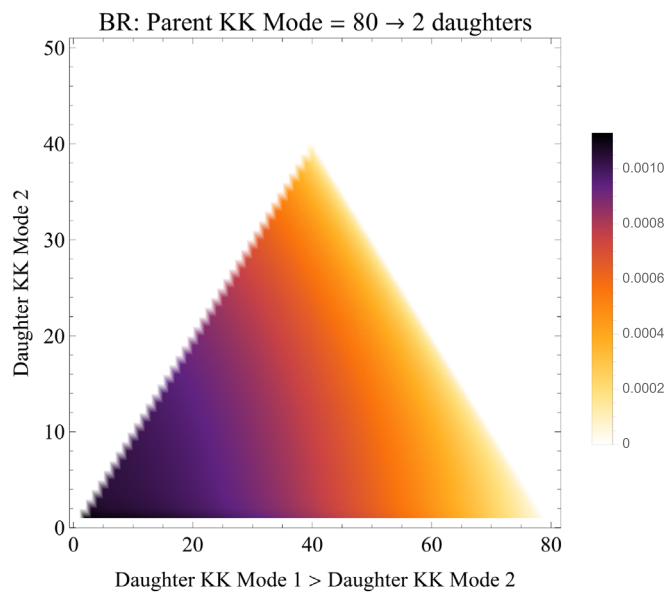

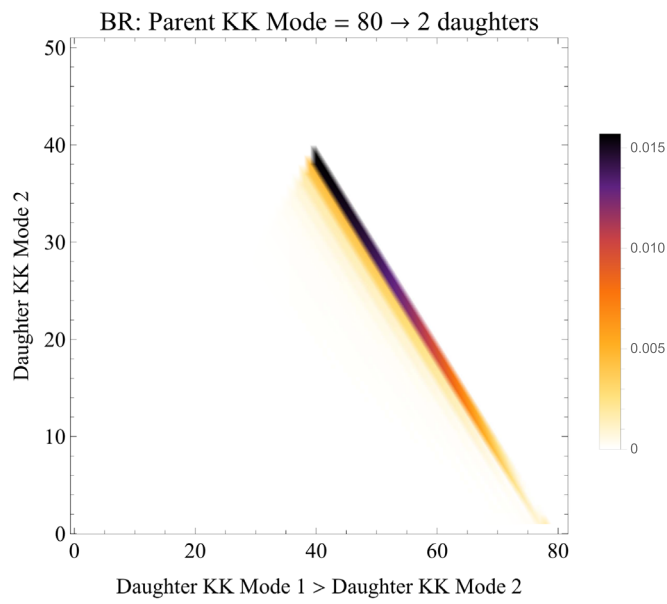

Figure 90. The branching ratio from a parent with KK-number 80 into two daughters for a cubic interaction on the bulk (top) or on the boundary (bottom). The nonzero probabilities occur along the line where KK-number is conserved for the bulk interaction, whereas the boundary interaction has non-zero probability to decay with large jumps in phase space.

Sphericity is defined as the scalar sum of the two smaller eigenvalues of the sphericity tensor

$$S^{ab} = \frac{\sum_i p_i^a p_i^b}{\sum_i |\mathbf{p}_i|^2}, \quad (7.5)$$

where the sum is over all final-state particles in the event [555]. With the eigenvalues λ_i defined in decreasing order, we have $S = \frac{3}{2}(\lambda_2 + \lambda_3)$, which can take on the values $0 \leq S \leq 1$. Thrust is instead defined via a maximization procedure with respect to all possible axes in the event [556],

$$T = \max_{|\mathbf{n}|=1} \frac{\sum_i |\mathbf{n} \cdot \mathbf{p}_i|}{\sum_i |\mathbf{p}_i|}. \quad (7.6)$$

Both observables essentially measure the divergence of an event from the pencil-like final-state structure of a $2 \rightarrow 2$ scattering process without making any direct reference to jets.

Historically, thrust had the advantage of being infrared and collinear safe. In a given event, the change in the thrust due to an additional radiated parton vanishes as the parton becomes soft or collinear to the thrust axis. Singular regions of phase space thus do not contribute to finite values of the thrust, and its measured distribution in QCD is well described by a perturbative calculation up to corrections that scale as $O(\Lambda_{\text{QCD}}/Q)^2$, where Q is a high-energy scale associated with the total system being probed by the thrust. This is not the case for sphericity—specifically a perfectly collinear splitting still changes the value of the sphericity tensor. A perturbative calculation of the sphericity is then divergent for finite values of sphericity, a divergence which can be tamed by either an explicit cutoff at the hadronization scale supplemented by a phenomenological hadronization model (the approach taken by MC generators) or by absorbing it into a form factor (as done in analytic calculations). In either case $O(1)$ sensitivity is induced to the region of phase space dominated by non-perturbative hadronization effects. For our concerns, this difference can be turned into an advantage, as any apparent difference between the two observables can act as a diagnostic of the sensitivity of our predictions to the non-perturbative parameters in the parton shower.

We generated events from models expected to yield a range of behaviors. We considered extra-dimensional models with both bulk and boundary interactions, with the former expected to yield very isotropic events. For the parton shower, we used a modified version of the VINCIA dipole-antenna parton shower [557] in which an $SU(N)$ gauge theory with only light quarks showers and hadronizes into light mesons with masses $m_{\pi_v}/\Lambda_v \sim m_{\pi}/\Lambda_{\text{QCD}}$. We then varied the Coupling boundary conditions and one-loop running while adjusting shower cutoffs to ensure that couplings remain perturbative throughout the parton shower.

We summarize the results in figure 91, with the uncertainty in the parton shower distributions coming from considering both transverse-momentum and dipole-virtuality shower ordering. The similar behavior of the two distributions indicates that sensitivity to non-perturbative effects from hadronization are not large. The lowest sphericity/highest thrust distribution is fairly close to that expected from QCD, but a wide range of non-QCD-like behaviors is observable. A significant fraction of the allowed range for these observables is populated by a combination of the extra-dimensional and the parton shower approaches, and the boundary interaction KK model and parton shower models give similar results.

Examining the behavior of observables that are perturbatively incalculable in the weakly coupled theory indicates that a degree of caution is warranted, however, with the two approaches giving qualitatively different results to certain questions. As an example, we look at the correlation between sphericity and total event multiplicity for the two closest parton

Figure 91. Comparison between accessible ranges of parton shower and AdS/CFT-inspired models (labeled ‘KK model’) for sphericity and thrust. In the parton shower, the curves correspond to events produced at $\sqrt{s} = 100\Lambda$, with confinement scale Λ ; the shading indicates the uncertainty resulting from comparing transverse momentum and dipole virtuality shower ordering. The β functions of the theories are tuned such that $g^2(100\Lambda)/4\pi$ is 0.06, 0.12, 0.24 for the 3 distributions. In the KK model case, the dashed curve corresponds to a bulk interaction while the solid curve corresponds to a boundary interaction. We also show expectation values for all distributions.

shower and extra-dimensional models. Displayed in figure 92, we see that multiplicity is broadly correlated with sphericity in the parton shower, while being nearly sphericity independent for the KK model. Such qualitative differences between the parton shower and the extra-dimensional models warrant more detailed study of event behavior in the transition region, while both approaches would benefit from further consideration of how jet-level observables, whether physically well-justified or not, vary over their accessible ranges.

7.4. Decay

In general, the mass spectrum of confining hidden sectors is poorly known, with the exception of a few special cases, like pure glue confining theories [558] and the SM QCD sector. The

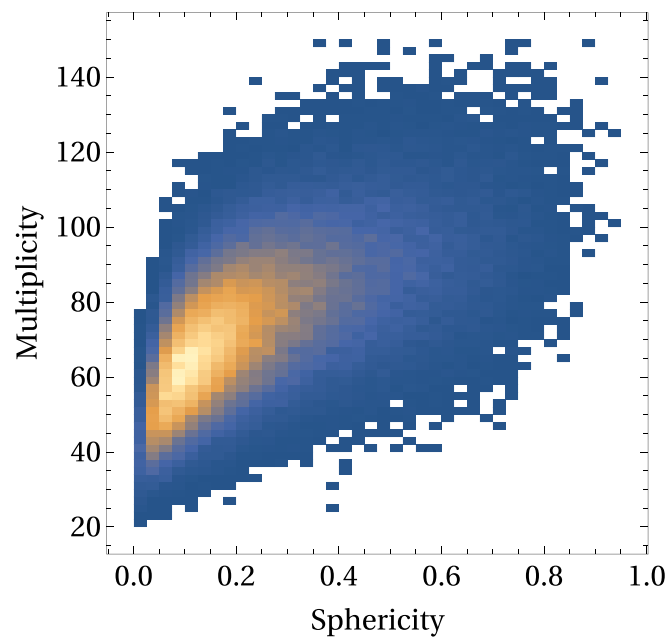

Figure 92. Correlation between sphericity and hadron multiplicity for events generated with parton shower (top) and AdS/CFT-inspired models with boundary interaction (bottom).

dynamical process of hadronization is even less well understood, and one must typically resort to uncontrolled extrapolations from the measured fragmentation functions in the SM. Moreover, states with different CP and spin quantum numbers can have greatly different lifetimes even in well-understood examples [66, 540, 559], a problem that is further exacerbated if the hidden sector contains one or more approximate flavor symmetries. For concreteness we here primarily focus on the case where only one dark species has a detector-scale lifetime; other dark states may either decay promptly to the SM or appear as MET. A useful special case realizing this scenario is one in which all internal hidden sector decays are sufficiently rapid for heavier hidden states to promptly decay down to the lightest state in the spectrum, which in turn decays to the SM. The discussion below is focused on the possible properties of this lightest hidden state which decays to the SM. We refer to it as ‘the’ LLP, keeping in mind that in complete models there may very well be multiple species of LLPs. It is therefore important to emphasize that *experimental strategies should not be overly optimized* towards the naïve assumption of a single LLP giving rise to all visible decays, as it may not be generically true. In particular, an inclusive experimental strategy should avoid making detailed assumptions about the distributions of proper lifetimes of long-lived states in the event.

7.4.1. Portals and branching ratios. The available decay channels and branching ratios of the LLP are critical both for the trigger strategy and the off-line analysis. In particular, various (multi-)muon triggers can be very effective for models where the LLP branching ratio to muons is not too small. At the same time, displaced hadronic decays tend to give more discriminating power in the off-line analysis, since they produce a larger number of tracks as compared to the leptonic modes. Since each event contains multiple LLPs, a single event can contain *both* leptonic and hadronic vertices, where one uses the former for the trigger and the latter for off-line background rejection. For this reason it is not straightforward to interpolate sensitivity between lepton-rich and hadron-rich hidden showers, since the optimal search strategy for the intermediate cases is qualitatively different from the strategies for the two extremes.

As a starting point for our exploration, we therefore recommend a small number of theoretically motivated decay portals, which cover the fully leptonic and fully hadronic cases, as well as two other intermediate scenarios. We focus our attention on operators of dimension four or five which do not induce additional flavor violation in the quark sector:

- *Neutrino portal:* If the LLP is a neutral, possibly composite, fermion X , it may decay through a small mixing with the SM neutrinos. This state predominantly decays through the $X \rightarrow \ell^+ W^{-(*)}$ and $X \rightarrow \nu Z^{(*)}$ channels and its decays tend to be rich in leptons. The muon fraction in the final states depends on the mixing angle of the X with the muon neutrino, which is model dependent. However, even if this angle is accidentally small as compared to the mixing angles with electron and tau neutrinos, one still expects a muon in roughly $\sim 10\%$ of all decays through the $W^{(*)}$ channel. In τ -rich scenarios, muons also originate from leptonic τ decays.
- *Hypercharge portal:* It is plausible for a dark sector to contain a vector particle, whether it is an elementary $U(1)$ gauge boson or a composite (the analogue of the ρ in the SM). An elementary vector boson can be copiously produced through decays of a hidden sector meson through a chiral anomaly, analogous to π^0 decay in the SM. Whether elementary or composite, such a vector state generically mixes with SM hypercharge through the kinetic mixing operator $\epsilon B^{\mu\nu} F'_{\mu\nu}$, where $F'_{\mu\nu}$ is the dark vector boson field strength. The

Table 11. Probability of finding exactly one muon/two muons in one LLP decay through the photon and Higgs portals. For the lowest mass points, the branching ratios for the photon and Higgs portals were taken from [458, 440], respectively. For the 8 and 15 GeV benchmark the hadronization was performed with Pythia 8 [219, 501].

Mass (GeV)	Photon	Higgs
0.5	0/0.4	0/0.09
1.2	0/0.35	/
8	0.08/0.16	0.25/0.02
15	0.1/0.15	0.3/0.05

branching ratios of such a state then depend on its mass and can be extracted from data, as shown in table 11 (see, e.g. [230, 458]).

- *Higgs portal:* In the same spirit, it is possible that a hidden sector scalar S mixes with the SM Higgs boson through the $SH^\dagger H$ operator. In this case, its branching ratios to SM fermions are proportional to m_f^2 , with the caveat that non-perturbative effects modify the story substantially for $m_S \lesssim 5$ GeV. For $m_S \gtrsim 1$ GeV, hadronic branching ratios can be obtained through chiral perturbation theory; however, in the intermediate range $1 \text{ GeV} \lesssim m_S \lesssim 5 \text{ GeV}$, the theory uncertainties are substantial and we do not attempt to make any quantitative statements in this regime (see [560] and references therein). As shown in table 11, the muon branching fraction predicted by Higgs-portal decays is smaller than for the previous two portals, but it can still be relevant if the (non-isolated) muons from B -meson decays are taken into account.
- *Gluon portal:* The hidden scalar (S) or pseudoscalar (a) could also decay to the SM through a coupling to gluons of the form $S \text{Tr} G^{\mu\nu} G_{\mu\nu}$ or $a \text{Tr} G^{\mu\nu} \tilde{G}_{\mu\nu}$. In this case the direct leptonic branching ratio is zero, although a small number of muons may still be produced in the hadronization process of the gluons.
- *Photon portal:* Similar to the gluon portal, the LLP could decay to two photons through the $S F^{\mu\nu} F_{\mu\nu}$ or $a F^{\mu\nu} \tilde{F}_{\mu\nu}$ operators. The signature for this case is qualitatively different from the previous four, since there are many fewer tracks. In particular, tracks only originate from photon conversions in the detector and suppressed Dalitz decays to $e^+e^-\gamma$. The signal is therefore a trackless jet with a high rate of energy depositions in the ECAL relative to the HCAL.

If the lifetime of the LLP is $\mathcal{O}(50)$ m, dark showers generically give rise to multiple decays within the detector volume. In table 12 we show the probability for the Higgs and hypercharge portals to produce an event which contains at least three or four muons, as a function of the number of decaying LLPs in the event. Assuming the event has at least four LLP decays, a multi-muon trigger has good efficiency for the Higgs portal above the $b\bar{b}$ threshold¹⁹⁹ and for all masses for the hypercharge portal²⁰⁰. This trigger strategy should also have good efficiency for neutrino-portal decays, although this scenario is more model dependent. For the gluon and photon portals a different set of triggers is needed, as discussed below. The lesson is that multi-muon triggers do not suffice to cover all possible options, but could provide a reasonably generic trigger path for an important subset of the relevant models.

¹⁹⁹ The importance of muons in decays which are rich in heavy flavor was emphasized in [71].

²⁰⁰ Again, this statement is LLP-lifetime dependent, and for sufficiently long-lived LLPs this strategy will break down as the probability of getting sufficiently large numbers of LLP decays within the detector becomes small.

Table 12. Probability of finding at least 3 muons/at least 4 muons in an event for the photon and Higgs portals, as a function of the number of LLP decays. Branching ratios and hadronization were determined as in table 11.

	Mass (GeV)	3 decays	4 decays	5 decays	6 decays	7 decays
Photon	0.5	0.36/0.36	0.53/0.53	0.67/0.67	0.77/0.77	0.85/0.85
	1.2	0.29/0.29	0.44/0.44	0.57/0.57	0.68/0.68	0.77/0.77
	8	0.13/0.07	0.23/0.13	0.33/0.21	0.42/0.28	0.5 /0.35
	15	0.14/0.07	0.23/0.13	0.33/0.2	0.42/0.27	0.51/0.35
Higgs	0.5	0.02/0.02	0.04/0.04	0.07/0.07	0.1/0.1	0.13/0.13
	8	0.04/0.0	0.09/0.02	0.15/0.04	0.23/0.07	0.31/0.12
	15	0.11/0.02	0.21/0.07	0.33/0.13	0.44/0.21	0.55/0.31

7.4.2. Lifetime. Without additional model assumptions, the theory prior on the lifetime of the LLP is rather weak. We can, however, extract some insight from the generic scaling of the width of the LLP as a function of its mass (m): for the Higgs and hypercharge portals, $\Gamma \sim m$; for the photon and gluon portals, $\Gamma \sim m^3/f^2$ with f the decay constant of the LLP (in this case, the LLP behaves similar to an axion-like particle, or ALP); for the neutrino portal, $\Gamma \sim m^5/m_W^4$. The obvious trend in all cases is that the lifetime rises as the mass decreases, steeply so for the case of the neutrino portal. It is furthermore important to note that the above scalings are lower bounds, and in many models the leading decay portal involves a higher-dimensional operator, leading to a stronger scaling with mass. This is especially relevant in confining models where the hidden states are composite particles. For example, in a pure-gluon hidden valley coupled through the Higgs portal [559], the lightest glueball can decay through its mixing with the Higgs, but as the portal coupling contains the dimension-four combination of dark gluon field strengths $G_{\mu\nu}^a G^{a\mu\nu}$, its width scales as $\Gamma \sim m^7 \times (v_h/M^2 m_h^2)^2$, where we have taken $m \sim \Lambda_D$, the scale of dark QCD, and M is the suppression scale of the portal operator.

An additional consideration is that the LLP can be discovered directly in (low energy) collider or beam-dump experiments. Since the LLP has an irreducible production cross section through the same coupling that governs its decay, collider experiments effectively impose a lower bound on the lifetime of these states. Beam-dump and supernova constraints on the other hand rely on a displaced signal and constrain the lifetime from above. These bounds are, however, not typically applicable for masses above a few hundreds of MeV (and for a summary of some of the latest constraints on the hypercharge, photon and gluon portals see, e.g. [561, 562]). However, particles that can be produced in sizable numbers at the LHC are in general coupled sufficiently strongly to the SM that they face upper limits on their lifetimes from BBN. In most cases, this upper bound is essentially mass independent and requires $\tau \gtrsim 1$ s, but this upper bound can be much weaker for lighter particles and/or particles that decay to hadron-poor final states. For the photon, gluon and hypercharge portals, prompt decays are currently allowed for masses all the way down to the electron threshold, though for the hypercharge portal LHCb is expected to completely close this window below ~ 100 MeV [341, 382]. For the Higgs portal, current LHCb results from b to s transitions [267, 268] already require $c\tau \gtrsim 0.5$ mm for masses below 4 GeV. For the neutrino portal, lifetimes $c\tau \gtrsim 10$ m are excluded if the mass is below 1 GeV and the mixing is predominantly with the electron and muon neutrino [563].

As argued above, if the mass of the LLP is larger than a few hundred MeV, their lifetime is only constrained from above by BBN. In the context of a dark-shower topology, there is, however, a much more stringent upper bound to lifetimes that can be probed at the LHC. In particular, to observe at least a handful of decays in the detector volume, the lifetime in the lab frame should satisfy

$$c\tau_{\text{lab}} \lesssim 10 \text{ m} \times \frac{N_{\text{LLP}}}{N_{\text{decays}}} \quad (7.7)$$

with N_{LLP} the typical LLP multiplicity and N_{decays} the number of observed decays in the detector²⁰¹. For instance, for $N_{\text{decays}} \sim \text{few}$ and $N_{\text{LLP}} \sim \mathcal{O}(10)$ this implies $c\tau_{\text{lab}} \lesssim 50 \text{ m}$.

Near this heuristic upper limit in the LHC's sensitivity to lifetime, the shower effectively gets stretched out over the detector elements, and it is useful to study how the decays are distributed over the different detector elements. We can use a toy MC to make some simple estimates of this effect by making the following simplifying assumptions: (1) the number of LLPs is Poisson distributed; (2) their decay lengths follow the usual exponential distribution with uniform average lifetime in the lab frame $c\tau_{\text{lab}}$; (3) the angular distribution of the vertices is approximately spherical in the lab frame. Figure 93 shows the distribution of the number of decays occurring in the tracker, calorimeter and muon chamber for two benchmark points. We hereby assume for concreteness the approximate CMS geometry with the 'tracker', 'calorimeter' and 'muon chambers' defined by $r < 100 \text{ cm}$, $100 \text{ cm} < r < 200 \text{ cm}$ and $400 \text{ cm} < r < 700 \text{ cm}$, respectively. We find that the number of decays in all detector components is roughly equal, with slightly more decays in the muon chamber for a higher number of LLP decays in the shower. The latter result is easily understood from the larger size of the MS as compared to the tracker and the calorimeter. The qualitative conclusion is that tracker-based searches for multiple DV are likely to have reasonable sensitivity over the whole relevant lifetime range. For the longer lifetimes, the sensitivity necessarily degrades although it can be partially recovered by incorporating the muon chamber in the analysis. On the other hand, searches relying exclusively on the muon chamber or the calorimeter are less sensitive to a wide range of lifetimes. To quantify this effect more accurately, detailed simulations for specific benchmark models accounting for more realistic boost and η distributions are needed, although the relative importance of the tracker is likely to continue to hold. The displaced SUEP scenario is an interesting exception, as discussed in section 7.6.2.2.

7.5. Trigger strategies

7.5.1. General considerations. Due to the immense diversity of hidden sector models, there is no trigger strategy which can comprehensively cover all options, nor is it straightforward to compile a list of such strategies. This problem is further compounded by the lack of available MC simulations, except in a handful of special cases. Many of the considerations informing the trigger strategies discussed for singly and doubly produced LLPs in chapters 3 and 5 apply to dark shower events as well. However, the four characteristic features of dark showers laid out in section 7.1 can pose both additional opportunities and challenges:

1. *The particle multiplicity can range from high to very high.* This in itself can provide a very powerful trigger strategy, especially when the muon fraction in final states is appreciable, as discussed in section 7.4.1. For models where this is not the case or where the muons are too soft to fire the trigger, triggers relying on a large multiplicity of tracks

²⁰¹ If only one or two LLPs are expected in the detector, then the dark shower maps onto the topologies with one or two DV discussed earlier in this document.

Figure 93. Distribution of decays occurring in the various detector elements, for those events with more than three decays occurring in the fiducial volume.

or an over-density of pixel hits could provide an alternative strategy. We will return to this discussion later in this section.

2. *The hidden sector may contain states with vastly different lifetimes.* While this makes it challenging to get a comprehensive grasp on the full space of possible event topologies, this feature provides interesting opportunities from the point of view of the trigger. For instance, often the most striking off-line signature is a set of DV in the tracker, which are notoriously challenging targets for the trigger. It is completely plausible that these vertices would originate from the decay of one species of hidden sector particles, while a second species decays either promptly or very displaced. This means that the event may very well come with prompt leptons, H_T , an appreciable amount of E_T , and/or activity in the muon chamber.
3. *The decay products may not be isolated.* Combining the first two features, we should prepare for the possibility that the objects we aim to use as trigger handles may not be

isolated. Especially for triggers on muons and (displaced) tracks, it is advisable to relax isolation criteria as much as possible and instead rely on the presence of one or more additional objects to reduce rates as necessary. For example, one would expect that a trigger on two isolated muons would be less effective than a trigger on three or four non-isolated muons or a trigger with two non-isolated muons and a moderate amount of \cancel{E}_T . Non-isolation is likely to be a limiting factor for the acceptance of dark shower events in specialized triggers designed for singly- or doubly-produced LLPs.

4. *The energy flow in the dark shower may be non-standard.* This implies that a dark shower may be broader or narrower than SM QCD jets, and the momentum distribution of the particles in the shower may also differ substantially from QCD predictions. This means that triggers for (trackless) jets could be effective for some models, but would by no means capture the full range of possibilities. Since such p_T distributions are very model dependent, it is moreover sensible to keep object p_T thresholds as low as possible, and instead rely on the high multiplicity by requiring multiple low p_T objects, rather than a few high p_T objects.

In summary, while some dark shower models will be very challenging to trigger on, this is not true for the entire class of models. For example, some (although certainly not all) models can readily be captured on the traditional \cancel{E}_T , H_T or lepton triggers. This means that these traditional triggers *are an excellent place to start, but a bad place to stop*. Indeed, in the context of limited resources, it makes sense to first pursue the scenarios where the trigger is not a major challenge and use these scenarios to develop off-line reconstruction techniques. It is, however, crucial to follow up with more innovative trigger strategies. While this is largely still a topic of study, we can identify two categories of non-traditional triggers:

1. *Triggers on displaced objects:* This type of trigger is notoriously challenging due to bandwidth and online computing limitations, but nevertheless a lot of progress has been made in the last few years. This is discussed in chapters 3 and 5. For our purposes here, it suffices to note that high multiplicity of LLPs in dark shower events can help provide excellent acceptance in such triggers, provided that any isolation criteria in the trigger are not spoiled by shorter-lived objects in the event.
2. *Specialized triggers for dark showers:* There are a number of (speculative) ideas for triggers which exploit the high multiplicity and/or energy features of a dark shower, as described above, although this area is much less developed than the triggers on displaced objects. We will discuss these ideas for specialized triggers briefly in the remainder of this section, and comment on the unique capabilities of LHCb when it comes to triggering on dark showers.

7.5.2. Specialized trigger ideas. In this subsection we briefly highlight some proposals for specialized trigger strategies that inherently depend on the unique features of dark shower events.

7.5.2.1. Multiplicity triggers. As emphasized throughout this chapter, dark shower models can produce a high multiplicity of dark particles, ranging from several tens up to thousands of particles in the most extreme case. This motivates triggers that aim to minimize p_T thresholds and instead exploit high particle multiplicity. The most obvious option is a suitable multi-muon trigger (three, four, or more muons), where the priority should be to avoid tight isolation criteria, if needed at the expense of increasing the muon multiplicity and/or p_T thresholds. Prompt multi-muon triggers would, however, only capture (nearly) prompt

decays, and it is critical to pursue the design and implementation of a trigger with good efficiency for displaced muons; see section 5.1.3 for more on planned displaced muon triggers.

Another way of exploiting the particle multiplicity is to trigger on an anomalously large number of tracks originating from the PV. This would likely only work for prompt or nearly prompt decays, in models which produce a rather low muon fraction and/or a very soft p_T spectrum. For this strategy to work, one must first pass the L1 trigger with MET, which can be provided by the shower itself or by initial state radiation (ISR). At the HLT it may be possible to count the number of tracks with the planned ATLAS HTT system or the future CMS HTTs. Alternatively, if the tracks are too soft and the multiplicity high enough, it is possible to pass the HLT by looking for an over-density of hits in the innermost tracking layer, centered around the z -coordinate of the PV [242].

7.5.2.2. Substructure triggers. Substructure triggers may open up the possibility of using substructure techniques to distinguish between QCD jets and other types of showers already at the trigger level. CMS currently uses jet trimming at HLT level to enhance acceptance for jets with hard splittings, optimized for boosted electroweak gauge bosons, (see, e.g. [564, 565]), and we are aware of an effort within ATLAS to investigate the inclusion of substructure routines at the HLT level. This strategy could be helpful in cases such as photon-jets (dark showers that decay into SM photons), which can otherwise pose significant trigger challenges: substructure variables such as n -subjettiness [566] and energy-energy correlations can be very effective at separating QCD jets, photons and photon-jets [567, 568]. In practical terms, this means that one may be able to use the relatively low threshold jet/tau trigger for the L1 trigger. This could be followed by a HLT trigger that uses, for instance, the ratio of the energy deposited in the ECAL/HCAL or substructure variables.

An advantage of substructure methods is that they are fairly robust with respect to the lifetime of the dark shower final states, provided the lifetime is not too long compared to the size of the relevant detector sub-system. As long as the showering process itself happens quickly (and provided that hadronization represents a small correction to the typical particle momenta), the separation between energy depositions in the calorimeter is already pre-determined. In particular, under these assumptions it does not matter if the SM decay products of the lightest dark states are themselves collimated. A clear difficulty with substructure triggers is that the actual dark showering and hadronization process, and therefore the substructure, is theoretically only understood in a handful of example models as discussed in section 7.3. While such a trigger is clearly valuable for a number of models, it is at the moment difficult to evaluate how broadly applicable it could be to different shower shapes.

7.5.2.3. Non-isolated DV trigger in the ATLAS MS. For sufficiently LLPs, fallback trigger strategies can be provided by existing ATLAS triggers that require a cluster of hits in the MS [241, 257]. As these triggers look directly for the presence of displaced objects and do not rely on any features of the rest of the event, they offer potential sensitivity to signals dominantly produced at low mass scales. The existing MS DV trigger requires at least three (barrel) or four (endcap) tracks in the MS [257]; a dedicated vertex-finding algorithm is run on these events at the analysis level. Thus this trigger option offers good sensitivity to hadronic decays of particles with mass $\lesssim 5$ GeV, but cannot provide sensitivity to individual di-leptonic or photophilic decays, nor to decays of LLPs with GeV-scale masses.

In Run 1, LLP searches with DV in the MS relied on a trigger that recorded events where the DV additionally passed isolation requirements. Specifically, events were required to have no tracks with $p_T > 5$ GeV in the ID within $\Delta R < 0.4$ of the DV, and the distance to the

nearest jet (with $E_T > 30$ GeV) was required to be $\Delta R_j > 0.7$. However, this isolation cut was not imposed for jets with anomalously large energy deposition in the HCAL, $\log_{10}(E_{\text{had}}/E_{\text{EM}}) > 0.5$ in order to improve acceptance for LLPs decaying in the outer edges of the HCAL [241]. This isolation requirement can limit acceptance for models with dark showers where multiple BSM species can spoil each other's isolation, especially in cases where the shower contains both short-lived as well as long-lived dark particles. It is an open question whether tracks from sufficiently DV in the ID would contribute to the track veto, but particles that decay within the ID would be likely to spoil the isolation requirements through calorimeter deposits alone, unless their decays involved only muons.

New in Run 2 is a trigger on *non-isolated* clusters of hits in the MS [258], which uses the same triggering algorithm for the MS hits but does not impose isolation criteria. The primary aim of this trigger is to enable background estimation for single DV searches [262], but it would also efficiently record dark shower signal events, regardless of event shape or event energy scale, provided at least one particle species in the shower has $m \gtrsim 5$ GeV, decays to final states with at least three charged particles, and has reasonable probability to decay in the MS. This trigger may be especially useful for high-multiplicity signals, where the probability for getting one particle to decay in the MS can become appreciable even for shorter-lived LLPs.

7.5.2.4. Capabilities at LHCb. The LHCb detector is designed for studying displaced decays of SM mesons. This provides a good environment to search for dark shower events containing LLPs with lifetimes below the meter scale [68]. Although LHCb does not yet have a dedicated trigger for dark shower events, many of the trigger strategies used for SM meson searches may be applied to dark shower signals. The LHCb detector is a single-arm forward spectrometer covering the pseudorapidity range $2 < \eta < 5$, which means the signals for which it is optimal have typical p_T that is much lower than the signals targeted by ATLAS and CMS. Hence, the LHCb signal trigger usually has much weaker p_T requirements compared to an ATLAS or CMS search. This allows for better observation of dark shower events that come from the decay of light parent particles boosted in the forward direction, such as dark mesons from the decay of a light Z' .

For example, [387] searches for a pair of LLPs decaying into jet pairs. Although the signal is different from a dark shower, the trigger strategy in the search can be useful for dark shower events. The hardware trigger (L0) requires a single hadron, electron, muon, or photon with object-dependent p_T thresholds. For muons (hadrons), the thresholds are $p_T > 1.48$ (3.5) GeV, and given the rapidity range of the signal, this corresponds to momenta $p > 6$ (13) GeV for muons (hadrons). These low p_T requirements can thus keep soft and low-mass dark meson decays that can be hard to trigger on at ATLAS and CMS. The software trigger contains algorithms that run a simplified version of track reconstruction and an identification of displaced tracks and vertices, and the first software stage (HLT1) requires a high-quality displaced track satisfying the above p_T requirement. In [387], the final trigger stage (HLT2) further requires a DV with ≥ 4 charged tracks, and either a > 2 mm decay length in the transverse direction or the reconstructed vertex mass > 10 GeV. Since the search focuses on b -quark final states, the HLT2 trigger also contains a multivariate algorithm to identify b -hadron decays. Although the trigger is designed for LLPs heavier than 10 GeV scale, it is important for LHCb to determine if the same strategy can be applied to even lighter particles or different decay final states.

For specific decay channels of dark mesons, we can also adapt triggers from existing SM hadron searches that look for the same final states [383]. For example, if dark mesons decay into muon pairs or c -quarks, we can use similar triggers as in the $K_s \rightarrow \mu^+\mu^-$ [569] or

$B^0 \rightarrow D^+D^-$ [570] searches to study the signal. A more recent muon trigger is used for the 13 TeV dark photon $A' \rightarrow \mu^+\mu^-$ search [269], where a muon with $p_T > 1.8$ GeV is required at the hardware trigger level, and further quality cuts on the DV and muon identification are required. This search can be useful for dark mesons that decay through a kinetic mixing, in which muon final states have a sizable branching ratio.

Planned upgrades at LHCb are further discussed in section 5.2. These upgrades will make LHCb an even more powerful facility for studying LLPs, particularly in the low-mass and short-lifetime regime, and further study of LHCb's capabilities for dark showers is well warranted.

7.5.2.5. Low PU data. While Run 2 of the LHC has brought unprecedented opportunities for discovery of new physics with a large $\sim 150 \text{ fb}^{-1}$ dataset of 13 TeV pp collisions, the ability to explore the energy frontier comes at a cost: high trigger thresholds and challenging experimental conditions may limit the sensitivity of LHC experiments to BSM models such as SUEPs with soft and diffuse signatures. During Run 2 data-taking, the typical $\langle \mu \rangle$ value has already reached ~ 60 interactions per bunch crossing.

The low PU datasets provided by the LHC during Run 2 therefore present an interesting opportunity for dark showers. There are two such data sets: one with 0.5 fb^{-1} at 13 TeV and $\langle \mu \rangle = 2$ and one with 0.3 fb^{-1} at 4 TeV and $\langle \mu \rangle = 5$. While the size of these datasets is much lower than the 13 TeV high- μ pp dataset, the change in data-taking conditions is amenable to searches for BSM scenarios which would normally be difficult to distinguish from PU noise, and low-background searches may be performed under circumstances that would otherwise be impossible.

In low PU data, object-multiplicity (track- or cluster-based) triggers (section 7.5.2.1) are typically run with lower thresholds and higher rates than otherwise may be possible. The ability to cleanly reconstruct low- p_T tracks and vertices or soft calorimeter clusters could provide the only way to experimentally access some low-mass LLP scenarios. Simple analyses in this modest dataset may provide the first limits on some models, and these results could help direct the more advanced developments discussed throughout this report.

7.5.2.6. Zero bias strategy. If all other strategies fail to capture the signal, the zero bias strategy is an ultimate fallback [571]. In this case one would simply rely on passing the L1 trigger due to an object in an unrelated PU event. The effective dataset one can ultimately obtain this way is only $\sim 0.5 \text{ fb}^{-1}$, though it might increase to $\sim 50 \text{ fb}^{-1}$ if a specialized selection could be made at the high level trigger.

7.6. Off-line analysis

In this section we discuss aspects of the off-line analyses needed to discover dark showers. As has been a primary theme throughout this chapter, hidden sector states with displaced decays are generic, but prompt decays are possible as well. Naturally cases with and without promptly decaying species require different strategies. Though the main focus of this document is on long-lived phenomena, showers where *all* species are short-lived are closely related to the signals of our main interest and provide valuable illustrations of tools and techniques that can ultimately shed light on the underlying hidden sector dynamics itself, and we accordingly provide a discussion of prompt showers as well.

7.6.1. Prompt decays. We begin by discussing dark showers with promptly decaying BSM states, i.e. with no reconstructable displaced decays in the event. Promptly-decaying dark

showers are substantially more challenging to separate from backgrounds than showers containing LLPs, as the presence of multiple displaced objects is a very powerful background-suppression tool. However, the techniques that have been proposed and/or used for prompt showers are important for several reasons. First, they provide a useful illustration of how the unique properties of showering events have been approached in analyses to date without introducing the separate complication of displacement. Second, dark showers that produce prompt SM particles may very well also produce LLPs, thanks to the hierarchies of lifetimes that are generic in confining theories. Such events can thereby produce *semi-visible jets* [372], which contain detector-stable invisible states as well as promptly-decaying states. These semi-visible jets pose some specific challenges in analysis and reconstruction, as we briefly review below.

If SM particles resulting from the dark shower are produced promptly, there are two possible experimental handles: the portal through which the hidden sector couples to the SM, and the structure of the dark shower itself. The former case depends on the operators mediating the production and decay of showering states, as described in sections 7.2 and 7.4. For example, for decays governed by the Higgs, photon, and neutrino portals, one may expect an unusually muon-rich jet (section 7.4). Similarly, the jet may be semi-visible (section 7.6.1.1) if some of the states do not decay in the detector volume. On the other hand, if the SM final states are almost purely hadronic, as when decays are governed by the gluon portal, no such obvious handles are available and one must look at the substructure of the jets themselves to find differences from those in typical QCD events. The discussion below is organized according to the typical size of the dark shower, going from narrow QCD-like jets to large-radius jets and finally to fully spherical topologies (SUEPs).

7.6.1.1. QCD-like jets ($R \approx 0.4$). The case of LJs, originally motivated by DM considerations, provides an example of showering with noticeably different particle content than a QCD shower. Here, visible decays of the dark states are primarily to leptons [155, 572], which can occur either due to other decays being kinematically inaccessible or due to selection rules. The most striking signature of the model is the presence of collimated sprays of leptons rather than hadrons in the final state. Reconstructing these objects requires the elimination of lepton isolation criteria typically imposed on leptonic final states, together with variables such as layer-specific cuts on energy deposited in the ECAL, and a fraction of HT TRT hits and/or activity in the muon chambers, selecting for electromagnetically dominated radiation. Searches for prompt lepton jets have been performed by the ATLAS and CMS collaborations [274, 573].

A more elaborate prompt scenario is the case of *semi-visible jets* [372]. Here, the visible final states are hadrons, as in typical QCD jets, but missing energy is interleaved with the visible final states as only some fraction of the states produced in the dark shower decay back to SM particles, while others escape the detector. Semi-visible jets fail to provide the dramatic handles of the lepton jet scenario. However, by considering combinations of large amounts of \cancel{E}_T and differing cuts on $\Delta\phi$, the angular separation between the \cancel{E}_T and the closest jet, control of both SM backgrounds and discrimination from more typical SUSY-like high \cancel{E}_T scenarios can be achieved. Bounds on showers with a fraction of between 0.2 and 0.9 of produced dark hadrons decaying invisibly should allow for bounds comparable to conventional resonance searches [574].

If event-level handles like lepton (or heavy flavor) multiplicity or \cancel{E}_T are not present, sensitivity might still be achieved by looking toward the internal structure of the jets themselves. While this topic is presently relatively uncovered, with only a few exploratory results available [575], similar techniques to those that have proven useful for quark/gluon

discrimination seem promising. In both cases the lack of a perturbatively-generated hard scale means that parametric separation of signal and background is challenging. Infrared and collinear (IRC) safe observables related to jet mass, such as girth and two-point energy correlations are reasonably well studied in QCD, with results readily generalizable to other gauge theories [576–578]. For quark/gluon discrimination, observables characterized by Poisson-like distributions such as particle/track multiplicities or production ratios of particular SM particles tend to yield better discrimination, but suffer from being IRC unsafe and thus subject to large non-perturbative modeling uncertainties [579], a significant point of concern when extending their use beyond QCD. Here, some recently developed IRC-safe generalizations of multiplicity [580] may prove useful. Another approach might be to explore machine-learning techniques that do not require fully labelled data for training (so-called weak supervision) [581–583]. These can be trained directly on data, here at least in the case of the QCD background, so that modeling concerns about the shower can be partially alleviated. While achieving a sizable signal-to-background ratio is likely to be the major challenge in using such jet observables to separate dark showers from QCD, it is vital to note that if signal/background separation can be achieved through other means, e.g. by reconstructing DV, these same tools offer an enormously powerful window onto the underlying dynamics of the dark shower.

7.6.1.2. Large- R jets ($R = 1.0$). As discussed in section 7.3, dark showers at larger couplings are currently poorly understood. If couplings controlling the shower can no longer be treated as small at any scale, the QCD-inspired picture of pencil-like jets starts to break down, and we might expect that showers radiate more copiously at ever larger angles, so that large- R jets can become necessary to adequately capture the underlying hard process. This is first and foremost a triggering challenge, since it is no longer clear that triggers designed for local hard depositions can maintain their sensitivity. It is likely that a viable trigger path either needs to rely on a prompt associated object from the production mechanism (ISR jet, lepton, etc) or on a high multiplicity of leptons in the shower itself. Of course, H_T triggers continue to be useful for those models with sufficiently high event energy scales, provided that a sufficient amount of the radiation in the event clusters into trigger objects of sufficiently high p_T ($\sim \text{few} \times 10 \text{ GeV}$) to be counted in the H_T trigger. As long as the event can be triggered on, observables similar to those at the end of section 7.6.1.1 should still prove useful to separate signal from background, possibly even more so, since the radiation pattern in the dark shower can now be expected to be substantially different from QCD.

7.6.1.3. Spherical showers. In the large- α Hooft coupling regime, in which we expect much more showering at large angles than in QCD (see section 7.3), the final states are soft and spherically distributed in the rest frame of the shower. This leads to so-called SUEPs in the detector. In the rest frame of the event, the momenta of the final-state SM particles are on the order of the hadronization scale of the dark strong dynamics. If this scale is much lower than 100 MeV, the decay products are too soft to be reconstructed as tracks and the entire shower is effectively invisible. In this case existing jets+MET searches can apply. For a hadronization scale around $\mathcal{O}(100 \text{ MeV})$, some amount of ISR can be needed to boost the particles enough to render a fraction of them reconstructable. Finally, if the decay products are on average harder than $\mathcal{O}(100 \text{ MeV})$, the tracks associated to the SUEP vertex can typically be reconstructed off-line, subject to momentum-dependent reconstruction efficiencies. The main parameters of interest are accordingly the number of charged particles produced and the corresponding p_T spectrum. Also important are the fraction of invisible particles and the composition of SM particles in the final state. In particular, since the momenta of the invisible

Figure 94. Charged particle multiplicities measured in minimum bias events with the ATLAS detector for events with at least one track with a minimum p_T of 500 MeV and $|\eta| < 2.5$ [584].

particles balance on average, they are not likely to give rise to a substantial \cancel{E}_T signal unless the dark shower is recoiling against a relatively hard ISR jet. A large fraction of invisible particles will instead degrade the sensitivity of a strategy relying on track multiplicity. The muon fraction, on the other hand, can be a powerful handle: even though the average muon p_T may be very low, due to the high particle multiplicity a handful of muons may still be hard enough to pass the trigger and reconstruction thresholds of the MSs.

A major background to SUEP-like signals comes from PU, which also yields a large number of isotropically distributed soft tracks, though in contrast to SUEP signatures, PU tracks arise from multiple vertices. Studies on the multiplicity of charged tracks from minimum-bias interactions like single, double or non-diffractive collisions are described in [584]. As shown in figure 94, the fraction of 13 TeV pp collisions having 80 or more associated charged tracks is $O(10^{-3})$, as measured in a PU-free environment. Some benchmark SUEP models are described in [242], one with a low-mass Higgs-mediator and two higher-mass scalar models, and charged particle multiplicities for these benchmarks are shown in figure 95; for these models, it is assumed that SUEP particles decay only to electrons and muons. Reference [242] demonstrates that counting tracks associated to the PV should provide a very powerful discriminant against PU background during off-line reconstruction for high-mass mediators, while discrimination for the Higgs-mediator model is extremely challenging. The crucial discriminating factor is the number of particle tracks that can actually be reconstructed, and both ATLAS and CMS can reconstruct tracks with a minimum momentum of roughly 400 MeV [585]. The multiplicity of tracks fulfilling this minimum- p_T requirement is shown in figure 95(c) for the three SUEP benchmark models. It was shown in [242] that, even for the highest-mass mediator, no significant losses of the

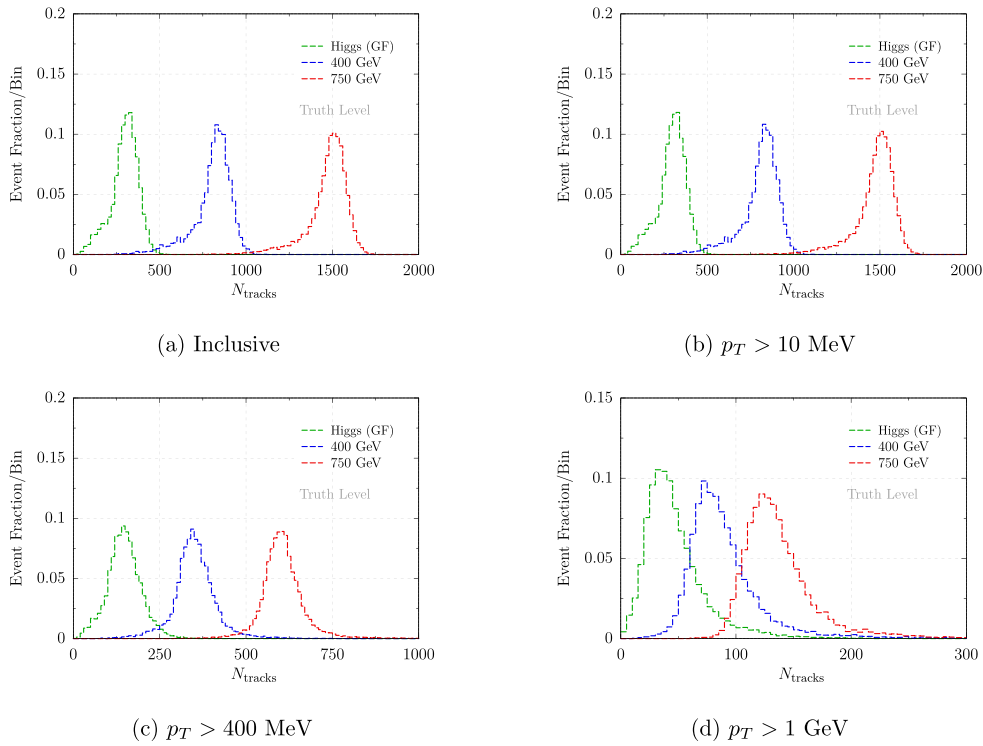

Figure 95. Event multiplicities of charged particle tracks fulfilling the respective indicated p_T requirements for three benchmark SUEP models. Figure from [242].

tracking efficiency are expected in spite of the hundreds of tracks present per event. It is moreover worth noting that, while the track multiplicity is large compared to what is generated by SM proton–proton collisions, it is still relatively small compared to the multiplicities that can be reconstructed in heavy ion collisions.

A large fraction of electrically neutral hadrons produced in the SUEP can further lower the number of associated tracks, which makes signal/background discrimination very difficult for the lowest-mass-mediator signals. A possible additional discriminant for those cases can be the hemisphere mass. This mass is estimated by dividing the event into a hemisphere associated to the ISR jet and one associated to the SUEP, while calculating the ‘jet’ mass, as in section 7.6.1.1, from the tracks in the SUEP hemisphere. This variable should be significantly higher for the SUEP events, where the heavy mediators are decaying, than for PU events.

Another possible background to SUEP signals is QCD multi-jet events. As described in section 7.5.2.1, triggering SUEP events based on \cancel{E}_T relies on the emission of an ISR jet recoiling against the system. QCD scenarios similar to SUEP signatures could arise when one hard jet is recoiling against a system of multiple soft jets. The mean number of charged tracks per jet is less than ten for jets $O(100 \text{ GeV})$ [586]. To get to $O(100)$ charged tracks, as expected from a SUEP signature, a very high number of jets is needed, hence the perturbative cross section is heavily suppressed by many orders in α_s . This background can nevertheless play a significant role for the low-mass mediator models, where significantly fewer tracks are

expected. A veto against large calorimeter deposits can be a powerful handle to reject those events, as rather hard jets are needed to get many associated charged tracks.

7.6.2. Displaced decays. Outside the prompt regime, the lifetimes of the various dark states and the composition of SM final states produced in their decays drive the phenomenology. LLPs result when there are one or more species of dark states in the hidden sector spectrum that would be stable in the absence of couplings to the SM. In particular, different species naturally come with vastly different lifetimes, as is the case for the SM π^0 and π^\pm mesons. In what follows, we consider the single-species case in most detail, and treat the case of primarily leptonic decays (LJs) separately from the cases with substantial branching fractions to hadrons (emerging jets). We finally comment on the multi-species case, and relate it to the semi-visible jet scenario mentioned in the previous section.

Even in high multiplicity events, the isolation of displaced decays from each other is not likely to pose difficulties in reconstructing DVs in the inner tracker. Two nearby DVs can be separately resolved down to separations of \sim mm. Even in the case where two DVs are closer than 1 mm, all of the tracks associated to both vertices will simply be reconstructed as a single DV with larger track multiplicity.

7.6.2.1. Single species leptonic dark showers (displaced LJs). One signature predicted by dark shower models is LJs [155, 572], whose prompt decays are discussed in section 7.6.1. Depending on the lifetime of the decaying state, these leptons can easily be produced with a measurable displacement. Explicit searches for this signature have been performed by the ATLAS Collaboration at both 8 and 13 TeV [272, 273], as detailed in section 3.2. It is worth remarking that the experimental signature of a displaced decay to electrons can be very similar to the signature of a displaced decay to a pair of charged pions, and thus searches for LJs frequently cover pionic final states as well. Searches to date have targeted LJs containing up to two lepton (pion) pairs.

To further extend coverage into low-mass regimes, it may be of interest here to investigate the samples stored through data scouting for, e.g. di-muon resonances, although the limited information retained in scouted events likely makes this a promising avenue only for sufficiently short lifetimes that dedicated displaced track reconstruction is not necessary.

7.6.2.2. Single species hadronic dark showers (emerging jets). The ATLAS, CMS, and LHCb collaborations have developed powerful searches for pairs of DVs in the trackers, typically in association with missing energy or large H_T , as described in section 3.1. These searches are nearly background-free and inclusive in the number of vertices, and thus have good sensitivity for any model of dark showers that has a large enough signal acceptance in such searches, regardless of the detailed features of the shower shape.

While these searches demonstrate the power and flexibility of inclusive low-background searches, it is unfortunately very easy for signal acceptances in existing DV searches to be prohibitively small. Primary drivers for the loss of acceptance are the requirement of associated objects (leptons, MET, sizable visible H_T , etc), and/or cuts on the invariant mass of or number of tracks belonging to the DV. Given that a hidden shower tends to produce a multitude of LLPs, it should be possible to maintain very low background levels—and therefore the power and inclusivity of the search—by relaxing many of these requirements and demanding a larger number of DV or even displaced tracks instead.

When the lightest decaying dark state has mass \gtrsim 10 GeV, backgrounds to DV searches do become more important, since the background DV rate rises rapidly as the number of tracks associated to the vertex falls; also, irreducible heavy-flavor backgrounds are important

in this mass range. The number of associated tracks is also crucial for the vertex reconstruction in both the ID and the MS. Hence, the composition of hadronic and leptonic particles in the final states may have a significant impact on the ability to reconstruct the associated vertices and/or the size of the expected backgrounds. Moreover, as the track momentum and multiplicity in the vertices drop, the odds increase that one or more tracks belonging to a particular vertex are not reconstructed. The efficiency of reconstructing displaced tracks in the inner tracker falls off substantially with displacement, as particles traverse fewer layers of the tracker: for particles produced at $r = 30$ cm from the IP, this efficiency is ~ 0.35 at ATLAS [255] and ~ 0.25 at CMS [587]. Explicitly requiring vertex reconstruction can thus come at a large cost in signal acceptance, especially for LLP decays that produce only two tracks per vertex. However, a large number of unassociated tracks with a large impact parameter is still a striking signature, despite the larger backgrounds that come with relaxing requirements on vertex reconstruction. This is the idea behind a recent CMS search [316], based on the model of [331] (see below). Whether or not explicit DV reconstruction is helpful depends on relative signal and background rates, and can be model dependent.

Backgrounds also increase as the lifetime of the decaying dark state becomes shorter; as track reconstruction efficiencies are very good for particles at small production radii, explicit vertex reconstruction is likely to be useful here to help keep backgrounds under control. Even in the short lifetime regime, a dark shower offers many additional handles for signal/background discrimination beyond the number of vertices, such as a common mass scale for reconstructed vertices and non-SM-like particle multiplicity distributions.

Given the striking nature of these high multiplicity signal events, it is typically not challenging to separate them from backgrounds once the event is on tape, provided that sufficiently many displaced tracks (and possibly vertices) can be reconstructed. At ATLAS, reconstructing displaced tracks can require running dedicated re-tracking algorithms in order to identify highly displaced tracks. This re-tracking can be computationally expensive, and necessitates the preselection of at most $\sim 5\%$ of the total event sample on tape. In this case, the preselection criteria are likely to be the limiting factor in signal acceptance at the analysis level. At CMS, the standard tracking algorithm is iterative and automatically reconstructs highly-displaced tracks, so preselection is not necessary.

Dark showers produced through mediators carrying SM charges, such as the scenario of [331], generally provide ample preselection criteria through associated objects and relatively high overall event H_T scales. For instance, typical events for the model in [331] contain two emerging jets and two QCD jets, though the additional two QCD jets can be absent in other models. The emerging jets can be reconstructed using default anti- k_t [366] $R = 0.4$ jets. A baseline preselection requires each jet to have $p_T > 200$ GeV, $|\eta| < 2.5$ and H_T exceeding 1000 GeV. These criteria assume that jets can be reconstructed using the calorimeters, which should be very efficient for the considered lifetimes in the model. CMS has recently published a search for this model [316], finding excellent sensitivity for the benchmark model developed in [331]; this analysis is an excellent demonstration that searches of this type are feasible despite the challenging nature of the signal.

When dark showers originate from a SM singlet, such as the Higgs boson or a Z' , the problem of preselection becomes more acute. The overall mass scale of signal events can easily be small, making event H_T useless for signal separation. Here perhaps one of the most robust avenues for preselection is muon multiplicity: as discussed in section 7.4, many of the operators governing LLP decays tend to predict muon-rich final states. With $\gg 2$ LLPs in an event, muon number becomes a useful and inclusive preselection criterion that places no demands on the possible presence of associated objects, event H_T , or detailed shower shape.

For muon-poor, low-mass dark shower events, pre-selection criteria become more model dependent. When such dark showers originate from an exotic Higgs decay, SM Higgs production provides a suite of associated prompt objects that offer pre-selection handles at some acceptance cost; see section 2.3.1. However it is also important to study to what extent features reflecting the presence of (multiple) LLPs in the event itself could be used as pre-selection criteria, e.g. anomalously track-poor jets, unusual ECAL/HCAL ratios (as realized by, for instance, LLPs with $c\tau \sim \text{m}$ decaying dominantly to electrons and/or photons), anomalously large numbers of poorly reconstructed or high impact parameter tracks, etc.

Off-line reconstruction for events with low-mass and/or very soft vertices, as occurs in SUEP-style models, poses additional challenges. For the reconstruction of secondary vertices in the ID in ATLAS and CMS, currently a minimum track p_T of 1 GeV is required [237, 588]. Having vertices with several tracks fulfilling this minimum p_T requirement might be rare if the hidden sector hadronization scale is low, and this is particularly true for low mediator masses. In this case, dedicated search strategies might be needed (particularly for short lifetimes). For example, it may be possible to look for increased multiplicity of hits in the outer layers of the ID compared to the inner parts, though unassociated hits from secondaries may be a significant background. A subtraction of hits from tracks stemming from vertices close to the beam pipe might be helpful, but dedicated studies are needed to assess the viability of this approach. In addition, the calorimeter may be another handle on this type of event: a large collection of soft particles could collectively contribute a non-standard energy pattern in the calorimeters provided the LLP lifetime is sufficiently long and if the calorimeter segmentation in radial direction is exploited. However, if the LLPs can reach the calorimeter, their decays typically take place over a distance longer than or comparable to the size of the calorimeter itself. This effect could wash out the signal to the extent that it may be difficult to observe above background, though a full truth-level simulation of this effect is certainly warranted.

Finally, one of the great advantages of an inclusive, low-background search strategy is that it enables a single search to apply robustly to a vast class of models. To fully realize the power and impact of such searches, it will be critical to make it possible to reinterpret searches with publicly available material. In searches for DVs in a particular detector element, it may be advantageous to bin signal and background in terms of the number of reconstructed vertices with very loose η and ϕ requirements. While more difficult experimentally, it would also be highly valuable to eventually supply the transverse distance of each vertex from the IP on an event-by-event basis, combining the different detector elements. This would allow for straightforward reinterpretation of searches to models with different shower shapes, lifetimes and p_T spectra, allowing a single search to transparently apply to a very broad model space. If possible, it would also be useful to provide the distribution of background vertices as a function of the number of tracks, as this would help theorists estimate the sensitivity to models with different masses and LLP decay modes.

For searches that rely directly on displaced tracks, it is especially important to publish information on displaced track reconstruction that allows for reliable recasting since this is challenging to model accurately using only public data. For instance, the analysis of [316] relies on the transverse impact parameter significance of a track to construct discriminating variables, but theorists cannot reconstruct impact parameter significance without clear examples of the detector response. For these searches, it would again be useful to bin signal and background in terms of the number of reconstructed objects and their geometric location within the detector, as well as their p_T .

We conclude by reiterating that, while inclusive searches are naturally desirable, there are substantial practical obstacles for such a program, some of which have been discussed above.

In reality, it is likely that a number of different semi-inclusive searches with partially overlapping acceptance are necessary. To that end, further theoretical studies are needed to map out which selection cuts are most robust against the varying of the specifics of particular models.

7.6.2.3. Multi-species dark showers. If there are multiple species in the dark shower that decay to SM final states, the lifetimes of these species will in general be very different. The intermediate case where most LLP species decay with a macroscopic lifetime produces similar phenomenology to the single-species models discussed above. Another regime occurs when at least one species decays promptly, while the others are either stable or decay outside of the detector, which gives rise to a semi-visible jet [372] (see section 7.6.1.1 above). The intermediate scenario, where some dark states decay promptly while others have macroscopic detector-scale lifetimes, is equally generic. A combination of semi-visible techniques with DV reconstruction can be used to boost sensitivity in this case. It is especially important to pay attention to potential isolation criteria on DVs, as the presence of potentially large numbers of promptly decaying dark particles may necessitate their relaxation.

7.7. Executive summary

Dark showers are a common prediction of a wide range of hidden sector theories. Although the model space is dauntingly enormous, it is possible to make some very general statements about the *signature* space of interest: dark shower events can be characterized by (1) a variable and frequently large multiplicity of particles per event; (2) BSM states with a hierarchy of proper lifetimes, making the existence of at least one LLP species generic; (3) frequently, non-isolation of LLPs from other objects in the event; and (4) non-SM-like energy flow and particle multiplicity. These features typically ensure that dark shower events are very distinctive signatures in the generic regime where at least one species has a detector-scale lifetime. Thus, it should be possible to design powerful and inclusive searches which would be sensitive to a very large portion of the vast model space without needing to rely on poorly predicted (and model-dependent) properties such as shower shape. Toward this end we have identified several promising directions for future study for both theory and experiment, and provide some recommendations here.

As always, one of the primary challenges in searches for dark showers is ensuring the events are recorded on tape. In some models, dark showers may be accompanied by E_T , H_T , or a number of associated leptons that can be triggered on, but there are many scenarios where this is not the case, or where these handles come at the expense of a large reduction in signal rate. The foremost example of this is when the dark shower is initiated by an exotic Higgs decay. It is thus critical to pursue dedicated trigger strategies, and we present a few ideas here. We expect that displaced triggers designed for singly- or doubly-produced LLPs will typically have reasonable acceptance for dark shower events, though we caution that in some cases the non-isolation of LLPs in dark shower events may limit their acceptance. Another promising avenue for triggering on dark showers exploits the high particle multiplicity typical of such events, and we recommend study of triggers on (displaced) multi-muons in particular.

The off-line analysis of dark shower events poses several challenges as well. At this time, only the limiting cases of pencil-like or fully spherical showers are under good theoretical control, and hadronization can introduce significant additional uncertainties, especially for models with a spectrum substantially different from QCD. New studies of showering in the intermediate regime were performed for the purpose of this document (presented in section 7.3), which revealed that different approaches can yield qualitatively different

phenomenology. On the one hand, this provides interesting opportunities for searches to make use of event shape and/or jet substructure variables, in particular if the decays of hidden sector states occur promptly or with small displacements. On the other hand, for larger displacements it implies that one should be careful not to heavily bias the selection choices of a search towards a particular shower shape, and rely instead on the displaced LLP decays to separate signal from background. We expect that the most inclusive, most broadly applicable, and most readily reinterpreted searches will be those in which the data is binned in terms of the number of reconstructed displaced objects and their locations within the detector. For recasting purposes, and to assist with unraveling the underlying physics in the event of a discovery, it would moreover be important to supply information concerning distributions of the number of tracks per vertex and/or the vertex mass whenever possible.

The presence of $N_{DV} \gg 2$ DV in an event will be enormously powerful for background suppression, provided those vertices can be reconstructed. To identify highly displaced tracks, it may be necessary to run dedicated and computationally expensive re-tracking algorithms, requiring the imposition of some pre-selection criteria to identify events of interest. As these pre-selection criteria are likely to be the limiting factor controlling post-trigger signal acceptance in many models, we recommend developing criteria for dark showers that rely on particle multiplicity and, if possible, the presence of multiple LLPs in the event, while keeping p_T thresholds as low as possible.

7.8. Appendix: example models

In this appendix we survey the models for which MC simulations are currently available. Please also see the [appendix](#) as some of the models are included in simplified model library.

7.8.1. Lepton-jets from radiating DM. One of the simplest and most widely discussed types of low-mass hidden sector particle is a dark photon A' , i.e. a new gauge boson associated with a local $U(1)$ symmetry in the dark sector. By kinetically mixing with the SM hypercharge gauge boson, a dark photon can act as the mediator of DM–SM interactions, in addition to being responsible for DM self-interactions. The range of dark photon masses of relevance to dark showers is between MeV and GeV. The dark sector Lagrangian in such a scenario reads

$$\mathcal{L}_{\text{dark}} \equiv \bar{\chi}(i\not{\partial} - m_\chi + ig_{A'}\not{A}')\chi - \frac{1}{4}F'_{\mu\nu}F'^{\mu\nu} + \frac{1}{2}m_{A'}^2 A'_\mu A'^\mu - \frac{\epsilon}{2}F'_{\mu\nu}F^{\mu\nu}. \quad (7.8)$$

Here, χ is the fermionic DM particle with mass m_χ , and $g_{A'} = \sqrt{4\pi\alpha'}$ is the $U(1)'$ gauge coupling. From the point of view of dark showers, interesting values for the coupling strength are $\alpha' \sim 0.01$. If α' is much smaller, there is too little radiation to form a dark shower. The dark photon mass is denoted by $m_{A'}$, and the kinetic mixing parameter by ϵ . Typically, ϵ is constrained by current limits to be $\sim 10^{-3}$. The particular mechanism by which the dark photon mass arises is not important in this context—it could originate from a dark sector Higgs mechanism or from the Stückelberg mechanism.

If $m_\chi \ll 100$ GeV, DM particles may be produced at the LHC with a large boost. This entails a large probability for radiating additional collinear A' bosons (see figure 96). A detailed analytical and numerical description of such dark photon showers is presented in [589]. The A' bosons eventually decay to observable SM particles through the kinetic mixing term in equation (7.8). Depending on the value of ϵ , the decays can be either prompt or displaced. Phenomenologically, the final state of the process $pp \rightarrow \bar{\chi}\chi + nA'$ thus consists of two ‘jets’ of collimated A' decay products, plus missing energy.

Figure 96. The process that gives radiating dark matter its name: production of two DM particles χ , followed by the emission of several soft or collinear dark photons A' [589].

Figure 97. Branching ratios of a kinetically mixed dark photon A' as a function of $m_{A'}$ [589].

The A' branching ratios into different SM final states depend sensitively on $m_{A'}$ (see figure 97). At $m_{A'} \approx 400$ MeV, the dominant decay modes are $A' \rightarrow e^+e^-$ and $A' \rightarrow \mu^+\mu^-$. The decay rate into each lepton flavor ℓ is

$$\Gamma(A' \rightarrow \ell^+\ell^-) = \frac{1}{3}\alpha\epsilon^2m_{A'} = \frac{1}{8} \times \frac{1}{10^{-6} \text{ cm}} \left(\frac{\epsilon}{10^{-3}}\right)^2 \left(\frac{m_{A'}}{\text{GeV}}\right), \quad (7.9)$$

where $m_\ell \ll m_{A'}$ has been assumed for simplicity. For purely leptonic decays, the A' shower thus corresponds to a ‘LJ’, i.e. a set of collimated leptons. This signature has been previously discussed, for instance, in [30, 32, 117, 127, 184, 572, 590–593]. Experimental searches for LJs have been presented in [270, 272, 273, 274], where [272, 510] focus on LJs with DV.

Lepton-jet searches may also be sensitive to dark photons with masses ≈ 400 MeV, even though the leptonic branching ratio is reduced to between 20% and 70% in this regime. The mix of leptons and hadrons expected from A' decays at $m_{A'} \approx 400$ MeV implies, however, that most leptons will not be isolated, but occur in conjunction with hadronic activity in the same detector region. In view of this, dedicated trigger and analysis strategies may significantly boost the sensitivity (see section 7.6.2.1).

In certain parameter regions, the decays of radiated A' bosons may closely resemble a purely hadronic QCD jet. This will happen in particular when $m_{A'}$ is close to a QCD resonance, or when the average A' multiplicity in each shower is low, and the hadronic

branching ratio is sizeable. In this case, separation of the signal from the QCD background will most likely be possible only if ϵ is so small that A' decays are displaced.

Let us summarize several important considerations to take into account when devising a search for dark sector radiation:

- *There may or may not be a signal in the tracking detector.* Prompt A' decays will typically lead to such signals, except for specific A' decay modes to neutral particles, for instance $A' \rightarrow K^0 \bar{K}^0$ and $A' \rightarrow \pi^0 \gamma$. Displaced A' decays can also leave a signal in the tracker, however if the lifetime is sufficiently long more decays will occur in the muon chamber (see section 7.4.2).
- *There may or may not be a signal in the calorimeters.* Most A' decay modes will be visible to the calorimeters. However, it is important to realize that a signal in the HCAL can arise not only from hadronic activity, but also from displaced decays to leptons occurring inside the calorimeter.
- *There will be missing energy contained within the LJ.* As the decaying A' bosons are aligned with the DM particle from which they were radiated, the corresponding missing momentum vector points in the same direction. However, unless there is significant ISR, the missing momentum will typically be balanced between the two showers shown in figure 96, and may therefore be small.

In figure 98, we show for illustration the exclusion limits that past LHC searches place on the dark photon parameters.

7.8.2. Emerging and semi-visible jets. Hidden valley models [66] with QCD-like hidden sectors allow for interesting collider signatures. Thus we consider a confined dark gauge group $SU(N_d)$, where $N_d \geq 2$, with confinement scale Λ_d which sets the mass of the dark hadrons. There are also n_f flavors of dark quarks whose bare masses are lighter than Λ_d . The hidden valley comes equipped with a portal that couples the dark sector to the SM, and the mass is usually taken to be $M \gg \Lambda_d$. The portal can be an s -channel vector mediator, Z_d , which couples to SM quarks and dark quarks:

$$\mathcal{L} \supset - Z_{d,\mu} \sum_{i,a} (g_q \bar{q}_i \gamma^\mu q_i + g_{q_d} \bar{q}_{d,a} \gamma^\mu q_{d,a}). \quad (7.10)$$

Here g_{q/q_d} are coupling constants and i, a are flavor indices. One can also have a t -channel scalar bifundamental mediator, X , which carries color and dark color and can decay to a quark and a dark quark. In the case of the scalar mediator, the only allowable coupling is of the form

$$\mathcal{L} \supset \kappa_{ij} \bar{q}_i q_{d,j} X + \text{h.c.}, \quad (7.11)$$

where κ_{ij} is a $3 \times n_f$ matrix of Yukawa couplings. One could also add multiple flavors of X mediators, something that has also been implemented [542].

When dark quarks are produced, they shower and hadronize and the same tools that are familiar for QCD can be used to simulate these processes. Because of the large gap between the mediator mass and the confining scale, there will be large particle multiplicity and the dark hadrons will typically form into jet-like structures. In the large N_d limit, the fraction of dark baryons produced is suppressed, and in the case of QCD this fraction is $\mathcal{O}(0.1)$. Therefore the hadronization in these simulations is typically dominated by dark mesons. The lightest hadronic states are the dark pions π_d , acting as goldstone bosons of the $U(n_f) \times U(n_f)$ dark flavor symmetry. When a heavier mesonic state is produced it will promptly decay into dark pions if kinematically allowed, making the dark pions the dominant component of the dark showering process.

Figure 98. Limits, at the 95% C.L., on the dark photon mass $m_{A'}$ and the kinetic mixing parameter ϵ , for $m_\chi = 4$ GeV, $\alpha_{A'} = 0.2$. We have assumed χ production through a Z' portal with a mass of 1 TeV, with a production cross section of 0.58 pb at $\sqrt{s} = 7$ TeV and 0.85 pb at 8 TeV. We show exclusion limits from the ATLAS search for prompt lepton-jets in 5 fb^{-1} of 7 TeV data [594] (blue shaded region) and from the ATLAS displaced lepton-jet search in 20.3 fb^{-1} of 8 TeV data [272] (red shaded region). The lighter colored region around $m_{A'} = 2$ GeV corresponds to the transition region in terms of quark final states and an analysis based on interpolation. The computation was carried out in Pythia 8 [220, 595, 596]; see [589] for details. We also show the existing 90% C.L. exclusion limits from the electron and muon anomalous magnetic moment [19, 597, 598], HADES [599], KLOE 2013 [600] and 2014 [601], the test run results from APEX [602], BaBar 2009 [603] and 2014 [604], beam dump experiments E137, E141, and E774 [605–607], A1 [608], Orsay [609], U70 [610], CHARM [611], LSND [612], as well as constraints from astrophysical observations [613, 614] and π^0 decays [615]. Figure based on [589].

These events can be simulated with the HV [595] module/package that appears in Pythia8 [220]. Pythia8 hosts a hidden valley class which incorporates the $SU(N_d)$ model, allowing the user to vary the masses of the spectrum (π_d, ρ_d , etc), number of flavors n_f and parameters of the running coupling (Version 8.226). Pair production of X and resonant production of Z_d are implemented at tree level, and the decay of dark mesons to SM states is also present.

In [574], production of the heavy mediators with ISR/FSR was considered. This was done by interfacing with Madgraph5_aMC@NLO [226] using a modified version of the spin-1 DMSimp model²⁰² implemented through FeynRules [616]. The models are located in the repository²⁰³ folder DMSimp_s_spin1. The generation files for the t -channel exchange of the scalar X are located in the folder DMSimp_tchannel. The bi-fundamentals are denoted with $su11, su12, su21, su22\dots$, where u explicitly specifies the QCD flavor index and the numbers are the explicit dark non-abelian group indices. Similarly, the dark quarks are labeled as $qv11, qv12, qv21, qv22$. A FeynRules model file (DMSimp_tchannel.fr) as well as the Mathematica notebook (DMSimp_tchannel.nb) used to generate the

²⁰² <http://feynrules.irmp.ucl.ac.be/wiki/DMSimp>

²⁰³ <https://github.com/smsharma/SemivisibleJets>

UFO output are also provided. The showering and hadronization in the dark sector can still be performed in `Pythia8`.

7.8.2.1. Semi-visible jets. Generically, some of the dark pions could decay promptly while some could be long-lived or even collider-stable, analogous to the appearance of neutral versus charged pions in the SM. If both stable and unstable hadrons are produced in a collision, the missing energy could be aligned along one of the jets, resulting in low acceptance for traditional monojet-style searches. This is the *semi-visible jet* scenario, and [372, 574, 617] introduce a simplified model-like parameterization to map the complicated dynamics of the underlying dark sector onto a limited number of physically-motivated variables—in particular, the fraction of stable versus decaying pions, the characteristic mass scale of dark pions and the dark coupling strength. The MC production described here along with the `Pythia8` HV module allows the user to vary these parameters for the *s*- and *t*-channel UV completions. See [372, 574, 617] for further details. Emerging jets By contrast, the dark pions can be taken to have detector-scale lifetimes in the *emerging jets* scenario [331]. The expected lifetime of the dark pion can be quantified using equation (7.11). Under the assumption of universal couplings $\kappa_{ij} = \kappa$ and $m_q > \Lambda_d$, we can calculate the proper lifetime of the dark pions:

$$c\tau_0 \approx 80 \text{ mm} \times \frac{1}{\kappa} \times \left(\frac{2 \text{ GeV}}{f_{\pi_d}} \right)^2 \left(\frac{100 \text{ MeV}}{m_q} \right) \left(\frac{2 \text{ GeV}}{m_{\pi_d}} \right) \left(\frac{M_X}{1 \text{ TeV}} \right)^4. \quad (7.12)$$

Here f_{π_d} is the dark pion decay constant, and m_q is the mass of the SM quark in the final state. A similar formula applies for the Z_d mediator. Therefore a jet of dark hadrons will be created as dominantly invisible particles, but at long distance, the dark pions will decay back to SM particles and appear in shape like an ordinary jet, although it contains a large number of DV. The jet emerges as it travels through the detectors. In the case of purely *t*-channel interactions, having a non-trivial κ_{ij} in equation (7.11) will break the $U(n_f) \times U(n_f)$ dark flavor symmetry. With an appropriate n_f , the dark quark flavors can be exactly aligned with the SM down quark flavors. It is immediately clear that such alignment leads to dark pions with lifetimes that differ significantly from one another. In return, the flavor composition of the emerging jets will vary throughout the detector volume. This differs from the *s*-channel interaction, in which no breaking occurs, and n_f -stable versus $n_f(n_f - 1)$ -unstable dark pions exist.

7.8.3. SUEPs. In the strongly coupled regime, dark showers can be become spherical and almost arbitrarily soft, leading to soft, unclustered energy patterns, or SUEPs, discussed earlier in this chapter. In this case the sheer multiplicity of the final states becomes the most important experimental handle. It has been shown through the AdS/CFT correspondence that their spectrum should follow an approximately thermal distribution [618], which is what was assumed in the phenomenological study in [242]. The production mechanism for these studies was the Higgs or a heavy Higgs-like scalar. The MC code that was written for this study is currently not available publicly, though events in `hepmc` format can be obtained by contacting the authors. At this time only leptonic decays of the hidden mesons are implemented.

8. Conclusions

The research program carried out over the first nine years of the LHC at CERN has been an unqualified success. The discovery, in 2012, at a center-of-mass energy of 7 and 8 TeV, of a new particle thus far consistent with the SM Higgs boson has opened numerous new research

directions and has begun to shed light upon the source of electroweak symmetry breaking, vector boson scattering amplitudes, and the origin of particle masses. And the establishment of a wide range of searches for new physics at 7, 8, and 13 TeV with the ATLAS, CMS, and LHCb detectors—searches thus far consistent with SM expectations—has inspired new ideas and thinking about the most prominent open issues of physics, such as the nature of DM, the hierarchy problem, neutrino masses, and the possible existence of supersymmetry.

The overwhelming majority of searches for new physics have been performed under the assumption that the new particles decay promptly, i.e. very close to the proton–proton IP, leading to well-defined objects such as jets, leptons, photons, and missing transverse momentum. Such objects are constructed requiring information from all parts of the detector including hits close to the IP, calorimeter deposits known to be signatures of particles originating from the IP, and muons with tracks that traverse the entirety of the detector, moving out from the IP. However, given the large range of particle lifetimes in the SM—resulting from general concepts such as approximately preserved symmetries, scale hierarchies, or phase space restrictions—and the lack of clear, objective motivation related to any particular model or theory BSM, the lifetime of hypothetical new particles is best treated as a free parameter. This leads to a wide variety of spectacular signatures in the LHC detectors that would evade prompt searches, and which have received modest attention compared to searches for promptly decaying new particles. Because such signatures require significantly customized analysis techniques and are usually performed by a smaller number of physicists working on the experimental collaborations, a comprehensive overview and critical review of BSM LLPs at the LHC has been performed by a community of experimentalists, theorists, and phenomenologists. This effort ensures that such avenues of the possible discovery of new physics at the LHC are not overlooked. The results of this initiative have been presented in the current document.

We developed a set of simplified models and tools, in chapter 2, that can be used to parametrize the space of LLP signatures. The simplified models were organized around generic ways that various BSM LLPs can be produced and decay to displaced or non-standard objects in the LHC detectors, rather than emphasizing any one particular theory or physics motivation. These can serve as a useful grammar by which to compare coverage of LLP signature space and model classes among current and future experiments.

To that end, in chapter 3, we utilized these models and tools to assess the coverage of current LLP searches and we identified multiple avenues for improving and extending the existing LLP search program. Opportunities for new and improved triggering strategies, searches, and open questions for the experimental collaborations to explore centrally were presented as a list at the end of the chapter.

Moreover, due to the non-standard nature of LLP searches, many of them are performed under very low-background conditions. As a result, sources of backgrounds largely irrelevant to searches for promptly decaying BSM particles are important for LLP analyses and can be surprising and unexpected. In chapter 4 we discussed several sources of backgrounds for LLP searches, collecting the knowledge gained, often by trial-and-error, by experimentalists over many years of searches.

Also with an eye to the future, in chapter 5 we explored the potential for the expanded capabilities of proposed detector upgrades at ATLAS, CMS, LHCb, and related dedicated detectors, highlighting areas where new technologies can have a large impact on sensitivity to LLP signatures and suggesting several studies to be performed by the collaborations to ensure new physics potential is not missed for the upcoming era of the HL LHC.

Additionally, to ensure that current and future searches can be maximally useful in the future, in chapter 6 we explored how current searches can apply to new models and performed

a comprehensive overview of some of the challenges and pitfalls inherent in attempting to recast existing LLP analyses, leading to recommendations for the presentation of search results in the future.

Finally, in chapter 7, we looked toward the newest frontiers of LLP searches, namely high-multiplicity or ‘dark shower’ LLP signals that can, for example, be signatures of complex hidden sectors with strong dynamics and internal hadronization. In this chapter, we elaborated on the theoretical and experimental challenges and opportunities in expanding the LHC reach of these signals. Such dark shower signatures have a high potential for being overlooked with existing triggering strategies and analysis techniques. Moreover, the dark-QCD-like theoretical models from which they can arise are currently being explored in depth and the resulting LHC phenomenology is in the process of being understood. We discussed the current state of this work and we anticipate exciting independent developments in the near future.

This document is incomplete by design, since it is a record of the critical thinking and examination of the state of LLP signatures by a large number of independently organized members of the LHC LLP Community as it has evolved from 2016 to 2019, and a major component of the work has been the identification of several open questions and opportunities for discovery in such signatures. As these questions are addressed and new searches emerge from the experimental collaborations, so, too, will new ideas emerge and evolve from the community. We expect this document to be followed by future papers to record, review, and summarize the evolution of LLP signatures and searches, always with the intention of more effectively facilitating the discovery of new particles at the LHC and beyond.

Acknowledgments

We are very grateful to Andreas Albert, Tao Huang, Laura Jeanty, Joachim Kopp, Matt LeBlanc, Larry Lee, Haolin Li, Simone Pagan Griso, Michele Papucci, Matt Strassler, and Tien-Tien Yu for helpful conversations and comments on the draft.

A.1. Instructions for the Simplified Model Library

The simplified model library is available at the LHC LLP Community website²⁰⁴, hosted at CERN. We refer here extensively to the simplified models in tables 1–3. Because it is already quite an extensive task to come up with simplified models for so many (production)×(decay) modes, we for now restrict ourselves predominantly to the ‘filled’ entries in tables 1–3. If you are interested in performing an experimental search or developing a simplified model library entry for one of the ‘unfilled’ entries, please contact the chapter editor.

There are essentially two possible pipelines to simulate LLP events with the library:

1. *LLP decay as part of matrix-element calculation:* Using UFO models in the library, it is possible to generate the production and decay of LLPs at the parton level using calculations of the matrix element for production and decay. As a concrete example, we provide cards that allow the production and decay of LLPs using MadGraph5_aMC@NLO [226] and the accompanying MadSpin [227] package. This employs the narrow-width approximation, but otherwise gives rise to the correct angular

²⁰⁴ <http://cern.ch/longlivedparticles>

distribution of LLP decay products. The downside is that if a particular decay is not allowed from the interactions in the UFO model file, the UFO must be modified to include the new coupling. The output of `MadGraph5_aMC@NLO` is then fed into programs such as `Pythia 8` [219, 220] for showering, implementation of underlying event and other particle-level processes.

2. *Phenomenological LLP decays*: Using UFO models in the library, it is possible to generate the production of LLPs, leaving them stable as outputs of the matrix-element-level calculation recorded in LHE format [224]. The LLP can then be subsequently decayed in programs such as `Pythia 8`, which allows a particle to decay into any final state, albeit without correctly modeling the angular distribution. This could be convenient for models where the interactions leading to LLP decay are not included in the UFO, or where computational time is a concern and the angular distribution of LLP decays is irrelevant. We provide detailed instructions in the library files for how to implement decays of LHE files via `Pythia`.

In the final version of the library, we aim to provide example cards to direct the production and decay of LLPs in both pipelines. Note that in all of the simplified model proposals below, any particles *not* present in the production or decay chain should have their masses set to a very large value ($M = 5 \text{ TeV}$) to ensure they are sufficiently decoupled from direct production at the LHC.

Currently, we only provide simplified model libraries for neutral LLPs. The simplified models for LLPs with electric or color charges are equally compelling, but their simulation is more subtle. In particular, the simulation of the propagation and decay of the LLPs are more challenging if the LLP carries a SM gauge charge. Such effects can be included in detector simulations using `GEANT4` [231], but decay processes typically need to be hard-coded into `GEANT` or otherwise interfaced with other MC programs. This is an important issue for the community to address, as discussed in sections 2.4.2 and 2.4.3. Without implementing the decays, it is straightforward to use the SUSY model to simulate the production of any of the electrically or color charged LLPs.

Finally, we note that there is not currently a set of minimal simplified models to cover dark showers. However, we are collecting models used in studies of dark showers that could potentially be helpful for experimentalists and theorists alike. The existing models are included in the library, along with a very brief description in section A.1.2.

A.1.1. Neutral LLPs. The instructions for simulating the simplified model channels for neutral LLPs are given below. Note that it is often true that the same simplified model production and decay channel can be simulated using several simplified models. However, the philosophy of the simplified model approach is that the UV model used to simulate the process is not important when sensitivity is expressed in terms of physical masses and cross sections. As a result, we typically provide only one set of instructions for simulating each simplified model channel.

We begin by presenting the simplified model library instructions for double pair production (DPP) in table A1, Heavy Parent (HP, QCD-charged parent) in table A2, and Heavy Parent (HP, EW-charged parent) in table A3. We then proceed to the Higgs (HIG) production modes in tables A4–A6. For the Z' (ZP) production modes, we use a set of simplified models described in tables A7–A9. A relatively simple model file is provided for each table. In addition, a more adjustable ‘advanced’ model file is provided which includes all ZP production and decay modes, and allows for features such as individual couplings to each generation of quarks. This comes at the cost of a greatly increased set of parameters, and the

Table A1. Simplified model library process proposals for double pair production (DPP) production mode. Where a ‘wino’ LSP is specified, an admixture of Higgsino is required to lead to direct pair production of the neutral wino component. As an alternative, one could have $pp \rightarrow \tilde{\chi}^\pm \tilde{\chi}^0$, $\tilde{\chi}^\pm \rightarrow W^{\pm*} \tilde{\chi}^0$ promptly, and take the $\tilde{\chi}^\pm$ to be degenerate with $\tilde{\chi}^0$ such that the additional charged decay products are essentially unobservable.

Decay mode	Simplified model library process
$X \rightarrow \gamma + \text{inv.}$	MSSM+GMSB. LLP is a bino ($\tilde{\chi}^0$) produced due to $pp \rightarrow \tilde{\chi}^0 \tilde{\chi}^0$ via t -channel squark exchange ($M_{\tilde{q}} > 5 \text{ TeV}$). Bino decays to photon + gravitino, $\tilde{\chi}^0 \rightarrow \gamma + \tilde{G}$
$X \rightarrow jj$	MSSM+RPV. LLP is sneutrino LSP ($\tilde{\nu}$) that is pair-produced via weak gauge interactions. $\tilde{\nu} \rightarrow q\bar{q}$ via the QLd^c operator
$X \rightarrow jj + \text{inv.}$	MSSM. LLP is second neutralino (wino) LSP $\tilde{\chi}_2^0$ that is pair-produced via weak gauge interactions. $\tilde{\chi}_2^0 \rightarrow q\bar{q}\tilde{\chi}_1^0$ via an off-shell sfermion, and the $\tilde{\chi}_1^0$ is invisible with arbitrary mass
$X \rightarrow jjj$	MSSM+RPV. While this is partially covered by $jj + \text{inv.}$ in the case where the additional quark is not reconstructed, we include it here for completeness. LLP is wino LSP ($\tilde{\chi}^0$) that is pair-produced via weak interactions. $\tilde{\chi}^0 \rightarrow q_\alpha q_\alpha q_\beta$ via an off-shell sfermion and the $u_\alpha^c d_\alpha^c d_\beta^c$ operator
$X \rightarrow jj\ell_\alpha$	MSSM+RPV. LLP is wino LSP ($\tilde{\chi}^0$) that is pair-produced via weak interactions $\tilde{\chi}^0 \rightarrow \ell_\alpha q\bar{q}$ via an off-shell sfermion and $L_\alpha Qd^c$ operator.
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$	MSSM+RPV. LLP is sneutrino $\tilde{\nu}_\beta$ of flavor β that is pair-produced via weak interactions $\tilde{\nu}_\beta \rightarrow \ell_\alpha^+ \ell_\alpha^-$ via the $L_\alpha L_\beta E_\alpha^c$ operator
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- (+\text{inv.})$	MSSM. LLP is second neutralino $\tilde{\chi}_2^0$ that is pair-produced via weak interactions $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \ell_\alpha^+ \ell_\alpha^-$ via an off-shell slepton
$X \rightarrow \ell_\alpha^+ \ell_\beta^- (+\text{inv.})$	MSSM+RPV. LLP is sneutrino $\tilde{\nu}_\alpha$ of flavor α that is pair-produced via weak interactions $\tilde{\nu}_\alpha \rightarrow \ell_\alpha^+ \ell_\beta^-$ via the $L_\alpha L_\beta E_\alpha^c$ operator. An additional massless invisible final state can be obtained with a wino LLP decaying into $\ell_\alpha^+ \ell_\beta^- \nu_\alpha$ through the same operator and an off-shell slepton. The massive invisible case is less motivated for $\alpha \neq \beta$

possibility of including unwanted diagrams if the process is not carefully specified. A simple python script is provided to generate the processes and set unwanted parameters to zero for those users wishing to use the advanced model files.

Finally, we provide instructions for the CC production modes in table A10. This production mode is most easily simulated using a left–right symmetric model or other right-handed-neutrino model.

A.1.2. Dark shower models. In the repository, we also include two models of dark showers. These are not meant to be representative in the same way that the simplified models are;

Table A2. Simplified model library process proposals for heavy parent (HP) production mode where the parent particle carries a QCD charge. In most of the above cases, a squark parent can be replaced by a gluino parent with an additional jet in its decay.

Decay mode	Simplified model library process
$X \rightarrow \gamma + \text{inv.}$	MSSM+GMSB. LLP is a bino ($\tilde{\chi}$) produced via $pp \rightarrow \tilde{q}\tilde{q}^*$, $\tilde{q} \rightarrow \tilde{\chi} + q$. Bino decays to photon+ gravitino, $\tilde{\chi} \rightarrow \gamma + \tilde{G}$
$X \rightarrow jj + \text{inv.}$	MSSM. LLP is wino LSP $\tilde{\chi}_2^0$ that is produced via $pp \rightarrow \tilde{q}\tilde{q}^*$, $\tilde{q} \rightarrow q\tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow q\tilde{q}\tilde{\chi}_1^0$ via an off-shell quark
$X \rightarrow jjj$	MSSM+RPV. LLP is bino LSP $\tilde{\chi}$ that is produced via $pp \rightarrow \tilde{q}\tilde{q}^*$, $\tilde{q} \rightarrow q\tilde{\chi}$. Then, $\tilde{\chi} \rightarrow q_\alpha q_\alpha q_\beta$ via the $u_\alpha^c d_\alpha^c d_\beta^c$ operator
$X \rightarrow jj\ell_\alpha$	MSSM+RPV. LLP is bino LSP ($\tilde{\chi}$) that is produced via $pp \rightarrow \tilde{q}\tilde{q}^*$, $\tilde{q} \rightarrow q\tilde{\chi}$. $\tilde{\chi} \rightarrow \ell_\alpha q\tilde{q}$ via an off-shell sfermion and $L_\alpha Q d^c$ operator
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$ or $\ell_\alpha^+ \ell_\beta^-$	MSSM+RPV. LLP is sneutrino ($\tilde{\nu}$) that is produced via $pp \rightarrow \tilde{g}\tilde{g}$, $\tilde{g} \rightarrow jj\tilde{\chi}$, $\tilde{\chi} \rightarrow \tilde{\nu}\tilde{\nu}$. Then, $\tilde{\nu}_\alpha \rightarrow \ell_\alpha^+ \ell_\beta^-$ or $\tilde{\nu}_\beta \rightarrow \ell_\alpha^+ \ell_\alpha^-$ via the $L_\alpha L_\beta E_\alpha^c$ operator
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	MSSM. LLP is second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow \tilde{q}\tilde{q}^*$, $\tilde{q} \rightarrow q\tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\alpha^- \tilde{\chi}_1^0$
$X \rightarrow \ell_\alpha^+ \ell_\beta^- + \text{inv.}$	MSSM+RPV. LLP is bino ($\tilde{\chi}^0$) that is produced via $pp \rightarrow \tilde{q}\tilde{q}^*$, $\tilde{q} \rightarrow q\tilde{\chi}^0$. Then, $\tilde{\chi}^0 \rightarrow \ell_\alpha^+ \ell_\beta^- \nu_\alpha$ via $L_\alpha L_\beta E_\alpha^c$ operator and off-shell slepton (massless invisible only)

Table A3. Simplified model library process proposals for heavy parent (HP) production mode where the parent particle carries electroweak charge.

Decay mode	Simplified model library process
$X \rightarrow \gamma + \text{inv.}$	MSSM+GMSB. LLP is a bino ($\tilde{\chi}^0$) produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow W^+ \tilde{\chi}^0$ ($\tilde{\chi}^+$ is a wino). Bino decays to photon+ gravitino, $\tilde{\chi} \rightarrow \gamma + \tilde{G}$
$X \rightarrow jj$	MSSM+RPV. LLP is sneutrino LSP ($\tilde{\nu}$) produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow \tilde{\nu} \ell^+$. The sneutrino decays via $\tilde{\nu} \rightarrow q\tilde{q}$ via the $u_\alpha^c d_\alpha^c d_\beta^c$ operator
$X \rightarrow jj + \text{inv.}$	MSSM. LLP is wino $\tilde{\chi}_2^0$ that is produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}_2^+ \rightarrow W^+ \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow q\tilde{q}\tilde{\chi}_1^0$ via an off-shell squark
$X \rightarrow jjj$	MSSM+RPV. LLP is bino LSP ($\tilde{\chi}^0$) that is produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow W^+ \tilde{\chi}^0$. Then, $\tilde{\chi}^0 \rightarrow qq\tilde{q}$ via an off-shell sfermion and the $u^c d^c d^c$ operator
$X \rightarrow jj\ell_\alpha$	MSSM+RPV. LLP is bino LSP ($\tilde{\chi}^0$) that is produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow W^+ \tilde{\chi}^0$. Then, $\tilde{\chi}^0 \rightarrow qq\ell_\alpha$ via an off-shell sfermion and the $Q d^c L_\alpha$ operator
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$ or $\ell_\alpha^+ \ell_\beta^-$	MSSM+RPV. LLP is sneutrino ($\tilde{\nu}$) that is produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow \ell^+ \tilde{\nu}$. Then, $\tilde{\nu}_\alpha \rightarrow \ell_\alpha^+ \ell_\beta^-$ or $\tilde{\nu}_\beta \rightarrow \ell_\alpha^+ \ell_\alpha^-$ via the $L_\alpha L_\beta E_\alpha^c$ operator
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	MSSM. LLP is second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow W^+ \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\alpha^- \tilde{\chi}_1^0$ via an off-shell slepton and the $L_\alpha L_\beta E_\alpha^c$ operator
$X \rightarrow \ell_\alpha^+ \ell_\beta^- + \text{inv.}$	MSSM+RPV. LLP is bino ($\tilde{\chi}^0$) that is produced via $pp \rightarrow \tilde{\chi}^+ \tilde{\chi}^-$, $\tilde{\chi}^+ \rightarrow W^+ \tilde{\chi}^0$. Then, $\tilde{\chi}^0 \rightarrow \ell_\alpha^+ \ell_\beta^- \nu_\alpha$ or $\tilde{\chi}^0 \rightarrow \ell_\alpha^+ \ell_\beta^- \nu_\alpha$ via an off-shell slepton and the $L_\alpha L_\beta E_\alpha^c$ operator

Table A4. Simplified model library process proposals for Higgs (HIG) production mode where the Higgs decays to two LLPs. These modes are particularly important because they can come in association with forward jets (VBF) or leptons and \cancel{E}_T (VH). Note that, in cases of $M_X > M_h/2$, the same production modes could still occur if the Higgs is taken to be off-shell.

Decay mode	Simplified model library process
$X \rightarrow \gamma\gamma$	(N)MSSM. LLP is the lightest pseudoscalar Higgs (a) produced via $pp \rightarrow h, h \rightarrow aa$ Then, $a \rightarrow \gamma\gamma$.
$X \rightarrow \gamma\gamma + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) produced via $pp \rightarrow h, h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \gamma\gamma$ via an off-shell SM Higgs
$X \rightarrow jj$	(N)MSSM. LLP is the lightest pseudoscalar Higgs (a) produced via $pp \rightarrow h, h \rightarrow aa$. Then, $a \rightarrow jj$.
$X \rightarrow jj + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h, h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow jj \tilde{\chi}_1^0$ via an off-shell squark
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$	(N)MSSM. LLP is the lightest pseudoscalar Higgs (a) produced via $pp \rightarrow h, h \rightarrow aa$. Then, $a \rightarrow \ell_\alpha^+ \ell_\alpha^-$.
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) produced via $pp \rightarrow h, h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\alpha^- \tilde{\chi}_1^0$ via an off-shell slepton
$X \rightarrow \ell_\alpha^+ \ell_\beta^- + \text{inv.}$	MSSM+RPV. LLP is the second neutralino ($\tilde{\chi}_2^0$) produced via $pp \rightarrow h, h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\beta^- \nu$ via an off-shell slepton and RPV couplings
$X \rightarrow \ell_\alpha^+ jj$	MSSM+RPV. LLP is the second neutralino ($\tilde{\chi}_2^0$) produced via $pp \rightarrow h, h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ jj$ via an off-shell slepton and RPV couplings

however, it does allow theorists and experimentalists to simulate these particular dark showers. The currently-included models are:

1. *Radiating lepton jets*: This is a model where DM is charged under a dark $U(1)'$ gauge interaction. The dark photon can be produced via final-state radiation from DM produced in a collider. Due to the collinear enhancement radiation of the dark photon, this can lead to a perturbative dark shower [589].
2. *Semi-visible jets*: This is a model in which hidden-sector states are charged under a new confining gauge group, leading to QCD-like showers. The showers produce both stable, invisible DM, as well as unstable states that decay back to the SM. This produces ‘semi-visible’ jets [372, 574].

Table A5. Simplified model library process proposals for Higgs (HIG) production mode where the Higgs decays to two LLPs plus invisible. These modes are particularly important because they can come in association with forward jets (VBF) or leptons and E_T (VH). Note that, in cases of $M_X > M_h/2$, the same production modes could still occur if the Higgs is taken to be off-shell.

Decay mode	Simplified model library process
$X \rightarrow \gamma\gamma$	(N)MSSM. LLP is a pseudoscalar or singlino (a) produced via $pp \rightarrow h, h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_2^0$, $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 a$. Finally, $a \rightarrow \gamma\gamma$
$X \rightarrow \gamma\gamma + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) produced via $pp \rightarrow h, h \rightarrow \tilde{\nu}\tilde{\nu}^*$, $\tilde{\nu} \rightarrow \tilde{\chi}_2^0 \nu$. Then, $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \gamma\gamma$ via an off-shell SM Higgs
$X \rightarrow jj$	MSSM+RPV. LLP is a sneutrino ($\tilde{\nu}$) produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_1^0 \tilde{\chi}_1^0, \tilde{\chi}_1^0 \rightarrow \tilde{\nu}\tilde{\nu}$. Then, $\tilde{\nu} \rightarrow jj$ via the RPV operator LQd^c
$X \rightarrow jj + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h$, $h \rightarrow \tilde{\nu}\tilde{\nu}^*, \tilde{\nu} \rightarrow \nu\tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow jj\tilde{\chi}_1^0$ via an off-shell squark
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$	MSSM+RPV. LLP is a sneutrino ($\tilde{\nu}_\beta$) produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_1^0 \tilde{\chi}_1^0, \tilde{\chi}_1^0 \rightarrow \tilde{\nu}_\beta \bar{\nu}_\beta$. Then, $\tilde{\nu}_\beta \rightarrow \ell_\alpha^+ \ell_\alpha^-$ via the RPV operator $L_\alpha L_\beta E_\alpha^c$
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h$, $h \rightarrow \tilde{\nu}\tilde{\nu}^*, \tilde{\nu} \rightarrow \nu\tilde{\chi}_2^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\alpha^- \tilde{\chi}_1^0$ via an off-shell slepton

Table A6. Simplified model library process proposals for Higgs (HIG) production mode where the Higgs decays to single LLP plus invisible. These modes are particularly important because they can come in association with forward jets (VBF) or leptons and E_T (VH). Note that, in cases of $M_X > M_h/2$, the same production modes could still occur if the Higgs is taken to be off-shell.

Decay mode	Simplified model library process
$X \rightarrow \gamma\gamma + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_1^0$. Then, $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \gamma\gamma$ via an off-shell SM Higgs
$X \rightarrow jj + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_1^0$. Then, $\tilde{\chi}_2^0 \rightarrow jj\tilde{\chi}_1^0$ via an off-shell squark
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	MSSM. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_1^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\alpha^- \tilde{\chi}_1^0$ via an off-shell slepton
$X \rightarrow \ell_\alpha^+ jj$	MSSM+RPV. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_1^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ jj$ via the RPV operator QLd^c
$X \rightarrow \ell_\alpha^+ \ell_\beta^- + \text{inv.}$	MSSM+RPV. LLP is the second neutralino ($\tilde{\chi}_2^0$) that is produced via $pp \rightarrow h$, $h \rightarrow \tilde{\chi}_2^0 \tilde{\chi}_1^0$. Then, $\tilde{\chi}_2^0 \rightarrow \ell_\alpha^+ \ell_\beta^- \nu_\sigma$ via the RPV operator $L_\beta L_\sigma E_\alpha^c$

Table A7. Simplified model library process proposals for Z/Z' (ZP) production mode where the Z' decays to two LLPs. For this section, we mostly use a DM simplified model, where fermion x_2 is the LLP for $X \rightarrow SM + \text{inv}$ modes and scalar s_2 is the LLP for $X \rightarrow SM$ modes. The same models can also be used for off-shell Z/Z' where $M_X > M_{Z'}/2$. The model file includes all processes in the table; the undesired couplings can be set to zero and energy scales to be very large. The final entry uses a left–right symmetric model; the mass of the intermediate $Z/Z'/h$ can be changed to simulate the desired decay kinematics.

Decay mode	Simplified model library process
$X \rightarrow \gamma\gamma$	DMSM. LLP is scalar s_2 , produced via $pp \rightarrow Z' \rightarrow s_2 s_2$, then $s_2 \rightarrow \gamma\gamma$
$X \rightarrow \gamma\gamma + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_2 x_2$, then $x_2 \rightarrow \gamma\gamma x_1$.
$X \rightarrow jj$	DMSM. LLP is scalar s_2 , produced via $pp \rightarrow Z' \rightarrow s_2 s_2$, then $s_2 \rightarrow q\bar{q}$ $s_2 \rightarrow \ell_\alpha^+ \ell_\alpha^-$ couplings are proportional to SM Yukawacouplings.
$X \rightarrow jj + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_2 x_2$, then $x_2 \rightarrow q\bar{q} x_1$
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$	DMSM. LLP is scalar s_2 , produced via $pp \rightarrow Z' \rightarrow s_2 s_2$, then $s_2 \rightarrow \ell_\alpha^+ \ell_\alpha^-$. $s_2 \rightarrow \ell_\alpha^+ \ell_\alpha^-$ couplings are proportional to SM Yukawa couplings
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_2 x_2$, then $x_2 \rightarrow \ell_\alpha^+ \ell_\alpha^- x_1$
$X \rightarrow \ell_\alpha^+ jj$.	LRSM. LLP is fermion ν_R , produced via $pp \rightarrow Z/Z'/h \rightarrow \nu_R \nu_R$, then $\nu_R \rightarrow \ell_\alpha^+ jj$ via off-shell W/W'

Table A8. Simplified model library process proposals for Z/Z' (ZP) production mode where the Z/Z' decays to two LLPs plus invisible. For this section, we use a DM simplified model, where the Z' decays into $x_3 x_3$, and x_3 then decays into the LLP (fermion x_2 for SM+inv decay mode or scalar s_2 for SM decay mode), plus invisible (scalar s_1 or fermion x_1 , respectively). The same models can also be used for off-shell Z/Z' where $M_X > M_{Z'}/2$. One model file (DMSM) includes all processes in the table.

Decay mode	Simplified model library process
$X \rightarrow \gamma\gamma$	DMSM. LLP is scalar s_2 , produced via $pp \rightarrow Z' \rightarrow x_3 x_3$, $x_3 \rightarrow s_2 x_1$, then $s_2 \rightarrow \gamma\gamma$
$X \rightarrow \gamma\gamma + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_3 x_3$, $x_3 \rightarrow x_2 s_1$, then $x_2 \rightarrow \gamma\gamma x_1$
$X \rightarrow jj$	DMSM. LLP is scalar s_2 , produced via $pp \rightarrow Z' \rightarrow x_3 x_3$, $x_3 \rightarrow s_2 x_1$, then $s_2 \rightarrow q\bar{q}$ $s_2 \rightarrow \ell_\alpha^+ \ell_\alpha^-$ couplings are proportional to SM Yukawa couplings
$X \rightarrow jj + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_3 x_3$, $x_3 \rightarrow x_2 s_1$, then $x_2 \rightarrow q\bar{q} x_1$
$X \rightarrow \ell_\alpha^+ \ell_\alpha^-$	DMSM. LLP is scalar s_2 , produced via $pp \rightarrow Z' \rightarrow x_3 x_3$, $x_3 \rightarrow s_2 x_1$, then $s_2 \rightarrow \ell_\alpha^+ \ell_\alpha^-$ $s_2 \rightarrow \ell_\alpha^+ \ell_\alpha^-$ couplings are proportional to SM Yukawa couplings
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_3 x_3$, $x_3 \rightarrow x_2 s_1$, then $x_2 \rightarrow \ell_\alpha^+ \ell_\alpha^- x_1$

Table A9. Simplified model library process proposals for Z/Z' (ZP) production mode where the Z/Z' decays to single LLP plus invisible. For this section, we use a DM simplified model, where the Z' couples to an $x_1 x_2$ or $s_1 s_2$ pair. x_1 and s_1 behave as DM, the LLP x_2 decays into $x_1 + \text{SM}$, and the LLP s_2 decays into SM. The DMSM model file again includes all processes in the table except for the last, which is LRSM.

Decay mode	Simplified model library process
$X \rightarrow \gamma\gamma + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_1 x_2$, then $x_2 \rightarrow \gamma\gamma x_1$; or a scalar s_2 , produced via $pp \rightarrow Z' \rightarrow s_1 s_2$, then $s_2 \rightarrow \gamma\gamma$
$X \rightarrow jj + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_1 x_2$, then $x_2 \rightarrow jj x_1$; or a scalar s_2 , produced via $pp \rightarrow Z' \rightarrow s_1 s_2$, then $s_2 \rightarrow jj$
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	DMSM. LLP is fermion x_2 , produced via $pp \rightarrow Z' \rightarrow x_1 x_2$, then $x_2 \rightarrow \ell^+ \ell^- x_1$; or a scalar s_2 , produced via $pp \rightarrow Z' \rightarrow s_1 s_2$, then $s_2 \rightarrow \ell^+ \ell^-$
$X \rightarrow \ell_\alpha^+ jj$	LRSM. LLP is fermion ν_R , produced via $pp \rightarrow Z/Z'/h \rightarrow \bar{\nu}_L \nu_R$, then $\nu_R \rightarrow \ell^+ jj$

Table A10. Simplified model library process proposals for charged current (CC) production mode, $W_{\text{SM}}^\pm/W'^\pm \rightarrow X + \ell^\pm$; these can be simulated using left–right symmetric models using either the W or W' (for simplicity, in the table above we only state explicitly W). Right-handed neutrino lifetimes are most naturally long for sub-weak-scale masses.

Decay mode	Simplified model library process
$X \rightarrow jj + \text{inv.}$	LRSM. LLP is the right-handed neutrino (ν_R) produced via $pp \rightarrow W^\pm, W^\pm \rightarrow \ell^\pm \nu_R$. Then, $\nu_R \rightarrow q\bar{q}\nu$ via an off-shell Z . For massive invisible state, it may be possible to use a cascade $\nu_{R2} \rightarrow q\bar{q}\nu_{R1}$ treating the lightest right-handed neutrino as stable
$X \rightarrow jj\ell^\pm$	LRSM. LLP is the right-handed neutrino (ν_R) produced via $pp \rightarrow W^\pm, W^\pm \rightarrow \ell^\pm \nu_R$. Then, $\nu_R \rightarrow q\bar{q}'\ell^\pm$ via an off-shell W . Alternately, production and decay can be mediated by W_R .
$X \rightarrow \ell_\alpha^+ \ell_\alpha^- + \text{inv.}$	LRSM. LLP is the right-handed neutrino (ν_R) produced via $pp \rightarrow W^\pm, W^\pm \rightarrow \ell^\pm \nu_R$
or $X \rightarrow \ell_\alpha^+ \ell_\beta^- + \text{inv.}$	Then, $\nu_R \rightarrow \ell_\alpha^+ \ell_\alpha^- \nu_\beta$ or $\nu_R \rightarrow \ell_\alpha^+ \ell_\beta^- \nu_\alpha$ via an off-shell W/Z

Beam test performance of prototype silicon detectors for the Outer Tracker for the Phase-2 Upgrade of CMS

Tracker group of the CMS collaboration

E-mail: suvankar.roy.chowdhury@cern.ch

ABSTRACT: A new CMS tracker detector will be installed for operation at the High Luminosity LHC (HL-LHC). This detector comprises modules with two closely spaced parallel sensor plates and front-end ASICs capable of transmitting tracking information to the CMS Level-1 (L1) trigger at the 40 MHz beam crossing rate. The inclusion of tracking information in the L1 trigger decision will be essential for selecting events of interest efficiently at the HL-LHC. The CMS Binary Chip (CBC) has been designed to read out and correlate hits from pairs of tracker sensors, forming so-called track stubs. For the first time, a prototype irradiated module and a full-sized module, both equipped with the version 2 of the CBC, have been operated in test beam facilities. The efficiency of the stub finding logic of the modules for various angles of incidence has been studied. The ability of the modules to reject tracks with transverse momentum less than 2 GeV has been demonstrated. For modules built with irradiated sensors, no significant drop in the stub finding performance has been observed. Results from the beam tests are described in this paper.

1 Introduction

The Large Hadron Collider (LHC) at CERN will undergo major upgrades by 2025 to be able to deliver peak instantaneous luminosities of $5 - 7.5 \times 10^{34} \text{cm}^{-2}\text{s}^{-1}$. This High Luminosity upgrade of the LHC (HL-LHC) will allow the CMS (Compact Muon Solenoid) [1] experiment to collect data corresponding to integrated luminosities of the order of 300fb^{-1} per year. Eventually, a total of 3000fb^{-1} will be collected during ten years of operation. At the nominal instantaneous luminosity of the HL-LHC, a single bunch crossing will produce 140-200 proton-proton collisions. The vast majority of these collisions are “pileup” interactions with low momentum transfer that are of little physics interest.

In order to fully exploit the increased luminosity and to cope with the very high pileup environment, the detector and the trigger system of the CMS experiment need to be upgraded

significantly [2]. The present CMS tracker was designed to operate up to an integrated luminosity of 500 fb^{-1} [2, 3], beyond which radiation damage will lead to degradation of its performance. The CMS experiment will replace the current tracker with a new silicon tracker. The upgraded tracker [3] will feature increased radiation hardness, higher granularity, compatibility with higher data rates, and a longer trigger latency. In addition, the tracker will provide tracking information to the Level-1 trigger, allowing trigger rates to be kept at a sustainable level without sacrificing physics potential [3].

The CMS tracker for the HL-LHC period will consist of modules with two “stacked” silicon sensors, read out by front-end ASICs with the capability to discriminate tracks based on their transverse momentum (p_T). The concept of p_T discrimination by means of very short track segments called stubs, in so-called p_T modules, will be discussed in the following section.

A number of module prototypes described in the following section, each with two stacked strip sensors, also known as 2S modules, were subjected to particle beams at CERN, Fermilab, and DESY beam test facilities to measure the performance of the stub finding mechanism, the uniformity of the stub finding efficiency in the entire detector, the potential to reject low p_T tracks ($< 2 \text{ GeV}$), and the ability to work efficiently up to the expected overall HL-LHC radiation level. In this paper, results from beam tests carried out at CERN are reported and, where possible, compared to those obtained at Fermilab and DESY. The results from previous beam test are reported in ref. [4].

2 CMS tracker for HL-LHC

The layout of the new tracker is shown in figure 1. The new tracker will consist of two parts: an Inner Tracker (IT) and an Outer Tracker (OT). Both the IT and the OT will have a barrel section, made out of coaxial cylindrical layers, and two endcaps, one on each side of the barrel, made out of discs. The IT barrel will feature four layers of pixel detectors, providing three-dimensional hit coordinates, resulting in excellent vertex resolution. Each IT endcap will consist of 12 pixel discs on each side of the barrel. The OT barrel will comprise six layers of detector modules each having two silicon sensors separated by a small distance and read out by the same front-end electronics. The separation between the sensors of a module, defined by the distance between the sensor mid planes, will vary between 1.6 mm and 4 mm [3]. Of the six layers of the OT barrel, the three inner layers will be equipped with modules made of one macro-pixel sensor and one strip sensor (PS p_T module). The three outer layers will be equipped with modules with two strip sensors (2S p_T module). The OT endcaps will feature six discs and will be equipped with PS and 2S modules, as shown in figure 1. The main specifications of the PS and 2S modules for the OT are listed in table 1.

Table 1. Main parameters of the 2S and PS modules of the proposed CMS Phase-2 tracker [3].

2S module			PS module		
$\sim 2 \times 90 \text{ cm}^2$ active area			$\sim 2 \times 45 \text{ cm}^2$ active area		
No. of strips/sensor plane	Strip length	Pitch	No. of strips/macro-pixels	Strip/macro-pixel length	Pitch
2×1016	$\sim 5 \text{ cm}$	$90 \mu\text{m}$	$2 \times 960/32 \times 960$	$\sim 2.4 \text{ cm}/\sim 1.5 \text{ mm}$	$100 \mu\text{m}$

Figure 1. Sketch of one quarter of the tracker layout in $r-z$ view. The radial region below 200 mm is referred to as Inner Tracker and will be instrumented with pixel modules. In the Outer Tracker, the radial region between 200 and 600 mm is equipped with PS modules (blue lines), while the region beyond 600 mm will be populated with 2S modules (red lines). The CMS coordinate system is defined in ref. [1].

Figure 2. Illustration of the p_T module concept [3]. Correlation of signals in closely spaced sensors enables rejection of low- p_T particles. The channels shown in green represent the selection window to define an accepted stub; a low- p_T rejected track is shown in red.

2.1 The concept of p_T discrimination

In the presence of the 3.8 T solenoidal magnetic field inside the CMS detector, the trajectories of charged particles produced in a collision will bend in a plane transverse to the direction of the beam. The radius of the curvature of the trajectory of these particles depends on the particle p_T . The concept of p_T discrimination is shown in figure 2. As a charged particle passes through the module, it generates signals (hits) in the bottom and top sensors of the module. A hit in the bottom sensor is then matched to the one in the top sensor and if they are within a predefined window, these two hits are combined to form a short track segment or stub. These stubs will be used in the Level-1 (L1) track trigger.

The readout chips will provide the p_T discrimination logic described above. The window for hit matching can be set within the readout chip according to the p_T threshold to be used. For the 2S module, the readout chip is called the CMS Binary Chip (CBC) [5–9]. Each CBC has 254 readout

Figure 3. Left: sketch of the full-size 2S module. Right: cross section of the 2S module. The connection of the front-end chips to strips of both the top and the bottom sensor via routing lines in the flexible hybrid (flex kapton circuit), which is bent around a stiffener/spacer sandwich [3], is visible.

channels with alternate channels connected to the top and bottom sensors in a module, as shown in figure 3 (right), so that coincidences between channels of the two sensors can be obtained.

The 2S module, shown in figure 3, consists of two sensors (n-type strips in p-type silicon substrate), support structures made from Al-CF (carbon fibre reinforced aluminium), two front-end hybrids [10], each with eight CBCs and one concentrator integrated circuit (CIC) that aggregates data from the CBCs, and a service hybrid for powering and output data serialization followed by opto-electrical conversion.

All prototype modules discussed in this paper use the second prototype of the CMS Binary Chip, the CBC2 [7–9]. The block diagram of the analogue front-end (FE) of the CBC2 ASIC is shown in figure 4. Three I²C registers are used to control the main settings of the analogue FE: V_{plus} , which controls the global DC baseline of the post-amplifier output, V_{offset} (labelled “Offset” in figure 4) for fine control of the baseline of the post-amplifier output for individual channels on the CBC2, and V_{cTH} , which controls the comparator threshold. The readout for the CBC2 chip is binary, thus it does not measure the amount of charge induced on each strip. If the charge on a strip exceeds the comparator threshold, a hit is registered.

Figure 4. Block diagram of the analogue front-end (FE) of the CBC2 ASIC [7–9]. Three registers are used to control the analogue FE.

2.2 Prototype detectors

Prototypes of the 2S module have been investigated at different test beam facilities (table 2). For the beam tests described in section 3, two small prototype modules and one full-size module have

Table 2. Details of modules used in various beam tests.

Module type	No. of CBC2s	Sensor active thickness	Sensor separation	Bias voltage	Beam Test facility
Non-irradiated mini-module	2	270 μm	2.75 mm	250 V	CERN, DESY, Fermilab
Irradiated mini-module	2	240 μm	3.05 mm	600 V	CERN
Full-size module	16	240 μm	1.80 mm	240 V	CERN, Fermilab

Figure 5. Left: the irradiated 2S mini-module assembled from a small prototype hybrid comprising two CBC2 readout chips and two silicon sensors with 254 strips of 5 cm length. Right: the full-size 2S module comprising two hybrids with eight CBC2 readout chips each and two full-size 2S sensors.

been studied. The strip sensors of the modules have 5 cm long n-type strips at 90 μm pitch on about 300 μm thick silicon sensors with p-type bulk. A negative voltage is applied to bias the sensors at the sensor backplane but in the following the absolute values of the bias voltage applied are quoted.

The small prototype modules, called mini-modules, consist of a version of the front-end hybrid housing two CBC2s. The hybrid is made of a rigid material with bond-pads on both sides and the sensors are wire-bonded to the top and bottom sides of it. This contrasts with the flex-kapton design used for full-sized modules that folds over the CF spacer to provide bond-pads for the bottom sensor [3, 11]. The sensors have been glued on a small frame made of aluminium. One mini-module was left unirradiated. The sensors of this module have an active thickness of 270 μm and their separation is 2.75 mm. The second mini-module, shown in figure 5 (left), with an active sensor thickness of 240 μm and a sensor separation of 3.05 mm, was irradiated with 23 MeV protons at Irradiation Center Karlsruhe [12] to a fluence of 6×10^{14} $n_{\text{eq}}/\text{cm}^2$ with an annealing of approximately two weeks at room temperature. The maximum expected fluence for the innermost layer of the 2S modules of the OT is 3×10^{14} $n_{\text{eq}}/\text{cm}^2$ [3]. This value corresponds to 3000 fb^{-1} of proton-proton (pp) collisions at $\sqrt{s} = 14 \text{ TeV}$ assuming a total inelastic cross section, σ_{pp} , of 80 mb.

The current-voltage characteristic of the sensors before and after irradiation can be seen in figure 6. The effect of irradiation is reflected by an increase of the leakage current by three orders of magnitude.

The full-size module consists of two sensors of about $10 \text{ cm} \times 10 \text{ cm}$, with two columns of 1016 strips each. The active thickness of each sensor is 240 μm and the sensors are separated by 1.8 mm. Each of the front-end hybrids on both ends of the module houses eight CBC2s. A flex hybrid is used to provide bond-pads for the top and bottom sensors (figure 3). The module is built

Figure 6. The current-voltage characteristic of a sensor of the mini-module before (red) and after (black) irradiation to $6 \times 10^{14} \text{ n}_{\text{eq}}/\text{cm}^2$, showing the increased current after irradiation. The measurements were taken at -20°C and 20°C for the irradiated and non-irradiated sensors, respectively.

with a rotation angle between the strips of both sensors of below $400 \mu\text{rad}$. This module is shown in figure 5 (right).

3 Beam test infrastructure

The prototype modules have been studied at beam test facilities at CERN, Fermilab and DESY. In all of the facilities, the detector under test (DUT) is placed within a tracking detector, referred to as ‘telescope’ in the following. The telescope provides a reference to reconstruct the tracks of the incident particles. The beam test facility at CERN is described in detail in the following section, and the key features of the DESY and Fermilab test beam facilities are highlighted. The data acquisition systems (DAQ) of the three facilities are also described.

3.1 Beam test setup

A schematic diagram of the setup at CERN is shown in figure 7. Data were collected using a 120 GeV pion beam. The EUDET telescope [13] used in the CERN beam test of the 2S prototype modules is a tabletop tracking detector composed of six planes of MIMOSA-26 [14] silicon pixel sensors for accurate track reconstruction, a fast-timing reference plane (FE-I4) [15] for accurate timing resolution, and a pair of crossed scintillators with photomultiplier tubes (PMTs) located at either end of the telescope for trigger generation. The six MIMOSA-26 sensor planes, each covering an active area of $10.6 \times 21.1 \text{ mm}^2$, consist of $50 \mu\text{m}$ thick $18.4 \mu\text{m} \times 18.4 \mu\text{m}$ square pixels arranged in 576 rows and 1152 columns. The fast-timing plane covers an active area of $16.8 \times 20.0 \text{ mm}^2$ and consists of $200 \mu\text{m}$ thick pixels arranged in 336 rows and 80 columns read out by the FE-I4 chip, which was designed for the innermost layer of the upgraded pixel detector of the ATLAS

experiment. Each sensor plane is mounted inside a 20 mm thick aluminium jig, and two sets of three jigs are attached via rail systems to the upstream/downstream arms of the telescope. The minimum distance between sensor planes is defined by the thickness of the aluminium jig (and is therefore 20 mm), and the maximum distance between sensor planes is defined by the length of each arm (150 mm for equidistant spacing between the sensor planes). The resolution of the telescope system over the six sensors used is $3.24\ \mu\text{m}$ [16]. The jigs are cooled to a constant temperature of 16°C to increase the stability of operation.

Figure 7. Schematic drawing of the beam test setup at CERN showing the three detector systems used to characterize the performance of the 2S prototype module: the 6 MIMOSA planes, the ATLAS FE-I4 plane and the four scintillators used to generate the NIM trigger. The DUT is placed within the telescope system as shown.

The synchronization of the data streams from the three detector systems (the 2S prototype, the MIMOSA-26 sensor planes, and the FE-I4 plane) is performed by an FPGA-based Trigger Logic Unit (TLU) [17, 18]. During the beam tests, dedicated NIM logic is used to generate a trigger signal using the output signals from the two pairs of crossed scintillators at either extremity of the EUDET telescope. This trigger signal is provided as input to the TLU, which distributes this signal to the DUT and to the telescope’s sensor planes.

A simple handshake protocol is used by the DAQ system to maintain synchronization among the different detector systems. The detector systems assert busy signals on separate lines, which inhibit triggers from the TLU until all of the lines are cleared. No new triggers are sent by the TLU until all detectors drop their busy-lines. This ensures that detectors with different dead-times can be triggered and read out synchronously. In addition, the TLU can send a timestamp for each trigger via a dedicated clock-data line, or it can receive a back-pressure (veto) signal from the DUTs on the same line.

The additional ATLAS FE-I4 plane is used to improve the timing resolution of the telescope by associating the FE-I4 hits with the individual hits in the $115.2\ \mu\text{s}$ rolling-shutter frame of the telescope during event building. This allows the multiple tracks in a telescope frame to be correlated to individual triggers. Because the FE-I4 readout has no dead-time and runs on an internal 40 MHz clock, the required time resolution of 25 ns for the CBC DAQ is achieved. The data streams from the telescope and the FE-I4 are sent to the EUDAQ [13] online software via the TCP/IP protocol [19]. The two streams are stored together in the same format in a file, which makes the reconstruction easier in the EUDET [20] framework.

The beam test at DESY uses the EUDET based telescope called DURANTA [13], similar to the one used during the CERN beam test. It also uses six MIMOSA-26 pixel sensors with four crossed scintillators for triggering and a TLU, however it was equipped with a CMS Phase-1 pixel [21]

module as a timing reference plane instead of the FE-I4. The data were collected with a positron beam of 5 GeV energy.

The Fermilab Test Beam Facility, or FTBF [22], is equipped with two silicon telescopes aligned along the beam line and configured to operate synchronously. It has a pixel telescope assembled from eight planes and a telescope with strip modules made up of 14 detector planes. The strip telescope increases the coverage of the pixel telescope and improves its tracking performance. The trigger is generated by a coincidence signal of three scintillation counters, one placed in front and two placed behind the telescopes. The synchronization of the data streams from the two telescopes and the 2S module is performed by a Fermilab-designed FPGA-based trigger board. The data are taken with a 120 GeV proton beam.

3.2 Data acquisition system

The DAQ system for the CBC2 modules at CERN and Fermilab test beams is based on the CERN Gigabit Link Interface Board (GLIB) [23] μ TCA Advanced Mezzanine Card (AMC). Different firmware versions are used to read data from the 2 and 16 CBC2s on the tested modules. Control signals and readout data are exchanged between the GLIB and the control PC via the IPBus [24] protocol, whereas trigger, busy and veto signals are interfaced to the TLU/Fermilab equivalent via a dedicated five-channel I/O FPGA Mezzanine Card (FMC). A simple block diagram of the different components of the DAQ system is shown in figure 8.

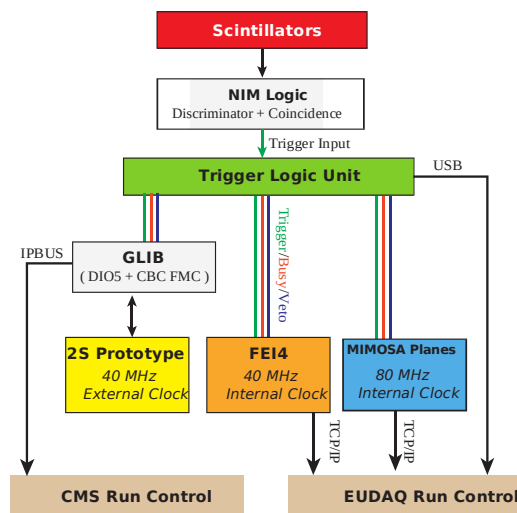

Figure 8. Block diagram of the DAQ system used in the CERN and Fermilab beam test setups. The correlation of the data from the two DAQ chains is described later in section 5.

An external high-precision clock generator was used to provide the clock signals to the GLIB via the same FMC that connects to the TLU. The CBC2 data are processed and formatted by the firmware and then sent to a XDAQ [25] application that formats events in a CMS compatible format and stores the data for later processing within the standard CMS reconstruction software, CMSSW [26]. The binary raw data stream is also stored and can be used for online data quality monitoring.

The beam test at DESY used a novel DAQ system, based on the FC7 [27] card. The FC7 hosts a Kintex-7 FPGA and comes with a system firmware allowing for communication with other devices

on the FC7 card and IPBus communication. A DIO5 FMC is used to send trigger and busy signals via LEMO connectors. These are fed into a custom-built LVDS converter box and sent to the TLU via a standard RJ45 connector.

4 Preparations for data-taking

4.1 Pedestal and noise

The pedestal and noise values of an individual channel in a system with binary readout can be inferred from a channel's S-curve. An S-curve is obtained by measuring the noise occupancy as a function of the comparator threshold (V_{CTH} in figure 4). The comparator threshold has been measured in V_{CTH} DAC units. One V_{CTH} DAC unit corresponds to 375 electrons, as measured using an X-ray source. The noise occupancy is given by the fraction of triggers for which a given channel registers a hit. Higher numerical values of V_{CTH} correspond to lower thresholds in the CBC2. Figure 4 also shows the per-channel 8-bit DAC used to control the offset of the output voltage of the second amplification stage to compensate for any channel-to-channel variations.

The pedestal value and the channel noise are extracted directly from the S-curve either by fitting the curve with a sigmoid of the form

$$f(x, \mu, \sigma) = \frac{1}{2} \left[1 + \operatorname{erf} \left(\frac{x - \mu}{\sqrt{2}\sigma} \right) \right], \quad (4.1)$$

or by numerically differentiating it. The mean parameter, μ , in eq. (4.1) (or the mean of a Gaussian fitted to the differential histogram) then corresponds to the pedestal and σ (or the RMS of a Gaussian fitted to the differential histogram) corresponds to the noise. An example of an S-curve recorded for a CBC2 on a non-irradiated prototype module and the corresponding differential histogram are shown in figure 9. Both methods return similar (i.e. consistent within 3σ) values for the pedestal and noise. The pedestal value, obtained from fitting the left plot of figure 9 with a sigmoid function, is $120.0 \pm 0.1 V_{\text{CTH}}$ DAC units. A pedestal value of $119.3 \pm 0.2 V_{\text{CTH}}$ DAC units has been obtained by fitting the distribution shown in figure 9, right, with a Gaussian function. For the noise, $2.12 \pm 0.06 V_{\text{CTH}}$ DAC units and $2.14 \pm 0.15 V_{\text{CTH}}$ DAC units are obtained, respectively.

Figure 10 shows the uniformity of the front-end response after adjustment of the individual channels' offsets. The pedestal and noise values were extracted from the fits to the individual channels' S-curves using eq. (4.1). The channel-to-channel variation in the pedestal, defined as the RMS of the measured distribution, is measured to be 0.30 ± 0.01 and $0.37 \pm 0.02 V_{\text{CTH}}$ DAC units for the first and second CBC2, respectively. The mean noise was found to be 1.36 ± 0.06 and $2.38 \pm 0.60 V_{\text{CTH}}$ DAC units for the first and second CBC2, respectively. The same figure also clearly shows that 11 of the strips connected to the second CBC2 on the hybrid are significantly noisier than the rest. These 11 strips are included in the noise figure quoted for the second CBC2. The strips exhibiting a value of noise larger than $3 V_{\text{CTH}}$ DAC units (1125 electrons) are not considered for analysis.

4.2 Latency scans

After the pedestal and noise scans, two latency scans, one for data and one for stubs, were carried out. The data latency, measured in units of 40 MHz clock cycles and set using an on-chip configuration

Figure 9. S-curve measured for a single input channel on one of the two CBC2s on a non-irradiated prototype module at room temperature with the sensor biased at 250 V. On the left the measured data are shown along with a fit to the measured data performed using eq. (4.1), while on the right the differential histogram is shown with the corresponding Gaussian fit.

register, defines the position in the on-chip RAM from which the data are read upon reception of a trigger. The stub latency, also measured in units of 40 MHz clock cycles and set by a configuration register in the back-end FPGA, defines the delay between hit and stub data arriving at the back-end of the data acquisition system and is required to assemble the data at the back-end.

The resolution of the data latency measurement was improved using a high-resolution time-to-digital converter (TDC) in the back-end FPGA. The TDC measures the time of arrival of the trigger signal at the back-end with respect to the 40 MHz clock edge in time slices of 3.125 ns, using a 3 bit counter operating at 320 MHz. The results of the latency scans performed in the CERN beam test are shown in figure 11. These scans were used to identify the stub and data latencies to use during data taking by counting the number of stubs and hits contained in the data stream for a fixed number of triggers and selecting values for the data and stub latency that maximize the fraction of events containing stubs and hits, respectively. Both scans were performed at a threshold of 113 DAC units (3σ away from the pedestal). For further data taking, the data latency and stub latency were fixed at 13 and 4, respectively, as shown by the dashed lines in figure 11.

5 Reconstruction

Dedicated software is used to reconstruct the data collected from the telescope system and the DUT. Initially, the reconstruction of tracks of the incident particle is carried out using the hits in the telescope system. The reconstruction of data from the DUT involves the formation of clusters and stubs using the hits from the individual channels. The reconstructed tracks are then extrapolated to the DUT, and the estimated position of the track on the DUT is computed. Using this information, an alignment is performed to correct for the relative offset in position of the DUT with respect to the telescope system. The reconstruction of tracks from the telescope data, clusters and stubs from the DUT data, and alignment procedures are described in the following sections.

Figure 10. Pedestal (top) and noise (bottom) for both CBC2s on a prototype module.

5.1 DUT reconstruction

The schematic diagram for the processing of the DUT data is shown in figure 12. The raw data received from the 2S modules by the FPGA are converted to the CBC2 event format by the DAQ software and served to the online Data Quality Monitoring (DQM) system. The raw data are also sent to the CMS event builder (EVB) [28] which provides data in the Event Data Model (EDM) format [29, 30]. The EDM data are then processed by the CMS offline software, CMSSW [26], to produce clusters and stubs used in the offline analysis. Hits in adjacent strips of the DUT are combined to form a cluster. The number of strips included in a cluster is called the cluster width. The cluster position is defined by the center of the cluster rounded down to an integer strip number.

Figure 11. Results from data (top) and stub (bottom) latency scans. The TDC phase gives fine resolution within a 40 MHz clock cycle ($1/8$). The dashed lines indicate the chosen values.

The CBC2 reconstructs stubs, by calculating the cluster positions in integer strip numbers. However, it outputs only the information that a stub was present, not its position (in contrast to later versions of the chip, which include this functionality). Therefore the stub reconstruction is done offline, by emulating the logic in the CBC2. Clusters with cluster width greater than 3 are excluded from stub formation. The difference in position (in number of strips) of the clusters in the bottom sensor is calculated with respect to clusters in the top sensor. If this difference is less than the predefined window, an offline stub is formed. The position of the stub is defined as the position of the cluster in the bottom sensor seeding the stub. As the DAQ systems for the telescope and for the DUT are different, an

additional processing step is needed to synchronize the events coming from telescope and DUT data streams by matching the individual trigger numbers using the ROOT data analysis framework [31].

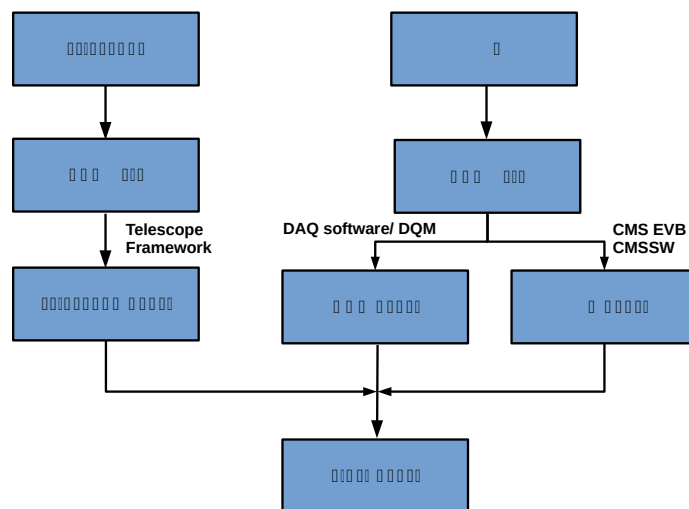

Figure 12. A schematic representation of the data processing for the beam tests at CERN. The Telescope event contains information about the incident track parameters. The DUT event contains the information of the hits as read from the DUT and also the clusters and stubs reconstructed using offline software. The CBC event contains the information about CBC errors. Data from all three sources are merged and stored into a single file for offline analysis.

5.2 Tracking

Tracks from the EUDET telescope are reconstructed in the EU Telescope [13] framework using MIMOSA-26 planes. A database of noisy pixels (pixels with exceptionally high occupancy), is built and used to exclude such pixels from subsequent steps of the analysis. Clusters are built according to the nearest neighbour search algorithm, which iteratively joins adjacent pixels with hits to form a cluster. A “*pre-alignment*” is performed in the telescope global frame, correcting only for the misalignment in X and Y directions (as shown in figure 7). The output of this step is used to constrain the alignment step itself, based on solving exact matrix equations with the Millipede II framework [32]. Shifts in X, Y and Z coordinates and 3 Euler rotation angles for each Mimosa plane are corrected for. Tracks are then reconstructed with a Deterministic Annealing Filter (DAF) algorithm [33, 34], where all hits within a given radius are used for the track reconstruction. Tracks reconstructed with the DAF are further cleaned to remove any duplicates, defined as two or more tracks with X and Y coordinates at the FE-I4 plane less than $1\ \mu\text{m}$ apart.

While Mimosa planes are read out with a rolling shutter having a window of $115\ \mu\text{s}$, the maximum acquisition rate for the DUT and the FE-I4 plane is 40 MHz. The presence of a hit in the FE-I4 plane that can be matched to the track is used as a timestamp, which largely reduces track combinatorics. Residuals at the FE-I4 plane are used to determine a nominal distance between

the track impact point and the FE–I4 hit. The residuals are fitted with a step rectangular function convolved with a Gaussian smearing. The maximum distance to accept a track is set to half the width of the step function, compatible with the FE–I4 pitch, plus two times the width of the Gaussian, compatible with the track pointing resolution.

Track reconstruction and telescope alignment at the Fermilab test beam facility are performed using a single dedicated software package [22] that provides a graphical interface to execute the various steps. An iterative algorithm implements a least-squares minimization to compute 1st-order roto-translational corrections using tracks reconstructed with a preliminary description of the geometry.

The reconstruction of beam test data at DESY follows a similar procedure to that used for beam tests at CERN. The main difference is that the entire reconstruction is performed within the EU Telescope framework and that the General Broken Lines (GBL) [35] algorithm for alignment is used. The GBL algorithm is required to account for the increased multiple scattering of the comparatively low-energy particles available at the DESY beam test facility.

5.3 DUT alignment

The DUT alignment procedure consists of minimizing the residuals at the DUT plane to constrain the degrees of freedom of the system:

$$\chi^2 = \frac{1}{N} \sum_{i=0}^N \left(\frac{x_{\text{DUT}} - x_{\text{TkAtDUT}}}{\sigma_{\text{tkres}}} \right)^2,$$

where x_{DUT} is the hit position in X and x_{TkAtDUT} the position of the hit as derived from the track extrapolation to the DUT location, while σ_{tkres} is the telescope pointing resolution. The sum runs over all events in which at least one cluster in the DUT and one track are reconstructed. For each event the closest pair is selected. To remove outliers, the sum is further restricted to events where the residual $|x_{\text{DUT}} - x_{\text{TkAtDUT}}|$ is less than $3\sigma_{\text{tkres}}$ away from the mean value of a Gaussian fit of the residual distribution.

The track impact point on the FE–I4 plane is propagated to the first sensor plane of the DUT, which corresponds to the plane of the sensor facing the beam direction, including degrees of freedom for the X position of the first plane, Z position of the first plane, θ angle around the Y-axis, and the distance between the two sensor planes of the DUT. This procedure eliminates the sign degeneracy of the θ angle. For efficiency studies reported in section 6, a track is matched to a hit, cluster or stub on the DUT if the residual, $|x_{\text{DUT}} - x_{\text{TkAtDUT}}|$, is less than $3\sigma_{\text{tkres}}$.

6 Results

After calibration, the threshold (V_{CTH}) and the angle of rotation of the DUT with respect to the beam were varied in suitable step sizes and the properties of hits, clusters and stubs were studied. The axis of rotation of the DUT was the Y axis, as shown in figure 7.

A scan of V_{CTH} was performed at vertical beam incidence and measurements of the cluster and stub efficiencies were carried out as a function of a number of functional parameters to fully characterize the mini-modules (section 6.1) and the full-size module (section 6.2).

Figure 13. Average number of hits per event on non-irradiated and irradiated sensors as a function of V_{CTH} . A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module.

6.1 Performance of mini-modules

Figures 13 and 14 show the average number of hits and clusters on the non-irradiated and irradiated mini-modules, respectively. Lower numerical values of V_{CTH} mean a higher signal threshold, as mentioned in section 4.1. For the non-irradiated mini-module, the average number of hits/clusters increases as V_{CTH} is increased and a plateau with a value close to 1 is visible, up to V_{CTH} values of about 110. However, for the irradiated module, the average number of hits/clusters is mostly less than 1 as V_{CTH} is increased. This indicates that, for a given value of V_{CTH} , we see a lower number of hits/clusters in the irradiated mini-module as compared to the non-irradiated one. As the V_{CTH} setting is increased further ($\gtrsim 110$), the noise increases in both mini-modules, leading to a sharp rise in the average number of hits/clusters. Differential histograms of cluster occupancy as a function of V_{CTH} , derived by numerically differentiating the distributions of the cluster occupancy as shown in figure 14, are shown in figure 15. The differential distributions show an inverted Landau distribution, caused by the actual signal generated from the incident particle, and a noise peak. Comparing the differential distributions, it can again be seen that the total number of clusters is lower in the irradiated mini-module. The loss in the number of clusters for the irradiated mini-module as seen in figure 14 and figure 15 indicates that the charge collection in the irradiated mini-module is worsened due to radiation induced effects. Along with radiation induced effects, the lower sensor active thickness of $240\ \mu\text{m}$ for the irradiated module, compared to $270\ \mu\text{m}$ of the non-irradiated module, also leads to lower charge collection. By choosing appropriate V_{CTH} values of 106 and 110 DAC units for the non-irradiated and irradiated module, respectively, signals from incident particles can be collected preferentially.

The cluster efficiency, defined as the ratio between the number of events with a cluster matched to a track in a single track event and the total number of events with a single track, is then measured as

Figure 14. Average number of clusters per event for non-irradiated and irradiated sensors as a function of V_{CTH} . A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module.

Figure 15. Differential cluster occupancy for non-irradiated and irradiated sensors as a function of V_{CTH} . A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module.

a function of V_{CTH} for different values of the trigger phase (TDC), to check for a potential dependency. The cluster efficiencies for one of the sensors of the non-irradiated and irradiated mini-modules are shown in figure 16. The lower charge collection in the irradiated module results in a smaller efficiency plateau (figure 16, bottom) compared to the non-irradiated module (figure 16, top). As the V_{CTH} increases further (> 110), the efficiency starts to degrade for both the mini-modules due to increase of noise. Due to the higher noise occupancy, the probability of a neighbouring strip to fire increases, resulting in larger cluster width. This shifts the position of the actual cluster away from the track causing the track matching to fail. A small dependency on the trigger phase is present for both sensors and is more evident at lower V_{CTH} . A trigger phase is present in the CERN beam test because the trigger signal is asynchronous with respect to the 40 MHz clock that drives the readout electronics.

Because there is no magnetic field, the dependence of the mini-module performance on the transverse momentum of tracks is emulated by rotating the DUT with respect to the beam direction. As the incident angle (referred to as α) of the particles increases, the charge deposited is shared by multiple strips and hence the cluster width is expected to increase, which is shown in figure 17. This effect is less evident on the irradiated module due to the radiation induced defects both in the sensor bulk and on the surface, that change the electric field inside the sensor. This leads to a modification of the charge sharing and further to a higher average cluster size at normal incidence. The same effect is also evident from the distribution of the fraction of clusters with different strip multiplicities, as shown in figure 18. The non-irradiated module shows a correlation between the cluster fractions and the angle. This dependence is much less significant for the irradiated module.

In figure 19 the cluster efficiencies for different TDC values as a function of the DUT rotation angle for the two modules are shown. The dependency on the trigger phase is negligible and the mean cluster efficiency for the full range of the angular scan is $99.56 \pm 0.01\%$ and $98.21 \pm 0.02\%$ for the non-irradiated and irradiated module, respectively.

For the CMS field strength of $B = 3.8$ T, the relationship between the beam incident angle (α) and the emulated transverse momentum p_{T} of the traversing particle for a radial position of the module (R) is given by $p_{\text{T}} [\text{GeV}] \approx \frac{0.57 \cdot R[\text{m}]}{\sin(\alpha)}$. The stub efficiency, defined as the ratio of the number of events with stubs matched to a track in single track events to the number of events with a single track, was measured for each incident angle. Tracks and stubs must match within 4σ of the spatial resolution. The stub efficiency of the two mini-modules as a function of effective p_{T} (beam-incident angle) is shown in figure 20. For larger angles of incidence the relative shift in cluster position in the two sensors of a module is larger, which leads to lower probability of correlating them as stubs. The stub efficiency drops for larger angles for this reason. A stub correlation window of 5 strips is used. A radius of 60 cm was used for the calculation of the effective p_{T} from the beam incident angle. The turn-on curve is different for the two modules due to different sensor spacing.

The turn-on curve was fitted with an error function of the form

$$f(p_{\text{T}}) = 0.5A \left(1 + \text{erf} \left(\frac{p_{\text{T}} - p_{\text{T}\mu}}{\sigma_{p_{\text{T}}}} \right) \right),$$

where A is the efficiency at the plateau, $p_{\text{T}\mu}$ is the turn-on threshold for which the efficiency is 50%, and $\sigma_{p_{\text{T}}}$ is the width of the Gaussian in the error function. The p_{T} resolution is defined as the ratio of the width of the Gaussian to the p_{T} value at 50% of the plateau height, or $\sigma_{p_{\text{T}}}/p_{\text{T}\mu}$. For the

Figure 16. Cluster efficiency of the non-irradiated (top) and irradiated (bottom) 2S mini-modules presented as a function of V_{CTH} for different phase differences between trigger and readout clocks. A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module.

non-irradiated module, the turn-on threshold is 1.88 GeV with a p_T resolution of 5%, whereas the expected turn-on threshold is 2 GeV. The plateau efficiency for the non-irradiated module is 99%. The high plateau efficiency with sharp turn-on demonstrates that the module can reject tracks with $p_T < 2$ GeV efficiently. For the irradiated mini-module, the plateau efficiency reaches 97% with a p_T resolution of 6%. This shows that the stub finding logic of the 2S modules will work even after being irradiated to a fluence of 6×10^{14} n_{eq}/cm^2 , which is twice the expected fluence for the first layer of 2S modules. The stub efficiency measured using data collected at the DESY test beam facility with the non-irradiated mini module is found to be 99%.

Figure 17. Mean cluster width of non-irradiated and irradiated 2S mini-modules as a function of the beam incident angle. Due to radiation induced defects, charge sharing is higher in the irradiated module, leading to a larger mean cluster size. A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module. A V_{CTH} value of 106 (110) DAC units was used for the non-irradiated (irradiated) mini-module.

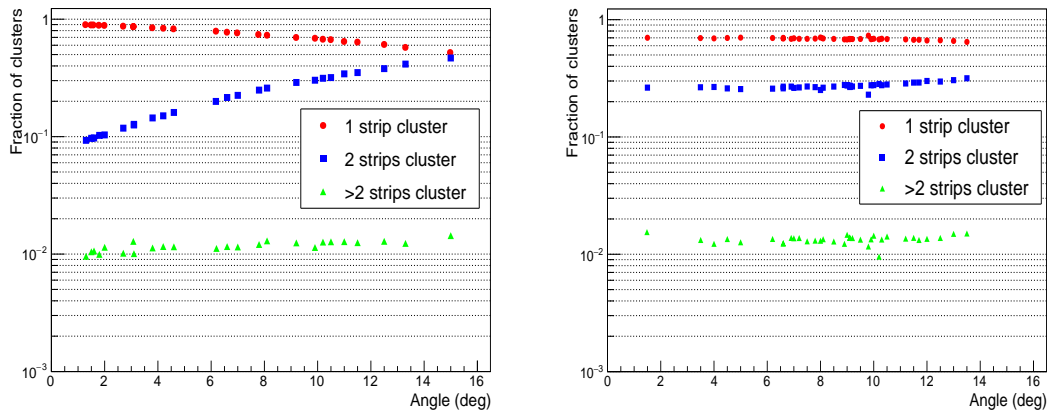

Figure 18. Fraction of clusters with different strip multiplicity; (left) non-irradiated module; (right) irradiated module. A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module. A V_{CTH} value of 106 (110) DAC units was used for the non-irradiated (irradiated) mini-module.

Figure 19. Cluster efficiency of the non-irradiated (top) and irradiated (bottom) 2S mini-modules as a function of the beam incident angle for different TDC phases. A bias voltage of 250 V (600 V) was applied to the non-irradiated (irradiated) mini-module. A V_{CTH} value of 106 (110) DAC units was used for the non-irradiated (irradiated) mini-module.

For the irradiated module three angular scans were performed, each with different stub correlation windows. As shown in figure 21, the turn-on curve of the efficiency depends on the selected correlation window, while the efficiency plateau does not.

6.2 Performance of the full-size module

For the full-size 2S module, the primary goal was to check the uniformity of the response across all strips. Figure 22 (top) shows the stub efficiency per strip for the full-size 2S module. The module

Figure 20. Stub efficiency for the irradiated (blue) and non-irradiated (red) modules as a function of the beam incident angle. As expected, for larger angles of incidence, which corresponds to smaller effective p_T , the stub efficiency drops. A radius of 60 cm was used for the calculation of p_T from the beam incident angle which is approximately the radius at which the first layer of 2S modules will be installed. The stub correlation window is set to 5 strips.

Figure 21. Stub efficiency comparison of different angular scans with different correlation windows for the irradiated module. The choice of window size leads to a shift in the turn-on p_T , but the efficiency at the plateau remains the same. A bias voltage of 600 V was applied to the irradiated mini-module.

was operated at a bias voltage of 250 V and V_{CTH} was set to 115 DAC units. The analysis techniques used are the same as reported for the mini-modules. The region between strips 185 and 239 has no data because it was not scanned by the beam. The large statistical uncertainty in efficiency at the edges is due to the limited data collected for the scans performed at the module edges. The mean stub efficiency extracted from a linear fit, where the asymmetric errors on each measurement are taken into account, is 97.4%, and the strip-to-strip variation of the stub efficiency was found to be 1.3%. The efficiency is approximately 2% lower than that measured in the 2S mini-module. The difference is due to a different operational configuration of the modules and a possible remaining contamination of events for which the module was not synchronized with the telescope. The stub efficiency per chip is shown in figure 22 (bottom). The results demonstrate that the response of the full-size 2S module is uniform across strips. The stub efficiency as a function of effective p_{T} for the full-size 2S module measured with data collected at the Fermilab test beam facility is shown in figure 23. The correlation window used for stub formation was set to 5 strips. The figure shows that the behaviour of the full-size module is similar to that of the mini-modules. From the fit, a turn-on threshold of 1.2 GeV is obtained with a p_{T} resolution of 7.9%. The turn-on threshold is lower compared to the non-irradiated mini-module since the sensor separation is smaller. The efficiency at the plateau is 99%.

7 Summary

A new silicon strip tracker will be installed in CMS for the HL-LHC period. The new Outer Tracker will comprise novel detector modules with two closely spaced sensors and a new front-end ASIC that is capable of correlating hits between the sensor layers. The performance of 2S prototype modules has been characterized at three test beam facilities. The presence of tracking detectors at these facilities has allowed for spatial matching of the tracks of the incident beam and the hits on the 2S modules. This has provided the first measurements of the absolute efficiency of these prototype detectors.

Cluster efficiencies of approximately 99.5% and 98% have been measured for non-irradiated and irradiated modules, respectively. These results are robust with respect to variations in particle arrival times relative to the trigger. For the non-irradiated module, an increase in the mean cluster width is observed as the beam incident angle increases. For the irradiated module, the average cluster size is higher in general and thus the variation of cluster width with angle is less evident.

The stub efficiency across all the strips of the sensors shows a uniform response. The stub efficiencies of both the non-irradiated mini-module and the full-size module are found to be around 99%. The stub efficiencies obtained from the analysis of data from the three test beam facilities are in agreement with each other. For the irradiated module, the stub efficiency was found to be 97%. All of the modules demonstrate the ability to reject tracks with $p_{\text{T}} < 2$ GeV. The high efficiency of the irradiated module provides evidence that the modules will be able to operate throughout the lifetime of the HL-LHC without much loss of efficiency.

Figure 22. Stub efficiency of a full-size 2S module measured at the CERN beam test facility. The module was operated at a bias voltage of 250V and the V_{CTH} value was set to 115 DAC units. Top: stub efficiency per strip, bottom: stub efficiency per chip computed using data from strips scanned by the beam.

Acknowledgments

The tracker groups gratefully acknowledge financial support from the following funding agencies: BMWFW and FWF (Austria); FNRS and FWO (Belgium); CERN; MSE and CSF (Croatia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); BMBF, DFG, and HGF (Germany); GSRT (Greece); NKfIA K124850, and Bolyai Fellowship of the Hungarian Academy of Sciences (Hungary); DAE and DST (India); IPM (Iran); INFN (Italy); PAEC (Pakistan); SEIDI, CPAN, PCTI and FEDER (Spain); Swiss Funding Agencies (Switzerland); MST (Taipei); STFC (United Kingdom); DOE and NSF (U.S.A.). Individuals have received support from HFRI (Greece).

Figure 23. Stub efficiency of the full-size 2S module as a function of particle p_T measured at the Fermilab beam test facility during the angular scan. The module was operated at a bias voltage of 250 V and the V_{CTH} value was set to 92. A radius of 60 cm is used to convert the beam incident angle to effective p_T .

ARTICLE INFO

ABSTRACT

This document is the final report of the ATLAS-CMS Dark Matter Forum, a forum organized by the ATLAS and CMS collaborations with the participation of experts on theories of Dark Matter, to select a minimal basis set of dark matter simplified models that should support the design of the early LHC Run-2 searches. A prioritized, compact set of benchmark models is proposed, accompanied by studies

Article history:

Keywords:
Dark Matter
Simplified models
EFT
LHC

of the parameter space of these models and a repository of generator implementations. This report also addresses how to apply the Effective Field Theory formalism for collider searches and present the results of such interpretations.

1. Introduction

Dark matter (DM)¹ has not yet been observed in particle physics experiments, and there is not yet any evidence for non-gravitational interactions between DM and the Standard Model (SM) particles. If such interactions exist, particles of DM could be produced at the LHC. Since DM particles themselves do not produce signals in the LHC detectors, one way to observe them is when they are produced in association with a visible SM particle $X(=g, q, \gamma, Z, W, \text{ or } h)$. Such reactions, which are observed at colliders as particles or jets recoiling against an invisible state, are called “mono- X ” or \cancel{E}_T+X reactions (see e.g Refs. [1–5]), where \cancel{E}_T is the missing transverse momentum observable in the detector.

Early Tevatron and LHC Run-1 searches for \cancel{E}_T+X signatures at CDF [6], ATLAS [7–14] and CMS [15–21], employed a basis of contact interaction operators in effective field theories (EFTs) [22,23] to calculate the possible signals. These EFTs assume that production of DM takes place through a contact interaction involving a quark–antiquark pair, or two gluons, and two DM particles. In this case, the missing energy distribution of the signal is determined by the nature and the mass of the DM particles and the Lorentz structure of the interaction. Only the overall production rate is a free parameter to be constrained or measured. Provided that the contact interaction approximation holds, these EFTs provide a straightforward way to compare the results from different collider searches with non-collider searches for DM.

The EFT describes the case when the mediator of the interaction between SM and DM particles are very heavy; if this is not the case, models that explicitly include these mediators are needed [5,22,24,24–28]. Some “simplified models” [29–31] of DM production were constructed, including particles and interactions beyond the SM. These models can be used consistently at LHC energies, and provide an extension to the EFT approach. Many proposals for such models have emerged (see, for example Refs. [32–48]). At the LHC, the kinematics of mono- X reactions occurring via a TeV-scale mediator can differ substantially from the prediction of the contact interaction. The mediator may also produce qualitatively different signals, such as decays back into the SM particles. Thus, appropriate simplified models are an important component of the design, optimization, and interpretation of DM searches at ATLAS and CMS. This has already been recognized in the CDF, ATLAS and CMS searches quoted above, where both EFT and selected simplified model results are presented.

1.1. The ATLAS/CMS dark matter forum

To understand what signal models should be considered for the upcoming LHC Run-2, groups of experimenters from both ATLAS and CMS collaborations have held separate meetings with small groups of theorists, and discussed further at the DM@LHC

workshop [39,40,49]. These discussions identified overlapping sets of simplified models as possible benchmarks for early LHC Run-2 searches. Following the DM@LHC workshop, ATLAS and CMS organized a forum, called the *ATLAS-CMS Dark Matter Forum*, to form a consensus on the use of these simplified models and EFTs for early Run-2 searches with the participation of experts on theories of DM. This is the final report of the ATLAS-CMS Dark Matter Forum.

One of the guiding principles of this report is to channel the efforts of the ATLAS and CMS collaborations towards a minimal basis of dark matter models that should influence the design of the early Run-2 searches. At the same time, a thorough survey of realistic collider signals of DM is a crucial input to the overall design of the search program.

The goal of this report is such a survey, though confined within some broad assumptions and focused on benchmarks for kinematically-distinct signals which are most urgently needed. As far as time and resources have allowed, the assumptions have been carefully motivated by theoretical consensus and comparisons of simulations. But, to achieve such a consensus in only a few months before the start of Run-2, it was important to restrict the scope and timescale to the following:

1. The forum should propose a prioritized, compact set of benchmark simplified models that should be agreed upon by both collaborations for Run-2 searches. The values for the scan on the parameters of the models for which experimental results are provided should be specified, to facilitate theory reinterpretation beyond the necessary model-independent limits that should be provided by all LHC DM searches.
2. The forum should recommend the use of the state of the art calculations for these benchmark models. Such a recommendation will aid the standardization the event generator implementation of the simplified models and the harmonization of other common technical details as far as practical for early Run-2 LHC analyses. It would be desirable to have a common choice of leading order (LO) and next-to-leading order (NLO) matrix elements corresponding to the state of the art calculations, parton shower (PS) matching and merging, factorization and renormalization scales for each of the simplified models. This will also lead to a common set of theory uncertainties, which will facilitate the comparison of results between the two collaborations.
3. The forum should discuss how to apply the EFT formalism and present the results of EFT interpretations.
4. The forum should prepare a report summarizing these items, suitable both as a reference for the internal ATLAS and CMS audiences and as an explanation of early Run-2 LHC benchmark models for theory and non-collider readers. This report represents the views of its endorers, as participants of the forum.

This document constitutes the basis for further recommendations from the LHC Dark Matter Working Group [50–52].

¹ Many theories of physics beyond the Standard Model predict the existence of stable, neutral, weakly-interacting and massive particles that are putative DM candidates. In the following, we refer to such matter as DM, even though the observation of such matter at a collider could only establish that it is neutral, weakly-interactive, massive and stable on the distance-scales of tens of meters.

1.2. Grounding assumptions

We assume that interactions exist between the SM hadrons and the particles that constitute cosmological DM. If this is not the case, then proton collisions will not directly produce DM particles, and DM will not scatter off nuclei in direct detection experiments.

The DM itself is assumed to be a single particle, a Dirac fermion WIMP, stable on collider timescales and non-interacting with the detector. The former assumption is reductionistic. The rich particle content of the SM is circumstantial evidence that the DM sector, which constitutes five times as much of the mass of the universe, may be more complex than a single particle or a single interaction. But, as was often the case in the discoveries of the SM, here only one mediator and one search channel might play a dominant role in the opening stages of an LHC discovery. The latter assumption focuses our work on early LHC searches, where small kinematic differences between models will not matter in a discovery scenario, and with the imminent re-start of the LHC our report relies heavily on a large body of existing theoretical work which assumed Dirac fermionic DM.

Different spins of DM particles will typically give similar results. Exceptions exist: For example, the choice of Majorana fermions forbids some processes that are allowed for Dirac fermions [22]. Aside from these, adjusting the choice of Dirac or Majorana fermions or scalars will produce only minor changes in the kinematic distributions of the visible particle and is expected to have little effect on cut-and-count² analysis. Thus the choice of Dirac fermion DM should be sufficient as benchmarks for the upcoming Run-2 searches.

One advantage of collider experiments lies in their ability to study and possibly characterize the mediator. A discovery of an anomalous \cancel{E}_T signature at the LHC would not uniquely imply discovery of dark matter, while at the same time e.g. discovery of an anomalous and annually-modulated signal in a direct-detection experiment would leave unanswered many questions about the nature of the interaction that could be resolved by the simultaneous discovery of a new mediator particle. Collider, direct, and indirect detection searches provide complementary ways to approach this problem [53], and it is in this spirit that much of our focus is on the mediator.

We systematically explore the basic possibilities for mediators of various possible spins and couplings. All models considered are assumed to produce a signature with pairs of DM particles. Though more varied and interesting possibilities are added to the literature almost daily, these basic building blocks account for much of the physics studied at hadron colliders in the past three decades.

We also assume that Minimal Flavor Violation (MFV) [54–57] applies to the models included in this report. This means that the flavor structure of the couplings between DM and ordinary particles follows the same structure as the SM. This choice is simple, since no additional theory of flavor is required, beyond what is already present in the SM, and it provides a mechanism to ensure that the models do not violate flavor constraints. As a consequence, spin-0 resonances must have couplings to fermions proportional to the SM Higgs couplings. Flavor-safe models can still be constructed beyond the MFV assumption, for example [58], and deserve further study. For a discussion of MFV in the context of the simplified models included in this report, see Ref. [49].

In the parameter scan for the models considered in this report, we make the assumption of a minimal decay width for the particles mediating the interaction between SM and DM. This means that only decays strictly necessary for the self-consistency of the model (e.g. to DM and to quarks) are accounted for in the definition of the mediator width. We forbid any further decays to other invisible particles of the Dark Sector that may increase the width or produce striking, visible signatures. Studies within this report show that, for cut-and-count analyses, the kinematic distributions of many models, and therefore the sensitivity of these searches, do not depend significantly on the mediator width, as long as the width remains smaller than the mass of the particle and that narrow mediators are sufficiently light.

The particle content of the models chosen as benchmarks is limited to one single kind of DM whose self-interactions are not relevant for LHC phenomenology, and to one type of SM/DM interaction at a time. These assumptions only add a limited number of new particles and new interactions to the SM. These simplified models, independently explored by different experimental analyses, can be used as starting points to build more complete theories. Even though this factorized picture does not always lead to full theories and leaves out details that are necessary for the self-consistency of single models (e.g. the mass generation for mediator particles), it is a starting point to prepare a set of distinct but complementary collider searches for DM, as it leads to benchmarks that are easily comparable across channels.

1.3. Choices of benchmarks considered in this report and parameter scans

Contact interaction operators have been outlined as basis set of theoretical building blocks representing possible types of interactions between SM and DM particles in [23]. The approach followed by LHC searches (see e.g. Refs. [7,15] for recent jet+ \cancel{E}_T Run-1 searches with the 8 TeV dataset) so far has been to simulate only a prioritized set of the possible operators with distinct kinematics for the interpretation of the constraints obtained, and provide results that may be reinterpreted in terms of the other operators. This report intends to follow this strategy, firstly focusing on simplified models that allow the exploration of scenarios where the mediating scale is not as large. In the limit of large mediator mass, the simplified models map onto the EFT operators. Secondly, this report considers specific EFT benchmarks whenever neither a simplified model completion nor other simplified models yielding similar kinematic distributions are available and implemented in one of the event generators used by both collaborations. This is the case for dimension-5 or dimension-7 operators with direct DM-electroweak boson couplings.³ Considering these models as separate experimental benchmarks will allow to target new signal regions and help validate the contact interaction limit of new simplified models developed to complete these specific operators. Results from these EFT benchmarks should include the condition that the momentum transfer does not probe the scale of the interaction; whenever there is no model that allows a direct mapping between these two quantities, various options should be tested to ensure a given fraction of events within the range of applicability of the EFT approach. Experimental searches should in any case deliver results that are independent from the specific benchmark tested, such as fiducial cross-sections that are excluded in a given signal region.

When choosing the points to be scanned in the parameter space of the models, this report does not quantitatively consider

² Cut-and-count refers to an analysis that applies a certain event selection and checks the inclusive number of events which pass. This is to be contrasted with a shape analysis, which compares the distribution of events.

³ An example of a dimension-5 operator for scalar DM is described in Appendix A. Dimension-7 operators of DM coupling to gauge bosons exist in the literature, but they require a larger particle spectrum with respect to the models studied in this report.

constraints that are external to the MET+X analyses. This is the case also for results from LHC experiments searching for mediator decays. The main reason for not doing so in this report is the difficulty of incorporating these constraints in a rigorous quantitative way within the timescale of the Forum. However, even if the parameter scans and the searches are not optimized with those constraints in mind, we intend to make all information available to the community to exploit the unique sensitivity of colliders to all possible DM signatures.

1.4. Structure of this report and dissemination of results

The report provides a brief theoretical summary of the models considered, starting from the set of simplified models and contact interactions put forward in previous discussions and in the literature cited above. Its main body documents the studies done within this Forum to identify a kinematically distinct set of model parameters to be simulated and used as benchmarks for early Run-2 searches. The implementation of these studies according to the state of the art calculations is detailed, including instructions on how to estimate theoretical uncertainties in the generators used for these studies. The presentation of results for EFT benchmarks is also covered.

Section 2 of this report is dedicated to simplified models with radiation of a hard object either from the initial state or from the mediator. These models produce primarily monojet signatures, but should be considered for all \cancel{E}_T+X searches. Section 3 contains studies on the benchmark models for final states specifically containing an electroweak boson ($W/Z/\gamma/H$). In this case, both simplified models leading to mono-boson signatures and contact interaction operators are considered. Details of the state of the art calculations and on the implementation of the simplified models in Monte Carlo generators are provided in Section 4. Section 5 is devoted to the treatment of the presentation of results for the benchmark models from contact interaction operators. Section 6 prescribes how to estimate theoretical uncertainties on the simulation of these models. Section 7 concludes the report.

Further models that could be studied beyond early searches and their implementation are described in Appendix A. For these models, either the implementation could not be fully developed by the time of this report, or some of the grounding assumptions were not fully met. Some of these models have been used in previous ATLAS and CMS analyses and discussed thoroughly within the Forum. They are therefore worth considering for further studies and for Run-2 searches, since they lead to unique \cancel{E}_T+X signatures that are not shared by any other of the models included in this report. Appendix B contains the necessary elements that should be included in the results of experimental searches to allow for further reinterpretation.

It is crucial for the success of the work of this Forum that these studies can be employed as cross-check and reference to the theoretical and experimental community interested in early Run-2 searches. For this reason, model files, parameter cards, and cross-sections for the models considered in these studies are publicly available. The Git repository of the Forum [59] contains the models and parameter files necessary to reproduce the studies within this report.

2. Simplified models for all \cancel{E}_T+X analyses

In this Chapter we review models that yield $X+\cancel{E}_T$ signatures, where X is a QCD parton or γ , W , Z or h .

The primary simplified models for Dirac fermion DM studied and recommended by this Forum for early LHC Run-2 searches are detailed in this Chapter, comprising spin-0 and spin-1 mediators.

Fig. 1. Representative Feynman diagram showing the pair production of DM particles in association with a parton from the initial state via a vector or axial-vector mediator. The cross section and kinematics depend upon the mediator and DM masses, and the mediator couplings to DM and quarks respectively: $(M_{\text{med}}, m_\chi, g_\chi, g_q)$.

Section 2.1 covers the s -channel exchange of a vector mediator,⁴ while we consider both s -channel and t -channel exchange for scalar mediators in Sections 2.2 and 2.3 respectively. Spin-2 mediators are briefly mentioned in Section 2.4. While these models are general and cover a broad set of signatures, the discussion and studies are focused on the monojet final state. Details on final states with electroweak (EW) boson radiation and with heavy flavor quarks from diagrams arising within these models are also discussed in this Chapter.

A summary of the state of the art calculations and implementations for these models is provided in Table 9. Section 4 details the implementation of these models that have been used for the studies in this Chapter and that will be employed for the simulation of early Run-2 benchmark models for LHC DM searches.

2.1. Vector and axial vector mediator, s -channel exchange

A simple extension of the SM is an additional $U(1)$ gauge symmetry, where a DM candidate particle has charges only under this new group. Assuming that some SM particles are also charged under this group, a new gauge boson can mediate interactions between the SM and DM.

We consider the case of a DM particle χ of mass m_χ that is a Dirac fermion and where the production proceeds via the exchange of a spin-1 mediator of mass M_{med} in the s -channel, illustrated in Fig. 1.

We consider two models with vector and axial-vector couplings between the spin-1 mediator Z' and SM and DM fields, with the corresponding interaction Lagrangians:

$$\mathcal{L}_{\text{vector}} = g_q \sum_{q=u,d,s,c,b,t} Z'_\mu \bar{q} \gamma^\mu q + g_\chi Z'_\mu \bar{\chi} \gamma^\mu \chi \quad (1)$$

$$\mathcal{L}_{\text{axial-vector}} = g_q \sum_{q=u,d,s,c,b,t} Z'_\mu \bar{q} \gamma^\mu \gamma^5 q + g_\chi Z'_\mu \bar{\chi} \gamma^\mu \gamma^5 \chi. \quad (2)$$

The coupling g_q is assumed to be universal to all quarks. It is also possible to consider other models in which mixed vector and axial-vector couplings are considered, for instance the couplings to the quarks are axial-vector whereas those to DM are vector.

⁴ Colored vector mediators can be exchanged in the t -channel, but there are no examples in literature as of this report.

As mentioned in the Introduction, when no additional visible or invisible decays contribute to the width of the mediator, the minimal width is fixed by the choices of couplings g_q and g_χ . The effect of larger widths is discussed in Section 2.5.2. For the vector and axial-vector models, the minimal width is:

$$\Gamma_{\min}^V = \frac{g_\chi^2 M_{\text{med}}}{12\pi} \left(1 + \frac{2m_\chi^2}{M_{\text{med}}^2}\right) \beta_{DM} \theta(M_{\text{med}} - 2m_\chi) \quad (3)$$

$$+ \sum_q \frac{3g_q^2 M_{\text{med}}}{12\pi} \left(1 + \frac{2m_q^2}{M_{\text{med}}^2}\right) \beta_q \theta(M_{\text{med}} - 2m_q),$$

$$\Gamma_{\min}^A = \frac{g_\chi^2 M_{\text{med}}}{12\pi} \beta_{DM}^3 \theta(M_{\text{med}} - 2m_\chi) \quad (4)$$

$$+ \sum_q \frac{3g_q^2 M_{\text{med}}}{12\pi} \beta_q^3 \theta(M_{\text{med}} - 2m_q).$$

$\theta(x)$ denotes the Heaviside step function, and $\beta_f = \sqrt{1 - \frac{4m_f^2}{M_{\text{med}}^2}}$ is the velocity of the fermion f with mass m_f in the mediator rest frame. Note the color factor 3 in the quark terms. Fig. 2 shows the minimal width as a function of mediator mass for both vector and axial-vector mediators assuming the coupling choice $g_q = g_\chi = 1$. With this choice of the couplings, the dominant contribution to the minimal width comes from the quarks, due to the combined quark number and color factor enhancement. We specifically assume that the vector mediator does not couple to leptons. If such a coupling were present, it would have a minor effect in increasing the mediator width, but it would also bring in constraints from measurements of the Drell–Yan process that would unnecessarily restrict the model space.

Therefore, the minimal set of parameters under consideration for these two models is

$$\{g_q, g_\chi, m_\chi, M_{\text{med}}\} \quad (5)$$

together with the spin structure of their couplings.

A thorough discussion of these models and their parameters can also be found in [60].

These simplified models are known and available in event generators at NLO + PS accuracy, as detailed in Section 4.1.1. Results in this Section have been obtained using the model implementation within the POWHEG generator (v3359) [61], interfaced to PYTHIA 8 [62] for the parton shower.

In addition, for the vector models considered, initial and final state radiation of a Z' can occur which can appear as a narrow jet if it decays hadronically and may not be distinguishable from a QCD jet, thus accounting for some fraction of the monojet signal. The ISR and FSR of Z' becomes more important at large values of the couplings [63].

2.1.1. Parameter scan

In order to determine an optimal choice of the parameter grid for the simulation of early Run-2 benchmark models, dependencies of the kinematic quantities and cross sections on the model parameters have been studied. Only points that are kinematically distinct will be fully simulated, while instructions on how to rescale the results according to models with different cross sections are presented in Section 2.5. The following paragraphs list the main observations from the scans over the parameters that support the final proposal for the benchmark signal grid.

Scan over the couplings. To study the dependence of kinematic distributions on the coupling strength, samples were generated where a pair of $m_\chi = 10$ GeV DM particles is produced on-shell from the mediator of $M_{\text{med}} = 1$ TeV. Fig. 3 compares the shapes of the \not{E}_T distribution for the different choices of the coupling

Fig. 2. Minimal width as a function of mediator mass for vector and axial-vector mediator assuming couplings of 1. The total width is shown as solid lines for DM masses of 10 GeV, 30 GeV, 100 GeV and 300 GeV in black, red, brown and green, respectively. The individual contributions from DM are indicated by dotted lines with the same colors. The contribution from all quarks but top is shown as magenta dotted line and the contribution from top quarks only is illustrated by the dotted blue line. The dotted black line shows the extreme case $\Gamma_{\min} = M_{\text{med}}$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

strength. This is a generator-level prediction with no kinematic selections or detector simulation. Coupling values in the scan range 0.1–1.45, fixing $g_q = g_\chi$, correspond to a rough estimate of the lower sensitivity of mono-jet analyses and a maximum coupling value such that $\Gamma_{\min} < M_{\text{med}}$. We observe that the shapes of the \not{E}_T or jet p_T distributions do not depend on the couplings (and consequently the width) in the ranges considered. A large width of the mediator implies a broad integral over the contributing parton distributions, which might not be well approximated by the midpoint of this integral. This study shows that the effect, in the p_T distribution of the observed gluon, is not important.

Based on similar findings for different choices of M_{med} and m_χ , we conclude that the shapes of kinematic distributions are not altered by coupling variations, neither for the on-shell mediator

Fig. 3. Scan over couplings. The \tilde{E}_T distribution is compared for the vector mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $\tilde{E}_T > 300$ GeV and $\tilde{E}_T > 500$ GeV cut, respectively. All figures in this Section have been obtained using the model implementation within the POWHEG generator (v3359) [61], interfaced to PYTHIA 8 [62] for the parton shower.

Fig. 4. Comparison of the \tilde{E}_T distributions from the D5 EFT sample and the vector models with 5 TeV heavy mediator of various widths. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $\tilde{E}_T > 300$ GeV and $\tilde{E}_T > 500$ GeV cut, respectively.

case where $M_{\text{med}} > 2m_\chi$, nor for the off-shell case where $M_{\text{med}} < 2m_\chi$. Only the production cross sections change. Differences in kinematic distributions are expected only close to the transition region between on-shell and off-shell mediators.

Special care needs to be taken when coupling strengths are combined with extremely heavy mediators. Fig. 4 suggests a change in the shape of the \tilde{E}_T distribution for a $M_{\text{med}} = 5$ TeV mediator once $\Gamma_{\text{min}}/M_{\text{med}}$ is of the order of a percent or lower.

Such heavy mediators, although inaccessible with early LHC data, are interesting since they provide a good approximation for benchmark EFT models. The observed difference among the simplified models in the plot arises from the fact that the region of low invariant masses of the DM pair, $m_{\tilde{\chi}\chi}$, is suppressed due to narrow Breit–Wigner peak that only probes a narrow window of parton distribution functions. For wider mediators, the low mass region is significantly enhanced by parton distribution functions at low Bjorken x , as illustrated in Fig. 5(a). This explains why the sample with the narrowest mediator in Fig. 4 is heavily suppressed in terms of production cross section and also gives different \tilde{E}_T shape. Furthermore, Fig. 4 compares the vector model with 5 TeV mediator to the D5 EFT sample and reveals that the simplified models with larger mediator widths (e.g. for couplings of 1 where $\Gamma_{\text{min}}/M_{\text{med}} \sim 0.5$) are the ones resembling the kinematics of contact interactions. This reflects the fact that in an EFT there is no enhancement due to on-shell mediators, leading to a closer resemblance to an off-shell regime where no peak in the $m_{\tilde{\chi}\chi}$ distribution is present. In case of narrow width mediators, e.g. $\Gamma_{\text{min}}/M_{\text{med}} \sim 0.05$, even larger mediator masses need to be chosen in order to significantly suppress the peak in the $m_{\tilde{\chi}\chi}$

distribution and reproduce the kinematic shapes of an EFT model. Fig. 5(b) verifies that the choice of 10 TeV mediator mass is sufficient to achieve that.

Since kinematic distributions are robust to changes in the specific values of coupling,⁵ the choice of $g_q = 0.25$ and $g_\chi = 1$ is reasonable to reduce the parameter space to be scanned. There are no complications associated with small couplings, but, also, the early part of Run 2 will not be sensitive to them. The range of couplings we recommend to generate limit the calculated width of the mediator to be near or below M_{med} .

For direct mediator searches, such as $q\bar{q} \rightarrow Z' \rightarrow q\bar{q}$, different couplings ($g_q \neq g_\chi$) might also be considered. A scan in g_χ vs. g_q can then be performed for a fixed mediator mass. Such searches may restrict g_q to a greater degree than g_χ .

Scan over m_χ . For a fixed mediator mass M_{med} and couplings, the DM mass falls into three regimes:

On-shell: When $M_{\text{med}} \gg 2m_\chi$, most mediators are on-shell.

The hardness of the ISR is set by M_{med} , and the kinematic distributions do not strongly depend on m_χ . This is illustrated in Fig. 6 for an example of $M_{\text{med}} = 1$ TeV, $10 \text{ GeV} < m_\chi < 300 \text{ GeV}$. The cross section decreases as the m_χ approaches $M_{\text{med}}/2$. A coarse binning along m_χ is sufficient.

⁵ This applies as long as heavy narrow mediators are generated without any truncation of low-mass tails at the generator-level.

Fig. 5. Invariant mass of the DM pair in the vector mediator samples with $m_\chi = 10$ GeV, $M_{\text{med}} = 5$ TeV and different coupling strengths (a). A similar comparison is shown for the samples with different mediator masses considering $\Gamma_{\text{min}}/M_{\text{med}} = 0.05$ and 0.1 (b). An EFT sample is also displayed in the latter case. The distributions are normalized to unit area.

Threshold: When $M_{\text{med}} \approx 2m_\chi$, the production is resonantly enhanced, and both the cross section and kinematic distributions change more rapidly as a function of the two masses, and finer binning is needed in order to capture the changes.

Off-shell: When $M_{\text{med}} \ll 2m_\chi$, the DM pair is produced by an off-shell mediator. The mediator propagator gives an explicit suppression of $(M_{\text{med}}/Q)^2$ that suppresses hard ISR. The $m_\chi = 1$ TeV case, shown in Figs. 6 and 7 demonstrates that the \cancel{E}_T spectrum hardens with increasing m_χ , accompanied by the gradual decrease of the cross section. Due to the significant cross section suppression, it is not necessary to fully populate the parameter space. Imminent LHC searches are not expected to be sensitive to these signals.

Scan over the mediator mass. Changing the mediator mass for fixed DM mass and couplings leads to significant differences in cross section and shapes of the kinematic variables for the on-shell regime, as shown in Fig. 8. As expected, higher mediator masses lead to harder \cancel{E}_T spectra. On the other hand, the \cancel{E}_T shapes are similar for off-shell mediators. This is illustrated in Fig. 9. Therefore, a coarse binning in M_{med} is sufficient in the off-shell regime.

Spin structure of the couplings. This section compares the kinematic properties of vector, axial-vector and mixed vector/axial-vector models. The samples with pure vector and pure axial-vector couplings are compared for $M_{\text{med}} = 100$ GeV and different DM masses in Fig. 10. No differences in the shape of the \cancel{E}_T distributions are observed between the samples with coincident masses. In the case of the on-shell mediators, where $2m_\chi \ll M_{\text{med}}$, the cross sections of the pure vector and pure axial-vector models are similar. With increasing DM mass towards the $2m_\chi = M_{\text{med}}$ transition and further into the off-shell regime, the relative difference between the cross sections of the two samples is increasing, with the vector ones having larger cross sections.

Fig. 11 shows the samples generated with pure and mixed couplings for $m_\chi = 100$ GeV and $M_{\text{med}} = 1$ TeV, i.e. where the mediator is on-shell. The mediator width between the pure vector and pure axial-vector couplings differ only by 2% in this case, and $<10\%$ agreement between the cross sections is found. The mediator widths for the samples with the same type coupling to quarks agree at better than 1% since the width is dominated by the quark contribution, as expected from Eq. (3). No significant differences between the samples with same type DM coupling are seen, given the statistical precision of the generated samples. This is expected since the mediator is on-shell, and the details of the invisible decay are unimportant in cut-and-count searches.

For the off-shell case, shown in Fig. 12 for $m_\chi = 100$ GeV and $M_{\text{med}} = 100$ GeV, there is approximately a factor 2 difference between the cross-sections of the samples with pure couplings is observed. As in the previous case, the samples with the same type coupling to DM are similar both in terms of cross sections and \cancel{E}_T shape. Since the contribution to the mediator width from DM is closed in this case, only the quark couplings define the width. Only couplings to light quarks are opened in the case of $M_{\text{med}} = 100$ GeV for which the differences between the partial widths of vector and axial-vector couplings are marginal. This explains the similar minimal widths for all four samples stated in Fig. 12.

In general, the coupling to quarks is not expected to play an important role in the kinematics as it is only needed to produce the mediator which is confirmed by the observations above. Based on this argument and on the observations above, we recommend to consider only the models with pure vector couplings or pure axial-vector couplings for simulation.

Proposed parameter grid. The final step in proposing a parameter grid is to evaluate the sensitivity of Run-2 LHC data with respect to rate and/or kinematics. The parameter scan focuses on two important regions, the light mediator region and the heavy mediator limit to reproduce the EFT limit, and takes into account the projected sensitivities for the mono-jet analysis.

Considering simplified models also allows to discuss constraints from different search channels. In the case of the s-channel exchange, the results from the mono-jet final states, where the mediator decays to a DM pair, one can also take into account dijet constraints on the processes where the mediator decays back to the SM particles. The importance of the dijet results depend on the magnitude of the coupling g_q . We recommend to keep the two channels rather independently by choosing $g_q = 0.25$ and $g_\chi = 1$, based on the findings given in Ref. [64]. Furthermore, it is also important to mention this choice leads to $\Gamma_{\text{min}}/M_{\text{med}} \lesssim 0.06$. Note that the usual choice of $g_q = g_\chi = 1$ used in literature leads to $\Gamma_{\text{min}}/M_{\text{med}} \sim 0.5$, questioning the applicability of the narrow width approximation.

The expected upper limit at 95% confidence level on the product of cross section, acceptance and efficiency, $\sigma \times A \times \epsilon$, in the final Run-1 ATLAS mono-jet analysis [7] is 51 fb and 7.2 fb for $\cancel{E}_T > 300$ GeV and $\cancel{E}_T > 500$ GeV, respectively. Projected sensitivities for a 14 TeV mono-jet analysis are available from

Fig. 6. Scan over DM mass. The E_T distribution is compared for the vector mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively.

Fig. 7. Scan over DM mass. The E_T distribution is compared for the vector mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively.

Fig. 8. Scan over mediator mass. The E_T distribution is compared for the vector mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively.

ATLAS [14]. These ATLAS studies estimate a factor of two increase in sensitivity with the 2015 data. The generator level cross section times efficiency times acceptance at $E_T > 500$ GeV for the model with couplings $g_q = 0.25$ and $g_\chi = 1$, a light DM particle of $m_\chi = 10$ GeV and a $M_{\text{med}} = 1$ TeV vector mediator is at the order of 100fb, i.e. the early Run-2 mono-jet analysis is going to be sensitive to heavier mediators than this. The value of $\sigma \times \epsilon \times A$ at $E_T > 500$ GeV for a 5 TeV vector mediator is at the order of 0.1fb, therefore this model lies beyond the reach of the LHC in the early Run-2. However, models with high enough mediators are still useful to reproduce the EFT result.

Following these arguments, M_{med} grid points are chosen, roughly equidistant in a logarithmic scale: 10 GeV, 20 GeV, 50 GeV, 100 GeV, 200 GeV, 300 GeV, 500 GeV, 1000 GeV and 2000 GeV. In the threshold regime $M_{\text{med}} = 2m_\chi$, the m_χ grid points are taken at approximately $M_{\text{med}}/2$, namely: 10 GeV, 50 GeV, 150 GeV, 500 GeV and 1000 GeV. Points on the on-shell diagonal are always chosen to be 5 GeV away from the threshold, to avoid numerical instabilities in the event generation. The detailed studies of the impact of the parameter changes on the cross section and kinematic distributions presented earlier in this section support removing some of the grid points and relying on interpolation. The optimized grids proposed for the vector and

Fig. 9. Scan over mediator mass. The \vec{E}_T distribution is compared for the vector mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $\vec{E}_T > 300$ GeV and $\vec{E}_T > 500$ GeV cut, respectively.

Fig. 10. Comparison of the pure vector and pure axial-vector couplings. The \vec{E}_T distribution is shown for the samples generated with $M_{\text{med}} = 100$ GeV and different DM masses. Ratios of the normalized distributions are shown for between the samples with coincident masses. A_{300} and A_{500} in the table denote the acceptance of the $\vec{E}_T > 300$ GeV and $\vec{E}_T > 500$ GeV cut, respectively.

Fig. 11. Comparison of the pure vector, V-V, and pure axial-vector, A-A, couplings with mixed couplings, A-V and V-A where the first (second) letter indicates the SM (dark sector) vertex. The \vec{E}_T distribution is shown for the samples generated with $m_\chi = 100$ GeV and $M_{\text{med}} = 1$ TeV. Ratios of the normalized distributions are shown for A-V over V-V and for V-A over A-A. A_{300} and A_{500} in the table denote the acceptance of the $\vec{E}_T > 300$ GeV and $\vec{E}_T > 500$ GeV cut, respectively.

axial-vector mediators are given in Table 1. One point at very high mediator mass (10 TeV) is added for each of the DM masses scanned, to aid the reinterpretation of results in terms of contact interaction operators (EFTs), as discussed in Section 5.2.

Tables 2 and 3 give the $\Gamma_{\text{min}}/M_{\text{med}}$ ratio for the parameter grid proposed for vector and axial-vector s -channel models, respectively. The numbers range from ~ 0.02 in the off-shell regime at $2m_\chi > M_{\text{med}}$ to ~ 0.06 in the on-shell regime for heavy mediators where all coupling channels contribute.

2.1.2. Additional considerations for $V + \vec{E}_T$ signatures

All models detailed in this Section are applicable to signatures where a photon, a W boson, a Z boson or a Higgs boson is radiated from the initial state partons instead of a gluon. The experimental signature is identified as $V + \vec{E}_T$ and it has been sought by ATLAS and CMS in Refs. [8–11, 16, 17]. This signature is also produced by the models described in Section 3.

Monojet searches are generally more sensitive with respect to final states including EW bosons, due to the much larger rates of signal events featuring quark or gluon radiation with respect to

Fig. 12. Comparison of the pure vector, V-V, and pure axial-vector, A-A, couplings with mixed couplings, A-V and V-A where the first (second) letter indicates the SM (dark sector) vertex. The E_T distribution is shown for the samples generated with $m_\chi = 100$ GeV and $M_{\text{med}} = 100$ GeV. Ratios of the normalized distributions are shown for A-V over V-V and for V-A over A-A. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively. The suppression by β^3 for $m_\chi \sim M_{\text{med}}$ can be seen for the curves representing axial DM coupling.

Table 1

1000	10							1000	1995	10 000

radiation of bosons [65], in combination with the low branching ratios if leptons from boson decays are required in the final state. The rates for the Higgs boson radiation is too low for these models to be considered a viable benchmark [48]. However, the presence of photons, leptons from W and Z decays, and W or Z bosons decaying hadronically allow backgrounds to be rejected more effectively, making $Z/\gamma/W+\cancel{E}_T$ searches still worth comparing with searches in the jet+ \cancel{E}_T final state (see e.g. Ref. [66]).

In the case of a spin-1 mediator, an example Feynman diagram for these processes can be constructed by taking Fig. 1 and replacing the gluon with γ , W or Z.

When the initial state radiation is a W boson, Run-1 searches have considered three benchmark cases, varying the relative coupling of the W to u and d quarks. The simplified model with a vector mediator exchanged in the s -channel includes only the simplest of these cases, in which the W coupling to u and d quarks is identical, as required naively by SU(2) gauge invariance. With some more complex model building, other cases are possible. The case in which the u and d couplings have opposite sign is particularly interesting, since this enhances the $W+\cancel{E}_T$ signal over the jet+ \cancel{E}_T signal [44,67,68]. An example of a model of this type is discussed in Appendix A.4.

Simulations for the models in this Section have been done at the LO+PS level using MADGRAPH5_AMC@NLO 2.2.3 interfaced to PYTHIA 8, and therefore no special runtime configuration is needed for pythia 8. Even though merging samples with different parton multiplicities is possible, this has not been deemed necessary as the visible signal comes from the production of a heavy SM boson whose transverse momentum distribution is sufficiently well described at LO+PS level.

In these $V+\cancel{E}_T$ models, as in the case of the jet+ \cancel{E}_T models, p_T of the boson or the \cancel{E}_T does not depend strongly on the width of the mediator. An example of the particle-level analysis acceptance using the generator-level cuts from Ref. [8] for the

photon+ \cancel{E}_T analysis, but raising the photon p_T cut to 150 GeV, is shown in Table 4, comparing a width that is set to $\Gamma = M_{\text{med}}/3$ to the minimal width (the ratio between the two widths ranges from 1.05 to 1.5 with increasing mediator masses).

Examples of relevant kinematic distributions for selected benchmark points are shown in Fig. 13.

2.2. Scalar and pseudoscalar mediator, s -channel exchange

In this section, we consider a parallel situation to the vector and axial-vector mediators in the previous sections: a real scalar or a pseudoscalar where the associated scalar is decoupled at higher energies.⁶ This section is largely based on Refs. [41–43] which contain a thorough discussion of these models.

Assuming MFV, spin-0 resonances behave in a similar fashion as the SM Higgs boson. If the mediators are pure singlets of the SM, their interactions with quarks are not $SU(2)_L$ invariant. To restore this invariance, one could include the mixing of such mediators with the Higgs sector. This leads to extra interactions and a more complex phenomenology with respect to what considered in this Section (for a more complete discussion, see Refs. [42,43]). In the interest of simplicity, we do not study models including those interactions in this report as early Run-2 benchmark models, but we give an example of a model of this kind in Appendix A.6.

Relative to the vector and axial-vector models discussed above, the scalar models are distinguished by the special consequences of the MFV assumption: the very narrow width of the mediator and its extreme sensitivity to which decays are kinematically available, and the loop-induced coupling to gluons. The interaction Lagrangians are

$$\mathcal{L}_\phi = g_\chi \phi \bar{\chi} \chi + \frac{\phi}{\sqrt{2}} \sum_i (g_u y_i^u \bar{u}_i u_i + g_d y_i^d \bar{d}_i d_i + g_\ell y_i^\ell \bar{\ell}_i \ell_i), \quad (6)$$

$$\mathcal{L}_a = i g_\chi a \bar{\chi} \gamma_5 \chi + \frac{ia}{\sqrt{2}} \sum_i (g_u y_i^u \bar{u}_i \gamma_5 u_i + g_d y_i^d \bar{d}_i \gamma_5 d_i + g_\ell y_i^\ell \bar{\ell}_i \gamma_5 \ell_i) \quad (7)$$

where ϕ and a are respectively the scalar and pseudoscalar mediators, and the Yukawa couplings y_i^f are normalized to the Higgs vev as $y_i^f = \sqrt{2} m_i^f / v$.

The couplings to fermions are proportional to the SM Higgs couplings, yet one is still allowed to adjust an overall strength of the coupling to charged leptons and the relative couplings of u - and d -type quarks. As in the preceding sections, for the

⁶ This assumption does not hold in a UV-complete model where the two components of the complex scalar mediator would be approximately degenerate. The complex scalar case could be studied separately in the case of heavy flavor final states given the sufficiently different kinematics.

sake of simplicity and straightforward comparison, we reduce the couplings to the SM fermions to a single universal parameter $g_q \equiv g_u = g_d = g_\ell$. Unlike the vector and axial-vector models, the scalar mediators are allowed to couple to leptons.⁷

The relative discovery and exclusion power of each search can be compared in this framework. However, we again emphasize the importance of searching the full set of allowed channels in case violations of these simplifying assumptions lead to significant modifications of the decay rates that unexpectedly favor different channels than the mix obtained under our assumptions. The coupling g_χ parametrizes the entire dependence on the structure between the mediator and the dark sector.

Given these simplifications, the minimal set of parameters under consideration is

$$\{m_\chi, m_{\phi/a} = M_{\text{med}}, g_\chi, g_q\}. \quad (8)$$

Fig. 14 shows the one-loop diagrams producing a jet+X signature. The full calculation of the top loop is available at LO for DM pair production in association with one parton.

The minimal mediator width (neglecting the small contributions from quarks other than top in the loop) is given by

$$\Gamma_{\phi,a} = \sum_f N_c \frac{y_f^2 g_q^2 m_{\phi,a}}{16\pi} \left(1 - \frac{4m_f^2}{m_{\phi,a}^2}\right)^{x/2} + \frac{g_\chi^2 m_{\phi,a}}{8\pi} \left(1 - \frac{4m_\chi^2}{m_{\phi,a}^2}\right)^{x/2} + \frac{\alpha_s^2 g_q^2 m_{\phi,a}^3}{32\pi^3 v^2} \left| f_{\phi,a} \left(\frac{4m_t^2}{m_{\phi,a}^2}\right) \right|^2 \quad (9)$$

where $x = 3$ for scalars and $x = 1$ for pseudoscalars. The loop integrals, with f as complex functions, are

$$f_\phi(\tau) = \tau \left[1 + (1 - \tau) \arctan^2 \left(\frac{1}{\sqrt{\tau - 1}} \right) \right], \quad (10)$$

$$f_a(\tau) = \tau \arctan^2 \left(\frac{1}{\sqrt{\tau - 1}} \right) \quad (11)$$

where $\tau = 4m_t^2 / m_{\phi,a}^2$.

The minimal widths for scalar and pseudo-scalar mediators with $g_q = g_\chi = 1$ are shown in Fig. 20, illustrating the effect of choosing the SM Higgs-like Yukawa couplings for the SM fermions. For the mediator mass above twice the top quark mass m_t , the minimal width receives the dominant contribution from the top quark. For lighter mediator masses, DM dominates as the couplings to lighter quarks are Yukawa suppressed.

As shown in the diagram of Fig. 14, the lowest order process of these models already involves a one-loop amplitude in QCD, and only LO predictions are currently available. The generator used for the studies for the jet+ \cancel{E}_T signature is POWHEG [43,61,69–71], with PYTHIA 8 [62] for the parton shower; within this implementation, the scalar and pseudoscalar mediator benchmark models are known at LO+PS accuracy.

2.2.1. Parameter scan

Similarly as in the case of the vector and axial-vector couplings of spin-1 mediators, scans in the parameter space are performed also for the scalar and pseudo-scalar couplings of the spin-0 mediators in order to decide on the optimized parameter grid for the presentation of Run-2 results. Figs. 15–19 show the scans

⁷ This contribution plays no role for most of the parameter space considered. The choice to allow lepton couplings follows Refs. [41,42].

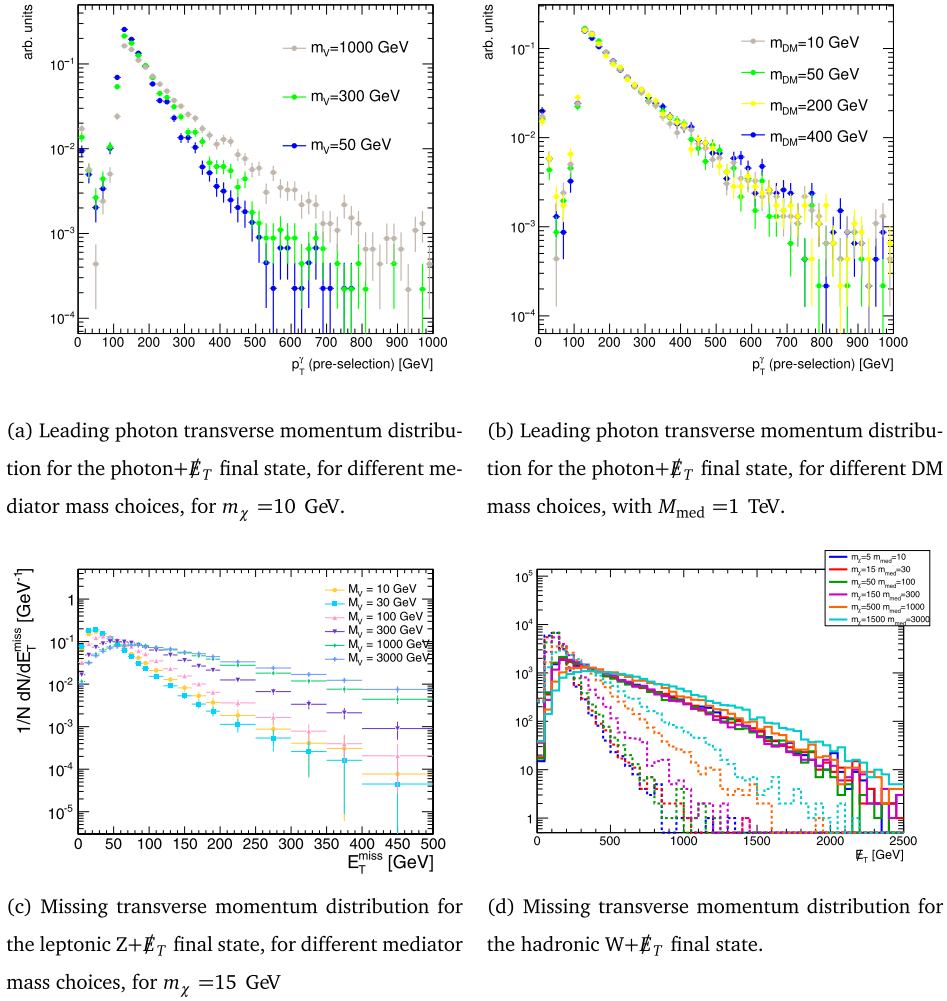

Fig. 13. Kinematic distributions relevant for searches with W, Z and photons in the final state, for the simplified model with a vector mediator exchanged in the s-channel.

Fig. 14. One-loop diagrams of processes exchanging a scalar (S) or pseudoscalar (P) mediator, leading to a mono-jet signature.

over the couplings, DM mass and mediator mass and the same conclusions apply as in Section 2.1.

A scan over the mediator mass is shown in Fig. 19 where $M_{\text{med}} = 300$ GeV and 500 GeV are chosen to be below and above $2m_t$. The off-shell case is assumed by taking an extreme limit ($m_\chi = 1$ TeV) in order to study solely the effects of the couplings to quarks. No differences in the kinematic distributions are observed and also the cross sections remain similar in this

case. No significant changes appear for mediator masses around the $2m_t$ threshold.

It can be seen in Fig. 21 that the kinematics for the scalar and pseudoscalar models coincides when considering the diagrams in Fig. 14. For this reason, we recommend to fully simulate only one of the two models. No preference is given between the two models as they have the same kinematics, although it is worth noting that the pseudo-scalar model has been used for a DM interpretation of the DAMA signal and of the galactic center

Fig. 15. Scan over couplings. The E_T distribution is compared for the scalar mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively. Studies in all figures for the jet+ E_T signature is POWHEG, with PYTHIA 8 for the parton shower.

Fig. 16. Scan over DM mass. The E_T distribution is compared for the scalar mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively.

Fig. 17. Scan over DM mass. The E_T distribution is compared for the scalar mediator models using the parameters as indicated. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $E_T > 300$ GeV and $E_T > 500$ GeV cut, respectively.

excess [72]. Like in the case of the vector and axial-vector models described in , the differences between the cross sections for the scalar and pseudo-scalar samples with the same m_χ and M_{med} are increasing with the DM mass for fixed mediator mass, with the pseudo-scalar model yielding larger cross sections. There is an increasing difference between the minimal widths close to the $2m_\chi = M_{med}$ threshold.

Proposed parameter grid. The optimized parameter grid in the $M_{med}-m_\chi$ plane for scalar and pseudo-scalar mediators is motivated by similar arguments as in the previous section. Therefore,

a similar pattern is followed here, with the exception of taking $g_q = g_\chi = 1$. The choice of $g_q = 0.25$ for the vector and axial-vector models is motivated by suppressing constraints from di-jets, which is not a concern in the scalar and pseudo-scalar mediator case. Here a di-jet signal emerges only at the 2-loop level through diagrams where the mediator is produced via gluon-gluon fusion and decays back into two gluons through a top loop. The strong loop suppression renders such signals unobservable at the LHC. Further constraints on the scalar and pseudo-scalar mediators may emerge from searches in $t\bar{t}$ final states. Studies

of the electroweak effects to $t\bar{t}$ production suggest that one can only expect percent level contributions for $g_q \sim O(1)$ [73]. Therefore, keeping $g_q = g_\chi = 1$ is a reasonable choice in the case of the scalar and pseudo-scalar mediators. Contrary to the vector and axial-vector models, note that couplings of 1 lead to $\Gamma_{\text{min}}/M_{\text{med}} \lesssim 0.1$, ensuring the narrow width approximation is applicable. Furthermore, the sensitivity to the highest mediator masses has to be re-evaluated. The generator level cross section times the acceptance at $\cancel{E}_T > 500$ GeV for the model with couplings $g_q = g_\chi = 1$, light DM of $m_\chi = 10$ GeV and a $M_{\text{med}} = 500$ GeV scalar mediator is at the order of 10 fb, i.e. just at the edge of the early Run-2 sensitivity. Increasing the mediator mass to 1 TeV pushes the product $\sigma \times A$ down to approximately 0.1 fb, below the LHC sensitivity. Therefore, we choose to remove the 2 TeV mediator mass from the grid and present the final grid with 33 mass points only, as shown in Table 5. One point at very high mediator mass (10 TeV) is added for each of the DM masses scanned, to aid the reinterpretation of results in terms of contact interaction operators (EFTs).

For the parameter grid for scalar and pseudo-scalar mediator s-channel exchange, the $\Gamma_{\text{min}}/M_{\text{med}}$ ratio is given in Tables 6 and 7, respectively. In the on-shell regime, the ratio is between 0.04 and 0.1. Very narrow resonances with $\Gamma_{\text{min}}/M_{\text{med}} < 0.001$ correspond to the mass points where the mediator is off-shell. Note that the loop-induced contribution from gluons is ignored in the width calculation.

2.2.2. Additional considerations for $V + \cancel{E}_T$ signatures

The discussion of parameters for the model with a color-singlet, spin-0 mediator parallels that in Section 2.

Table 5

Simplified model benchmarks for s-channel simplified models (spin-0 mediators decaying to Dirac DM fermions in the scalar and pseudoscalar case, taking the minimum width for $g_q = 1$ and $g_\chi = 1$).

m_χ (GeV)	M_{med} (GeV)								
1	10	20	50	100	200	300	500	1000	10000
10	10	15	50	100					10000
50	10		50	95	200	300			10000
150	10				200	295	500	1000	10000
500	10						500	995	10000
1000	10							1000	10000

Even though the sensitivity of mono-boson searches to this model is low and it may not be in reach of early LHC searches, this model can be generated for W, Z and photon searches in order to reproduce the kinematics of contact interaction operators that are further described in Section 3.2.1, to aid later reinterpretation.

Other models of DM that couple dominantly to electroweak gauge bosons through either pseudo-scalar or vector mediators can be found in Ref. [74].

2.2.3. Additional considerations for $t\bar{t}$ and $b\bar{b} + \cancel{E}_T$ signatures

With the MFV assumption, the top and bottom quark can play an important role in the phenomenology. The scalar and pseudo-scalar mediator models predict not only the monojet process described in Section 2.2, but also production of Dark Matter in association with top (or bottom) pairs, as illustrated in Fig. 22. Dedicated searches including jets from heavy flavor quarks in the final state can be designed for this signature. Another class of

Fig. 20. Minimal width as a function of mediator mass for scalar and pseudo-scalar mediator assuming couplings of 1. The total width is shown as solid lines for DM masses of $m_\chi = 10$ GeV, 30 GeV, 100 GeV and 300 GeV in black, red, brown and green, respectively. The individual contributions from DM are indicated by dotted lines with the same colors. The contribution from all quarks but top is shown as magenta dotted line and the contribution from top quarks only is illustrated by the dotted blue line. The dotted beige line shows the contribution from the coupling to gluons. The dotted black line shows the extreme case $\Gamma_{\min} = M_{\text{med}}$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

simplified models, which includes a Dark Matter interpretation among many others, and yields a single top quark in the final state, is detailed in [Appendix A.1](#).

In addition to the $t\bar{t}$ +DM models illustrated in [Fig. 22](#), some theoretically motivated scenario (e.g. for high $\tan\beta$ in 2HDM in the pMSSM) privilege the coupling of spin-0 mediators to down generation quarks. This assumption motivates the study of final states involving b -quarks as a complementary search to the $t\bar{t}$ +DM models, to directly probe the b -quark coupling. An example of such a model can be found in Ref. [\[42\]](#) and can be obtained by replacing top quarks with b quarks in [Fig. 22](#). Note that, because of the kinematics features of b quark production relative to heavy t quark production, a $b\bar{b}$ +DM final state may only yield one experimentally visible b quark, leading to a mono- b signature in a model that conserves b flavor.

Dedicated implementations of these models for the work of this Forum are available at LO+PS accuracy, even though the state of the art is set to improve on a timescale beyond that for early Run-2 DM searches as detailed in [Section 4.1.5](#). The studies in this Section have been produced using a leading order UFO model within MADGRAPH5_AMC@NLO 2.2.2 [\[75–77\]](#) using PYTHIA 8 for the parton shower.

Parameter scan. The parameter scan for the dedicated $t\bar{t}+\cancel{E}_T$ searches has been studied in detail to target the production mechanism of DM associated with heavy flavor quarks, and shares many details of the scan for the scalar model with a gluon radiation. The benchmark points scanning the model parameters have been selected to ensure that the kinematic features of the parameter space are sufficiently represented. Detailed studies were performed to identify points in the m_χ , $m_{\phi,a}$, g_χ , g_q (and $\Gamma_{\phi,a}$) parameter space that differ significantly from each other in terms of expected detector acceptance. Because missing transverse momentum is the key observable for searches, the mediator p_T spectra is taken to represent the main kinematics of a model. Another consideration in determining the set of benchmarks is to focus on the parameter space where we expect the searches to be sensitive during the 2015 LHC run. Based on a projected integrated luminosity of 30 fb^{-1} expected for 2015, we disregard model points with a cross section times branching ratio smaller than 0.1 fb , corresponding to a minimum of one expected event assuming a 0.1% efficiency times acceptance.

The kinematics is most dependent on the masses m_χ and $m_{\phi,a}$. [Figs. 23](#) and [24](#) show typical dependencies for scalar and pseudoscalar couplings respectively. Typically, the mediator p_T spectrum broadens with larger $m_{\phi,a}$. The kinematics are also different between on-shell ($M_{\text{med}} > 2m_\chi$) and off-shell ($M_{\text{med}} < 2m_\chi$) mediators as discussed in [Section 2.2](#). Furthermore, the kinematic differences in the \cancel{E}_T spectrum between scalar and pseudoscalar are larger for light mediator masses with respect to heavier mediators. It is therefore important to choose benchmark points covering on-shell and off-shell mediators with sufficient granularity, including the transition region between on-shell and off-shell mediators.

Typically only weak dependencies on couplings are observed (see [Fig. 25](#)) where the variation with width of the integral over parton distributions is unimportant. As shown in [Section 2.1.1](#), for couplings $\sim O(1)$ the width is large enough that the p_T of the mediator is determined mainly by the PDF.

At large mediator masses ($\sim 1.5 \text{ TeV}$) or very small couplings ($\sim 10^{-2}$), width effects are significant, but these regimes have production cross sections that are too small to be relevant for 30 fb^{-1} and are not studied here. However, with the full Run 2 dataset, such models may be within reach.

Another case where the width can impact the kinematics is when $m_{\phi,a}$ is slightly larger than $2m_\chi$. Here, the width determines the relative contribution between on-shell and off-shell mediators. An example is given in [Fig. 26](#). As the minimal width choice pursued in this document is the most conservative one, this effect can be neglected in order to reduce the number of benchmark points to be generated.

The points for the parameter scan chosen for this model are listed in [Table 5](#), chosen to be harmonized with those for other analyses employing the same scalar model as benchmark. Based on the sensitivity considerations above, DM masses are only simulated up to 500 GeV (but the 5 TeV mediator point is retained) leading to a total of 24 benchmark points. However for these searches we recommend to generate and simulate scalar and pseudoscalar models separately, as the kinematics differs due to the different coupling of the mediator to the final state top quarks in the two cases, as shown in [Figs. 23](#) and [24](#).

Table 6

Minimal width of the scalar mediator exchanged in s -channel divided by its mass, assuming $g_q = g_\chi = 1$. The loop-induced gluon contribution is ignored. The numbers tabulated under $2m_\chi = M_{\text{med}}$ correspond to the width calculated for $M_{\text{med}} = 5$ GeV.

Fig. 21. Comparison of the \vec{E}_T distributions for the scalar and pseudoscalar models for different $M_{\text{med}} = 300$ GeV and different DM masses. Ratios of the normalized distributions with respect to the first one are shown. A_{300} and A_{500} in the table denote the acceptance of the $\vec{E}_T > 300$ GeV and $\vec{E}_T > 500$ GeV cut, respectively.

Fig. 22. Representative Feynman diagram showing the pair production of Dark Matter particles in association with $t\bar{t}$ (or $b\bar{b}$).

Similar studies were performed in the $b\bar{b}$ case. It was found that they show the same weak dependence of the kinematics of the event on the mediator width. The same benchmark parameters of the $t\bar{t}$ case could then be chosen.

Fig. 23. Example of the dependence of the kinematics on the scalar mediator mass in the $t\bar{t} + \vec{E}_T$ signature. The Dark Matter mass is fixed to be $m_\chi = 1$ GeV.

Fig. 24. Example of the dependence of the kinematics on the pseudoscalar mediator mass in the $t\bar{t} + \cancel{E}_T$. The Dark Matter mass is fixed to be $m_\chi = 1\text{ GeV}$. All figures concerning the $t\bar{t} + \cancel{E}_T$ signature have been produced using a leading order model within MADGRAPH5_AMC@NLO 2.2.2, using PYTHIA 8 for the parton shower.

Fig. 25. Study of the dependence of kinematics on the width of a scalar mediator $t\bar{t} + \cancel{E}_T$. The width is increased up to four times the minimal width for each mediator and Dark Matter mass combination.

Fig. 26. Dependence of the kinematics on the width of a scalar mediator $t\bar{t} + \cancel{E}_T$. The width is increased up to the mediator mass. Choices of mediator and Dark Matter masses such that $m_{\phi,a}$ is slightly larger than $2m_\chi$ is the only case that shows a sizeable variation of the kinematics as a function of the width.

2.3. Colored scalar mediator, t -channel exchange

The preceding sections address models with a Dirac fermion coupled to the SM through exchange of a neutral spin-0 or spin-1 particle in an s -channel process. A t -channel process may couple the SM and DM directly, leading to a different phenomenology. For completeness, we examine a model where χ is a Standard Model (SM) singlet, a Dirac fermion; the mediating particle, labeled ϕ , is a charged scalar color triplet and the SM particle is a quark. Such models have been studied in Refs. [34,36,38,46,78,79]. However, these models have not been studied as extensively as others in this Forum.

Following the example of Ref. [78], the interaction Lagrangian is written as

$$\mathcal{L}_{\text{int}} = g \sum_{i=1,2} (\phi_{(i),L} \bar{Q}_{(i),L} + \phi_{(i),u,R} \bar{u}_{(i),R} + \phi_{(i),d,R} \bar{d}_{(i),R}) \chi \quad (12)$$

where $Q_{(i),L}$, $u_{(i),R}$ and $d_{(i),R}$ are the SM quarks of the i th generation and $\phi_{(i),L}$, $\phi_{(i),u,R}$ and $\phi_{(i),d,R}$ are the corresponding mediators, which (unlike the s -channel mediators) must be heavier than χ . These mediators have SM gauge representations under $(SU(3), SU(2))_Y$ of $(3, 2)_{-1/6}$, $(3, 1)_{2/3}$ and $(3, 1)_{-1/3}$ respectively. Variations of the model previously studied in the literature include coupling to the left-handed quarks only [79,80], to the $\phi_{(i),u,R}$ [34] or $\phi_{(i),d,R}$ [39,78], or some combination [36,38].

The minimal width of each mediator is expressed, using the example of decay to an up quark, as

$$\Gamma(\phi_{(i)} \rightarrow \bar{u}_{(i)} \chi) = \frac{g_{(i)}^2}{16\pi M_{\phi_{(i)}}^3} (M_{\phi_{(i)}}^2 - m_{u_{(i)}}^2 - m_\chi^2) \times \sqrt{(M_{\phi_{(i)}}^2 - (m_{u_{(i)}} + m_\chi)^2)(M_{\phi_{(i)}}^2 - (m_{u_{(i)}} - m_\chi)^2)}, \quad (13)$$

which reduces to

$$\frac{g_{(i)}^2 M_{\phi_{(i)}}}{16\pi} \left(1 - \frac{m_\chi^2}{M_{\phi_{(i)}}^2}\right)^2 \quad (14)$$

in the limit $M_{\phi_{(i)}}, m_\chi \gg m_{u_{(i)}}$.

The generation index i for $\phi_{(i)}$ is linked to the incoming fermion(s), and it runs on all three quark generations due to the MFV assumption. Ref. [78] considers two extreme cases for this model in terms of cross-sections: the case in which all mediator flavors are present, leading to the maximal cross-section, and the case in which only right-handed down-type mediators are present. Neither of the models in this reference include couplings to the third quark generation, leading to a violation of the MFV assumption. In the case of purely down-type right-handed squarks this is still safe from flavor constraints. Furthermore, reintroducing the third generation squarks would lead to models that produce qualitatively similar signals in the mono-jet and SUSY squark searches, the main difference being the production cross-section. At the same time the presence of third generation squarks will lead to further constraints from other searches such as those for mono-bjets, for stops and for sbottoms, as discussed in Section 2.3.2. The studies in this Section are performed using a model with a mediator coupling to all three generation, following Ref. [46]. Further differences between the two models (hypercharge, chirality) only lead to a change in the cross-section. The LO UFO model is interfaced to MADGRAPH5_AMC@NLO v2.2.3, but it was not possible to go beyond parton-level studies and interface those models to a parton shower in time for the conclusion of this Forum. The state of the art for calculating these models is LO+PS, and the implementation of multi-parton merging has been studied in detail [78,81–83], and further studies should be

Fig. 27. Leading order mono-jet t -channel processes.

Source: Adapted from [78].

undertaken prior to generating signal samples for early Run-2 LHC searches.

The leading-order processes involved in \cancel{E}_T +jet production are shown in Fig. 27. This model can also give a signal in the \cancel{E}_T + di-jet channel when, for example, the χ is exchanged in the t -channel and the resulting ϕ pair each decay to a jet + χ . Fig. 28 shows the leading order diagrams. Except for the gg induced process, di-jet production through the third-generation mediator $\phi_{(3),u}$ is not possible, and production through $\phi_{(3),d}$ is suppressed. However, if the coupling g includes a Yukawa coupling proportional to the quark mass, and g is sufficiently large, LHC searches will still be sensitive to this model, as explained in Section 2.3.2.

The diagram involving the t -channel exchange of χ is strongly dependent upon the Dirac fermion assumption. For a Majorana

fermion, $q\bar{q}$, $\bar{q}q$, and qq production would be possible with the latter having a pronounced enhancement at the LHC.

This model is similar to the simplified model considered in SUSY searches, implemented as the MSSM with only light squarks and a neutralino, except for two distinct points: the χ is a Dirac fermion and the coupling g is not limited to be weak scale ($g \ll 1$). In the MSSM, most of these processes are sub-dominant, even if resonantly enhanced, because the production is proportional to weak couplings. In the more general theories considered here, g is free to take on large values of order 1 or more, and thus diagrams neglected in MSSM simulation can occur at a much higher rate here. While constraints from SUSY jets+ \cancel{E}_T analyses on MSSM models can be recast to apply to the specific model in this report, DM searches should also directly test their sensitivity to the MSSM benchmark models.

Fig. 28. Leading order two-jet t -channel processes.
Source: Adapted from [78].

The state of the art calculation for these models is LO and they can be interfaced with a parton shower program. The studies in this Section use a LO model implementation within MADGRAPH5_AMC@NLO v2.2.3, but no parton shower could be employed in the time-frame of the conclusions of this Forum. Further implementation details can be found in Section 4.1.3.

2.3.1. Parameter scan

As for the s -channel models, we adopt the simplifying assumption that the mediator masses and couplings are equal for each flavor and handedness. The free parameters are then

$$\{m_\chi, M_\phi, g\}. \tag{15}$$

Ref. [78] studies the parameter space and obtains bounds on this model from LHC Run-1 mono-jet and dijets+ \cancel{E}_T data. The Forum did not exhaustively compare the kinematic distributions

of the t -channel models as done in the s -channel case. In particular, the absence of a parton shower simulation can affect some of the conclusions on the points and sensitivity chosen. While this means the conclusions on the parameter scan below should be taken with more caution, the model is plausible and distinctive, and it should be included in the design of early Run-2 LHC searches.

As in the s -channel models, scans should be performed over m_χ and M_ϕ . The viable ranges of both parameters nearly coincide with the scan proposed for the s -channel. For the early Run-2 searches, we recommend to generate and fully simulate a subset of the s -channel mono-jet grid that accounts for the on-shell and off-shell regions. In contrast to the s -channel case, the bounds one obtains from \cancel{E}_T+X searches depend strongly on the width of the mediator, as is visible in Figs. 5 and 6 of Ref. [78] and in

(a) \cancel{E}_T distribution for a 200 GeV t -channel mediator, when varying the couplings.

(b) Leading jet p_T distribution for a 2 TeV t -channel mediator with small ($g=0.5$) to large ($g=7$) couplings with a DM mass of 1 GeV

Fig. 29. Kinematic distributions normalized to unit area from the t -channel model from Ref. [46], using MadAnalysis [84,86] and simplified analysis cuts on the leading jet $p_T > 150$ GeV and $\eta < 2.8$, $\cancel{E}_T > 150$ GeV. For these models, a LO UFO model is interfaced to MADGRAPH5_AMC@NLO v2.2.3, and studies are at parton-level only.

Fig. 29(a), except in the heavy mediator limit ($M_\phi \approx 2$ TeV). This figure has been obtained applying a simplified analysis selection (cuts on the leading jet $p_T > 150$ GeV and $\eta < 2.8$, $\cancel{E}_T > 150$ GeV.) using MadAnalysis [84,85]. Fig. 29(b) also shows that, if the DM mass is low and the mediator is produced on-shell and its width is narrow, the cross-section is dominated by $qg \rightarrow q\chi\chi$ diagram. The mediator energy is then split evenly between the light DM particles and the quark, leading to a broad enhancement at $M_{\text{med}}/2$.

Points with distinct kinematic distributions for a preliminary scan in $\{m_\chi, M_\phi, g\}$ are selected taking into account the expected sensitivity of Run-2 searches, and requiring at least 100 events to pass the kinematic cuts outlined for Fig. 29 in 25 fb^{-1} of collected data, and respect $\Gamma/M_{\text{med}} < 1$. They are outlined in Table 8. The conclusions in this table may change when a parton shower is employed together with multiparton matching.

2.3.2. Additional considerations for $V + \cancel{E}_T$ signatures

The models and parameters with emission of an EW boson generally follow those in Section 2.3. even though different diagrams are involved. A representative Feynman diagram can be constructed by replacing a final-state gluon in Fig. 27 with a γ , W , Z boson, but radiation of electroweak bosons directly from the mediator also leads to a mono-boson signature.

Table 8

Simplified model benchmark points for t -channel simplified model (spin-0 mediators coupling to Dirac DM fermions, taking the minimum width).

m_χ /GeV	$M_{\text{med}}/\text{GeV}$		Couplings		
1	10	50	100	300	0.1, 1, 3, 7
1				500	0.25, 1, 3, 7

				2000	

Fig. 30. Missing transverse momentum distribution for the hadronic $Z + \cancel{E}_T$ final state, for the simplified model with a colored scalar mediator exchanged in the t -channel.

The models considered in Section 2.3 present a relevant difference concerning final states with an electroweak boson. In the model in [46], both right- and left-handed mediators can radiate a Z boson, while only the left-handed mediator in [46] allows for W and Z radiation.

The studies in this Section use the LO+PS UFO model from [46] in MADGRAPH5_AMC@NLO v2.2.3, using PYTHIA 8 for the parton shower. Fig. 30 shows the \cancel{E}_T distribution for the hadronic $Z + \cancel{E}_T$ final state, with varying DM and mediator mass, before any selection. The acceptance for a series of basic analysis selections ($\cancel{E}_T > 350$ GeV, leading jet $p_T > 40$ GeV, minimum azimuthal angle between jet and $\cancel{E}_T > 0.4$) applied at the generator level is shown in Fig. 31.

The discussion of the parameter scan for the t -channel model in the case of signatures including EW bosons parallels that of the monojet case for mediator and DM masses, but no kinematic dependence on the width is observed, so a coupling scan is not needed.

Additional considerations for signatures with b -quarks + \cancel{E}_T . Models of bottom-flavored Dark Matter that are closely related to the t -channel mediated model from this Section have been proposed in Refs. [87,88]. We describe the b -FDM model of Ref. [88], created to explain the Galactic Center (GC) gamma-ray excess observed in data collected by the Fermi-LAT collaboration [89,90]. This model favors couplings to third-generation quarks via Yukawa couplings, therefore respecting the MFV assumption.

Fig. 31. Acceptance for the hadronic $Z+\ell_T$ final state, for the simplified model with a colored scalar mediator exchanged in the t -channel.

The model contains a Dirac fermion transforming as a flavor triplet, exclusively coupling to right-handed down-type quarks. The third component of the triplet χ_b comprises the cosmological DM. Within the MFV framework, the other fermions in the flavor triplet can be made sufficiently heavy and weakly-coupled that they can be neglected in the analysis. A flavor singlet, color triplet scalar field Φ mediates the interactions between the DM and the Standard Model quarks. The model is similar to the MSSM with a light bottom squark and neutralino, and is thus a flavor-specific example of a t -channel model. Similar top-flavored models can exist, as e.g. in Refs. [91,92]. In the case where the top coupling is the main DM coupling, the signal is very similar to a signal from a stop quark, since unlike the other t -channel cases there is no top in the initial state parton distribution functions (PDFs). This is the reason why it was not considered as an additional model. More recent literature shows that other flavor states could also contribute to LHC signals, as shown in Ref. [93], but such models will have to be investigated on a longer timescale with respect to that of this Forum.

The Lagrangian considered is given by

$$-\mathcal{L} \supset g\Phi^* \bar{\chi}_b b_R + \text{h.c.} \quad (16)$$

This model is known at LO+PS accuracy, and the studies in this Section use a LO model implementation within MADGRAPH5_AMC@NLO v2.2.3 interfaced to PYTHIA 8 for the parton shower. Further implementation details can be found in Section 4.1.5.

Parameter scan. In this model, the interference of diagrams with QCD production of the mediator (which scale as g_s^2) with diagrams that are proportional to the coupling g in the $b+\ell_T$ and $b\bar{b}+\ell_T$ final states. In the case of large couplings, this is not conducive to a simple scaling behavior that would allow us to reduce the number of points to be simulated. This can be seen in Fig. 33.

A full study of the parameter scan for this model was not available for this report; thus for early Run-2 searches we recommend scanning a range of possible widths as discussed in a more limited way than for the t -channel mono-jet, spanning from the minimal width to a value approaching the particle limit, e.g. $g = 0.5, 1, 2, 3$. A coupling benchmark such as $g = 1$ should be considered for each mass point since this would be a distinctive feature of this benchmark from SUSY models with sbottom squarks (see Section 2.3 for further discussion).

A scan of Dark Matter and mediator masses should be done in the on-shell region $M_\Phi > m_\chi + m_b$, since the cross-sections in the off-shell region are too small to be probed with early LHC data, spanning from 10 to 500 GeV in m_χ and from 10 to 1300 GeV in M_Φ . Examples of the kinematic distributions produced by this model are shown in Fig. 32.⁸

2.4. Spin-2 mediator

In models with extra dimensions, the Kaluza–Klein excitations of the graviton could also serve as a mediator between the SM and dark sector physics. This kind of model was not studied in the forum and is not included in the recommendations, but models such as Ref. [94,95] may warrant further study on a longer timescale.

2.5. Presentation of results for reinterpretation of s -channel mediator models

The aim of the parameter grid optimization done for the s -channel models in the previous sections is to reduce the parameter space that must be simulated. We then need a procedure for populating the full parameter space by using the simulated grid points. We recommend doing this as follows:

- When the dependences on parameters are known, the cross sections and efficiencies at general points can be calculated from the grid data.
- In other cases, this information can be obtained by interpolation between the grid points. We have chosen the grid points so that the dependence is sufficiently smooth that this will be possible.

The results of the scan over the couplings presented in the previous sections indicate that there are no changes in kinematic distributions for different choices of the coupling strengths. This means that the acceptance remains the same in the whole g_q – g_χ plane and it is sufficient to perform the detector simulation only for one single choice of g_q, g_χ . The resulting truth-level selection acceptance and the detector reconstruction efficiency can then be applied to all remaining grid points in the g_q – g_χ plane where only the generator-level cross section needs to be known. This significantly reduces the computing time as the detector response is by far the most CPU-intensive part of the Monte Carlo sample production. However, the number of generated samples can be reduced even further if a parameterization of the cross section dependence from one grid point to another exists. In this section, we describe the details of a cross section scaling procedure that can be used to reinterpret results for a fixed coupling for s -channel mediator models. The studies in this section employ the POWHEG [43] generator.

The propagator for the s -channel exchange is written in a Breit–Wigner form as $\frac{1}{q^2 - M_{\text{med}}^2 + iM_{\text{med}}\Gamma}$, where q is the momentum

transfer calculated from the two partons entering the hard process after the initial state radiation, which is equivalent to the momentum of the DM pair.⁹ The size of the momentum transfer with respect to the mediator mass allows us to identify three cases:

⁸ Following the grounding assumptions in this report, the normalization to the relic density is considered only in these example plots rather than as a necessary ingredient for the parameter scan of this model.

⁹ Using a running width and replacing the denominator of the propagator with $q^2 - M_{\text{med}}^2 + iQ^2 \frac{\Gamma}{M_{\text{med}}}$ should be considered in the case of wide mediators [96].

Fig. 32. E_T (left) and jet multiplicity (right) for various DM and mediator masses and couplings normalized to the relic density observed in the early universe. Studies in this section use a LO UFO model implementation within MADGRAPH5_AMC@NLO v2.2.3 interfaced to PYTHIA 8 for the parton shower.

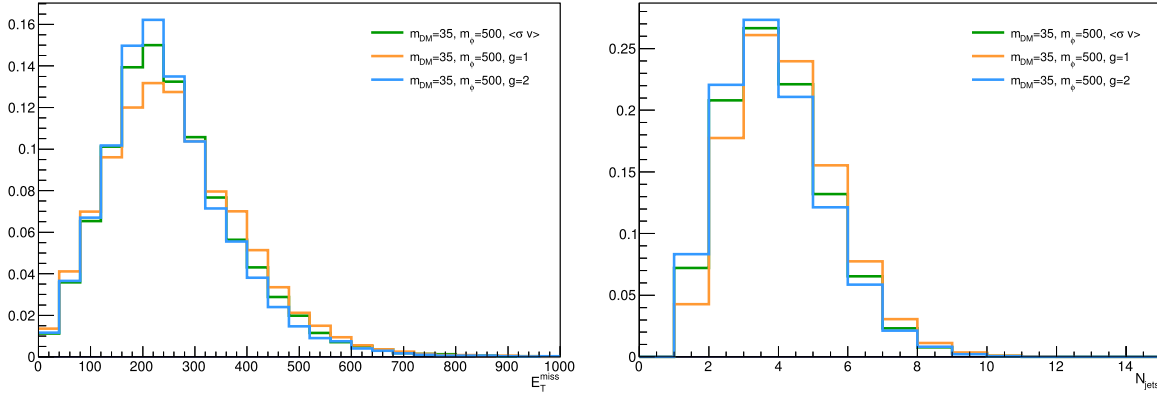

Fig. 33. E_T (left) and jet multiplicity (right) for $m_\chi = 35$ GeV and $M_\phi = 500$ GeV for varying couplings of $g = 1, 2$.

- off-shell mediator, when $q^2 \gg M_{\text{med}}^2$ leading to suppressed cross sections,
- on-shell mediator, when $q^2 \sim M_{\text{med}}^2$ leading to enhanced cross sections,
- effective field theory (EFT) limit when $q^2 \ll M_{\text{med}}^2$.

In the case of the off-shell mediator and the EFT limit, the first and second term in the propagator dominate, respectively, which reduces the dependence on the mediator width. Therefore, in these cases one can approximate the cross section as

$$\sigma \propto g_q^2 g_\chi^2. \quad (17)$$

The on-shell regime is the most interesting one as it gives the best chances for a discovery at the LHC given the cross section enhancement. The propagator term with the width cannot be neglected in this case and, in the narrow width approximation which requires $\Gamma \ll M_{\text{med}}$ (this is not necessarily the case in the benchmarks considered in the scans), one can integrate

$$\int \frac{ds}{(s - M_{\text{med}}^2)^2 + M_{\text{med}}^2 \Gamma^2} = \frac{\pi}{M_{\text{med}} \Gamma} \quad (18)$$

which further implies the cross section scaling

$$\sigma \propto \frac{g_q^2 g_\chi^2}{\Gamma}. \quad (19)$$

The narrow width approximation is important here as it ensures an integration over parton distribution functions (PDFs) can be neglected. In other words, it is assumed the integrand in Eq. (18) is non-zero only for a small region of s , such that the PDFs can be taken to be constant in this range. By simplifying the dependence of the minimal width on the couplings as $\Gamma \sim g_q^2 + g_\chi^2$, one can

approximate this scaling rule in the extreme cases as follows

$$\sigma \propto \frac{g_q^2 g_\chi^2}{g_q^2 + g_\chi^2} \xrightarrow{g_q \ll g_\chi} g_q^2 \quad (20)$$

$$\sigma \propto \frac{g_q^2 g_\chi^2}{g_q^2 + g_\chi^2} \xrightarrow{g_q \gg g_\chi} g_\chi^2. \quad (21)$$

However, it is important to keep in mind that this formula omits color and multiplicity factors as well as possible Yukawa suppression, and there is no simple scaling rule for how the cross section changes with the DM mass and the mediator mass, or for mediators with a large width, because PDFs matter in such cases as well. Therefore, the scaling procedure outlined above is expected to work only for fixed masses and fixed mediator width, assuming the narrow width approximation applies.

Fig. 34 shows the minimal width over the mediator mass in the g_q - g_χ plane for vector and scalar mediators for $M_{\text{med}} = 100$ GeV and 1000 GeV, taking $m_\chi = 10$ GeV. The individual colors indicate the lines of constant width, along which the cross section scaling may work for narrow mediators. The limiting case $\Gamma_{\text{min}} = M_{\text{med}}$ defines the upper values of the couplings below which the narrow width approximation can be considered and provides more stringent constraint than the perturbative limit $g_q = g_\chi = 4\pi$. For vector and axial-vector mediators, the minimal width is predominantly defined by g_q due to the number of quark flavors and the color factor. On the contrary, both the SM and DM partial width have comparable contributions in case of scalar and pseudo-scalar mediators if the top quark channel is open ($M_{\text{med}} > 2m_t$). However, mostly g_χ defines the minimal width for $M_{\text{med}} < 2m_t$ due to the Yukawa-suppressed light quark couplings.

Fig. 34. Minimal width over the mediator mass for vector (top) and scalar (bottom) mediators as a function of the individual couplings g_q and g_χ , assuming $M_{\text{med}} = 100$ GeV (left) and $M_{\text{med}} = 1$ TeV (right). $m_\chi = 10$ GeV is considered in all cases. Only the cases with $\Gamma_{\text{min}} < M_{\text{med}}$ are shown.

The performance of the cross section scaling is demonstrated in Fig. 35 where two mass points $M_{\text{med}} = 100$ GeV and 1 TeV with $m_\chi = 10$ GeV are chosen and rescaled from the starting point $g_q = g_\chi = 1$ according to Eq. (19) to populate the whole g_q - g_χ plane. This means the width is not kept constant in this test and this is done in purpose in order to point out deviations from the scaling when the width is altered. For each mass point, the rescaled cross section is compared to the generator cross section and the ratio of the two is plotted. For the given choice of the mass points, the scaling seems to work approximately within the precision of $\sim 20\%$ in the region where $\Gamma_{\text{min}} < M_{\text{med}}$. Constant colors indicate the lines along which the cross section scaling works precisely and there is a remarkable resemblance of the patterns shown in the plots of the mediator width. To prove the scaling along the lines of constant width works, one such line is chosen in Fig. 36 for a scalar mediator, defined by $M_{\text{med}} = 300$ GeV, $m_\chi = 100$ GeV, $g_q = g_\chi = 1$, and the rescaled and generated cross sections are found to agree within 3%.

2.5.1. Proposed parameter grid for cross-section scaling

We propose to deliver collider results in the g_q - g_χ plane using the following prescription, to ease reinterpretation through cross-section scaling:

- Since the shapes of kinematic quantities do not change for different couplings, use the acceptance and efficiency for the available $m_\chi = 50$ GeV, $M_{\text{med}} = 300$ GeV grid point from the $M_{\text{med}}-m_\chi$ plane for the scalar and pseudo-scalar mediator. In case of the vector and axial-vector mediator, use the grid point $m_\chi = 150$ GeV, $M_{\text{med}} = 1$ TeV.
- Generate additional samples in order to get generator cross sections only. For scalar and pseudo-scalar mediator, choose $m_\chi = 50$ GeV, $M_{\text{med}} = 300$ GeV with the following values for $g_q = g_\chi$: 0.1, 1, 2, 3. For vector and axial vector mediator, choose $m_\chi = 150$ GeV, $M_{\text{med}} = 1$ TeV with the following values for $g_q = g_\chi$: 0.1, 0.25, 0.5, 0.75, 1, 1.25, 1.5. The

upper values are defined by the minimal width reaching the mediator mass.

- Rescale the generator cross sections for on-shell resonance production along the lines of constant width in order to populate the whole g_q - g_χ plane in the region $\Gamma_{\text{min}} < M_{\text{med}}$. The scaling follows from Eq. (19) which for the constant width implies:

$$\sigma' = \sigma \times \frac{g_q^2 g_\chi^2}{g_q^2 g_\chi^2}. \quad (22)$$

2.5.2. Rescaling to different mediator width

In general it is also important to consider a larger mediator width than Γ_{min} in order to accommodate additional interactions of the mediator with the visible and hidden sector particles [41, 42]. If the narrow width approximation applies, the cross section scaling method described above can be used to reinterpret the results presented for the minimal width, since multiplying the width by factor n is equivalent to changing the coupling strength by factor \sqrt{n} , i.e.

$$\sigma(g_q, g_\chi, n\Gamma_{\text{min}}(g_q, g_\chi)) \propto \frac{g_q^2 g_\chi^2}{\Gamma_{\text{min}}(\sqrt{n}g_q, \sqrt{n}g_\chi)}. \quad (23)$$

The cross section for the sample with couplings g_q and g_χ and modified mediator width $\Gamma = n\Gamma_{\text{min}}$ can therefore be rescaled from a sample generated with the minimal width corresponding to the couplings scaled by \sqrt{n} as described in the following formula.

$$\sigma(g_q, g_\chi, n\Gamma_{\text{min}}(g_q, g_\chi)) = \frac{1}{n^2} \sigma(\sqrt{n}g_q, \sqrt{n}g_\chi, \Gamma_{\text{min}}(\sqrt{n}g_q, \sqrt{n}g_\chi)) \quad (24)$$

The advantage of doing this is in the fact that no event selection and detector response needs to be simulated since the changes in couplings do not have an effect on the shapes of kinematic distributions.

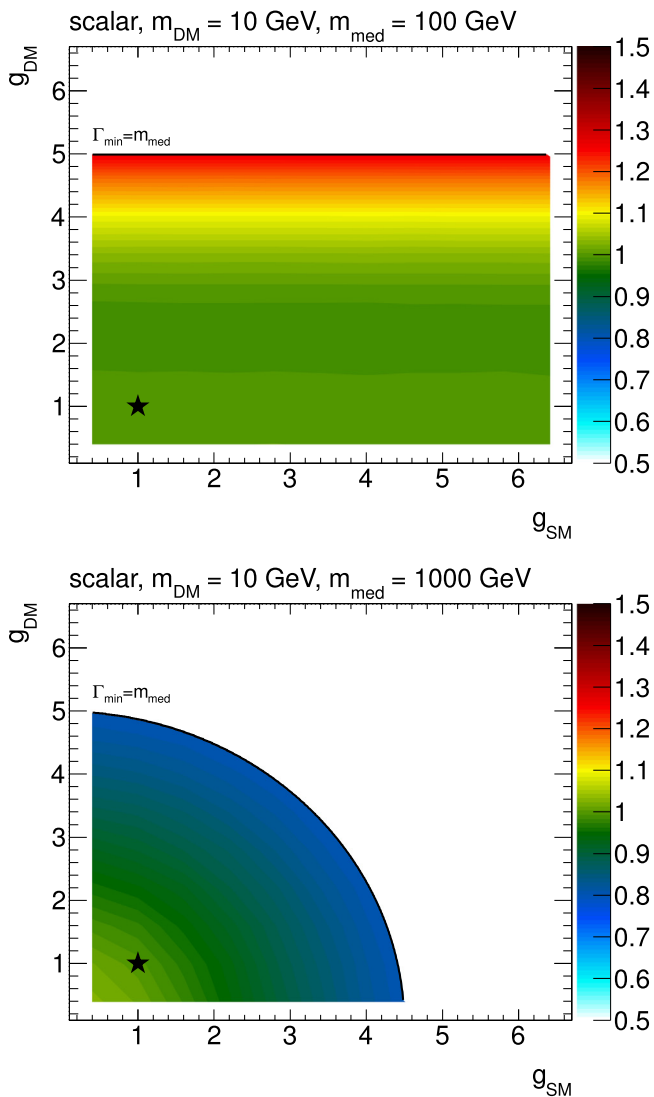

Fig. 35. Ratio of the rescaled and generated cross sections in the g_q - g_χ plane. The point at $g_q = g_\chi = 1$, taken as a reference for the rescaling, is denoted by a star symbol. Scalar model with $M_{\text{med}} = 100$ GeV (left) and 1 TeV (right) is plotted for $m_\chi = 10$ GeV. The limiting case $\Gamma_{\text{min}} = M_{\text{med}}$ is indicated by a black line and no results are shown beyond.

It should be noted again that this procedure is only useful when the narrow width approximation applies. Care must be taken to ensure that is the case. For example, in the vector and axial-vector cases, one quickly breaks this approximation even for small n .

Additional considerations for $t\bar{t}$ and $b\bar{b} + \cancel{E}_T$ signatures. The cross-section scaling considerations shown in Section 2.5 still apply for the reactions in the scalar and pseudoscalar models with explicit b and t quarks. Here we detail the specific studies done for the $t\bar{t}$ model.

Given that the kinematics are similar for all couplings $g \simeq 1$, we recommend to generate only samples with $g_\chi = g_q = 1$. It follows from this that these benchmark points should be a good approximation for non-unity couplings and for $g_\chi \neq g_q$, provided that the sample is rescaled to the appropriate cross section times branching ratio.

While the simple scaling function

$$\sigma' \times BR' = [\sigma \times BR] \times \left(\frac{g'_q}{g_q}\right)^2 \times \left(\frac{g'_\chi}{g_\chi}\right)^2 \times \frac{\Gamma}{\Gamma'} \quad (25)$$

is sufficient for a limited range of coupling values (see Fig. 37 for example), this scaling is only approximate (up to 20%) and relies on the narrow width approximation, ignoring PDFs effects.

3. Specific models for signatures with EW bosons

In this Section, we consider specific models with a photon, a W boson, a Z boson or a Higgs boson in the final state ($V + \cancel{E}_T$ signature), accompanied by DM particles that either couple directly to the boson or are mediated by a new particle. The common feature of those models is that they provide different kinematic distributions with respect to the models described in Section 2.

The models considered in this Section can be divided into two categories:

V-specific simplified models These models postulate direct couplings of new mediators to bosons, e.g. they couple the Higgs boson to a new vector or to a new scalar [48,97].

Models involving a SM singlet operator including a boson pair that couples to DM through a contact interaction Shown on the right-hand side of Fig. 38, these models allow for a contact interaction vertex that directly couples the boson to DM [45,97–99]. The models of this type included in this report are devoted to simplified models since UV completions for most of these operators proceed through loops and are not available to date. These models provide a benchmark to motivate signal regions that are unique to searches with EW final states and would otherwise not be studied. However, we recommend to use these models as placeholders and emphasize model-independent results especially in signal regions tailored to these models. Whenever results are interpreted in terms of these operators, a truncation procedure to ensure the validity of the EFT should be employed, as detailed in Section 5.

The following Sections describe the models within these categories, the chosen parameters for each of the benchmark models and the studies towards the choices of the parameters to be scanned.

3.1. Specific simplified models including EW bosons, tailored to Higgs+MET searches

Three benchmark simplified models [48,97] are recommended for Higgs+ \cancel{E}_T searches:

- A model where a vector mediator (Z'_B) is exchanged in the s -channel, radiates a Higgs boson, and decays into two DM particles (Fig. 39(a)). As in Section 2.1, we conservatively omit couplings of the Z'_B to leptons.
- A model where a scalar mediator S is emitted from the Higgs boson and decays to a pair of DM particles (Fig. 40).
- A model where a vector Z' is produced resonantly and decays into a Higgs boson plus an intermediate heavy pseudoscalar particle A^0 , in turn decaying into two DM particles (Fig. 39(b)).

These models are kinematically distinct from one another, as shown in the comparison of the \cancel{E}_T spectra in Fig. 41 for high and low masses of the pseudoscalar mediator. Fig. 41(a) shows the \cancel{E}_T distribution for models with high mediator masses ($m_S = 1$ TeV, $m_{Z'} = 1$ TeV, $m_{A^0} = 1$ TeV) and DM mass of either 50 (Z'_B and

Fig. 36. Scaling along the lines of constant width. The line of constant width for $M_{\text{med}} = 300$ GeV and $m_\chi = 100$ GeV, intercepting $g_q = g_\chi = 4$ is shown on left. The generated and rescaled cross sections are compared in the middle, the corresponding ratio is shown on right.

A^0 models) or 65 GeV (scalar mediator model). Fig. 41(b) shows the \cancel{E}_T distribution for models with low pseudoscalar mediator masses ($m_{Z'_B} = 100$ GeV, $m_{Z'} = 1$ TeV, $m_{A^0} = 100$ GeV) and DM mass of 1 TeV for all models.

Predictions for this class of models have been so far considered at LO+ Parton Shower (PS), even though they could be extended to NLO+PS in the near future. The studies in this Section have been performed using a model within MADGRAPH5_AMC@NLO v5.1.5.12, interfaced to PYTHIA 6 for the parton shower. The implementation details for these models are discussed in Section 4.2.1.

3.1.1. \cancel{E}_T +Higgs from a baryonic Z'

The model shown in Fig. 39(a) postulates a new gauge boson Z' corresponding to a new $U(1)_B$ baryon number symmetry. The stable baryonic states included in this model are the DM candidate particles. The mass of the Z' boson is acquired through a baryonic Higgs h_B , which mixes with the SM Higgs boson.

The interactions between the Z' , the quarks and the DM are described by the following Lagrangian:

$$\mathcal{L} = g_q \bar{q} \gamma^\mu q Z'_\mu + g_\chi \bar{\chi} \gamma^\mu \chi Z'_\mu. \quad (26)$$

The quark couplings g_q are fixed to be equal to one third of the gauge coupling g_B , while the DM coupling to the Z' are proportional to the baryon number and to the gauge coupling ($g_\chi = B g_B$). No leptonic couplings of the Z' are allowed, thus evading dilepton constraints. After incorporating the mixing of the baryonic and SM Higgs bosons, this model is described by the

following Lagrangian term at energies below $m_{Z'}$ ¹⁰:

$$\mathcal{L}_{\text{eff}} = -\frac{g_q g_\chi}{m_{Z'}^2} \bar{q} \gamma^\mu q \bar{\chi} \gamma_\mu \chi \left(1 + \frac{g_{hZ'Z'}}{m_{Z'}^2} h \right), \quad (27)$$

The first term of this equation is the standard DMV model in the large $M_{Z'}$ limit. This term can lead to a monojet signature, which can be also used to constrain this model. The second term describes the interaction between the Z' and the SM Higgs boson, via the coupling $g_{hZ'Z'} = \frac{m_{Z'}^2 \sin \theta}{v_B}$, where $\sin \theta$ is the mixing angle between the SM Higgs and the baryonic Higgs h_B , and v_B is the Baryonic Higgs vacuum expectation value.

In its most general form, this model can contribute to mono-Z signals due to the Z' mixing with the Z or photon. Note that EWSB and $U(1)_B$ breaking do not lead to this mixing at tree-level. Instead, kinetic mixing occurs between the $U(1)_Y$ and $U(1)_B$ gauge bosons due to the gauge invariant term $F_Y^{\mu\nu} F_{B\mu\nu}$. This mixing is a free parameter which we assume to be small in order to focus on the mono-Higgs signature. Mixing may also occur due to radiative corrections, however we choose to ignore this here as it is model dependent.

The predictions of the model depend upon the two additional parameters beyond an s-channel simplified model, namely the mixing angle between baryonic Higgs h_B and the SM-like Higgs boson $\sin \theta$ and the coupling of the mediator to SM-like Higgs

¹⁰ The operator in Eq. (27) is an effective one, to highlight the two main terms. The full dimension-4 simplified model is used in the model for event generation.

Fig. 37. An example comparing a simple cross section scaling versus the computation from the MADGRAPH5_AMC@NLO generator, for a scalar $t\bar{t} + \cancel{E}_T$ model with $m_\phi = 400$ GeV, $m_\chi = 1$ GeV and all couplings set to unity. In this example, the scaling relationship holds for Γ_ϕ/m_ϕ below 0.2, beyond which finite width effects become important and the simple scaling breaks down.

boson, $g_{hZ'Z'}$. Thus, a full model is specified by:

$$\{M_{\text{med}}, m_\chi, g_\chi, g_q, \sin \theta, g_{hZ'Z'}\}. \quad (28)$$

Parameter scan. The width of the Z' mediator is calculated using all possible decays to SM particles (quarks) and to pairs of DM particles if kinematically allowed as in the DMV model.

The dependence of the missing transverse momentum (\cancel{E}_T) on the model parameters is studied by varying the parameters one at a time. The variation of parameters other than M_{med} and m_χ does not result in significant variations of the \cancel{E}_T spectrum, as shown in Fig. 42. Fig. 43 shows that for an on-shell mediator, varying m_χ with the other parameters fixed does not affect the \cancel{E}_T distribution, while the distribution broadens significantly in the case of an off-shell mediator. For this reason, the same grid in M_{med}, m_χ as for the vector mediator of the jet + \cancel{E}_T search (Table 1)

Fig. 39. Examples of Feynman diagrams leading to Higgs + \cancel{E}_T events: (a) a model with a vector mediator (Z') coupling with DM and with the Higgs boson h , and (b) a 2HDM model with a new invisibly decaying pseudoscalar A^0 from the decay of an on-shell resonance Z' giving rise to a Higgs + \cancel{E}_T signature.

Fig. 38. Sketch of benchmark models including a contact interaction for V+MET searches.

Source: Adapted from [100].

is chosen as a starting point. The coupling $g_{hZ'Z'}$, along with g_q and g_χ , are subject to perturbativity bounds:

$$g_q, g_\chi < 4\pi,$$

and

$$g_{hZ'Z'} < \sqrt{4\pi} m_{Z'} \sin \theta.$$

The value $g_{hZ'Z'}/m_{Z'} = 1$ is chosen as a benchmark value for the generation of Monte Carlo samples since it maximizes the cross section (as shown in the following paragraph) without violating the bounds. The mediator-DM coupling g_χ is fixed to 1, and the mediator-quark g_q coupling is fixed to $1/3$. The kinematic distributions do not change as a function of these parameters, so results for other values of $g_{hZ'Z'}/m_{Z'}$, g_χ and g_q can be obtained through rescaling by the appropriate cross sections.

Figs. 44 and 45 show the kinematic distributions for the two leading jets in the $H \rightarrow \bar{b}b$ decay channel, for two values of the mediator mass and varying the DM mass.

Experimentalists should perform further studies, beyond those studies performed for the forum, to estimate the reach of the analysis with respect to all points in the grid and therefore decide on a smaller set of grid points to be generated.

3.1.2. \cancel{E}_T + Higgs from a scalar mediator

A real scalar singlet S coupling to DM can be introduced as a portal between SM and the dark sector through the Higgs field. The most general scalar potential is detailed in Ref. [101], including terms that break \mathbb{Z}_2 . The \mathbb{Z}_2 symmetry, which causes the new scalar to also be a DM candidate, is not covered in this report, but follows Ref. [48] introducing an additional coupling to

Fig. 40. Examples of Feynman diagrams leading to Higgs+ \bar{E}_T events for a model with a scalar mediator (S) coupling with DM and with the Higgs boson h .

DM that breaks \mathbb{Z}_2 and leads to a new invisible decay of S . For this reason, no symmetry is broken and no new interactions arise, so there is no dependence on the vacuum expectation value of S : a shift in the field leads to a redefinition of the model couplings. The new scalar S mixes with the SM Higgs boson, and couples to DM through a Yukawa term y_χ . The relevant terms in the scalar potential are:

$$V \supset a|H|^2S + b|H|^2S^2 + \lambda_h|H|^4 \\ \longrightarrow \frac{1}{2}a(h+v)^2S + \frac{1}{2}b(h+v)^2S^2 + \frac{\lambda_h}{4}(h+v)^4, \quad (29)$$

where a, b are new physics couplings and λ_h is the Higgs quartic coupling.

The additional Lagrangian terms for this model are:

$$\mathcal{L} \supset -y_\chi \bar{\chi} \chi (\cos \theta S - \sin \theta h) - \frac{m_q}{v} \bar{q} q (\cos \theta h + \sin \theta S) \quad (30)$$

where θ is the mixing angle between the Higgs boson and the new scalar.

Mono-Higgs signals in this second model arise through processes shown in Fig. 40 (a,b), or through the radiation of a Higgs boson from the t quark in the production loop, in Fig. 40(c). The first two processes depend on the h^2S and hS^2 cubic terms in Eq. (29). At leading order in $\sin \theta$, these terms are:

$$V_{\text{cubic}} \approx \frac{\sin \theta}{v} (2m_h^2 + m_S^2) h^2 S + b v h S^2 + \dots, \quad (31)$$

with a and λ_h expressed in terms of $\sin \theta$ and m_h^2 , respectively. At leading order of $\sin \theta$, the h^2S term is fixed once the mass eigenvalues m_h, m_S and mixing angle are specified. The hS^2 term is not fixed and remains a free parameter of the model, depending on the new physics coupling b .

This model also has mono-X signatures through h/S mixing. This model is related to the scalar model discussed in Section 2.2 in the case of $m_S \gg m_h$ or $m_h \gg m_S$ and M_{med} equal to the lighter of the two masses, albeit with different mono-Higgs signatures due to the hS^2 vertex.

Parameter scan. The model is described by five parameters:

1. the Yukawa coupling of heavy scalar to dark matter, g_χ (also referred to as y_χ)
2. the mixing angle between heavy scalar and SM-like Higgs boson, $\sin \theta$;
3. the new physics coupling, b ;
4. mass of heavy scalar, m_S , also termed M_{med} ;
5. mass of DM, m_χ ;

The mixing angle is constrained from current Higgs data to satisfy $\cos \theta = 1$ within 10% and therefore $\sin \theta \lesssim 0.4$. This provides a starting point for the parameter scan in this model: we recommend to set $\sin \theta = 0.3$.

Fig. 47 shows that the kinematics does not depend on the value of this angle, and results for different values can be obtained via rescaling the results for this mixing angle according to the relevant cross-section. It can also be observed from Figs. 46 and 48 that the kinematics of this model follows that of the equivalent jet+ \bar{E}_T model: only small changes are observed in the on-shell region, while the relevant distributions diverge when the mediator is off-shell. For this reason, the same grid in M_{med}, m_χ as for the scalar mediator of the jet+ \bar{E}_T search (Table 5) is chosen as a starting point. The Yukawa coupling to DM y_{DM} is set to 1, the new physics coupling between scalar and SM Higgs $b = 3$. Results for other values can be obtained via a rescaling of the results for these parameters.

(a) High mediator mass

(b) Low mediator mass

Fig. 41. Comparison of the missing transverse momentum distributions at generator level in different simplified models leading to a Higgs+ \cancel{E}_T signature. The model parameter settings are detailed in the text. The figures in this Section have been obtained using LO UFO models within MADGRAPH5_AMC@NLO v2.2.3, interfaced to PYTHIA 8 for the parton shower.

Figs. 49 and 50 show the kinematic distributions for the two leading jets in the $H \rightarrow b\bar{b}$ decay channel, for two values of the mediator mass and varying the DM mass.

3.1.3. Higgs+ \cancel{E}_T signal from 2HDM model with a Z' and a new pseudoscalar

In this simplified model [97], a new Z' resonance decays to a Higgs boson h plus a heavy pseudoscalar state A^0 in the 2HDM framework, which in turn decays to a DM pair. This model is represented in the diagram in Fig. 39(b).

The motivation for coupling the DM to the pseudoscalar is that DM coupling to a Higgs or Z' boson is generically constrained by other signal channels and direct detection. A reason to consider

Fig. 42. Missing transverse momentum distributions at generator level in the vector mediator scenario for different values of: the mediator-DM coupling g_x (left), and the coupling between the mediator and the SM-like Higgs boson, scaled by the mediator mass, $g_{hZ'Z'}/m_{Z'}$ (right).

this model is that it has different kinematics due to the on-shell Z' production, where for heavy Z' masses the \cancel{E}_T and p_T spectra are much harder. This model can satisfy electroweak precision tests and constraints from dijet resonance searches, and still give a potentially observable Higgs+ \cancel{E}_T signal.

The model comprises of two doublets, where Φ_u couples to up-type quarks and Φ_d couples to down-type quarks and leptons:

$$-\mathcal{L} \supset y_u Q \tilde{\Phi}_u \bar{u} + y_d Q \Phi_d \bar{d} + y_e L \Phi_d \bar{e} + \text{h.c.} \quad (32)$$

After electroweak symmetry breaking, the Higgs doublets attain vacuum expectation values v_u and v_d , and in unitary gauge the doublets are parameterized as

$$\Phi_d = \frac{1}{\sqrt{2}} \begin{pmatrix} -\sin \beta H^+ \\ v_d - \sin \alpha h + \cos \alpha H - i \sin \beta A^0 \end{pmatrix}, \quad \Phi_u = \frac{1}{\sqrt{2}} \begin{pmatrix} \cos \beta H^+ \\ v_u + \cos \alpha h + \sin \alpha H + i \cos \beta A^0 \end{pmatrix} \quad (33)$$

Fig. 43. Missing transverse momentum distributions at generator level in the vector mediator scenario: for different values of the DM mass m_χ and a mediator mass of $M_{\text{med}} = 100$ GeV (left) and $M_{\text{med}} = 1$ TeV (right).

where h, H are neutral CP-even scalars, H^\pm is a charged scalar, and A^0 is a neutral CP-odd scalar. In this framework, $\tan \beta \equiv v_u/v_d$, and α is the mixing angle that diagonalizes the $h-H$ mass squared matrix. This model also contains an additional scalar singlet ϕ that leads to spontaneous symmetry breaking. We take $\alpha = \beta - \pi/2$, in the alignment limit where h has SM-like couplings to fermions and gauge bosons as per Ref. [102], and $\tan \beta \geq 0.3$ as implied from the perturbativity of the top Yukawa coupling. The Higgs vacuum expectation values lead to $Z-Z'$ mass mixing, with a small mixing parameter given by

$$\begin{aligned} \epsilon &\equiv \frac{1}{M_{Z'}^2 - M_Z^2} \frac{g g_z}{2 \cos \theta_w} (z_d v_d^2 + z_u v_u^2) \\ &= \frac{(M_Z^0)^2}{M_{Z'}^2 - M_Z^2} \frac{2 g_z \cos \theta_w}{g} z_u \sin^2 \beta, \end{aligned} \quad (34)$$

where z_i are the Z' charges of the two Higgs doublets, and g and g_z related to the mass-squared values in absence of mixing $(M_Z^0)^2 = g^2(v_d^2 + v_u^2)/(4 \cos^2 \theta_w)$ and $(M_{Z'}^0)^2 = g_z^2(z_d^2 v_d^2 + z_u^2 v_u^2 + z_\phi^2 v_\phi^2)$.

(a) Leading b -jet transverse momentum

(b) Leading b -jet pseudorapidity

(c) Angular distance between the two leading b -jets

Fig. 44. Comparison of the kinematic distributions for the two leading b -jets (from the Higgs decay) in the vector Z' simplified model, when fixing the Z' mass to 100 GeV and varying the DM mass.

The production cross section for this model scales as $(g_z)^2$, as the decay width for this process to leading order in ϵ (Eq. (34)) is

$$\Gamma_{Z' \rightarrow h A^0} = (g_z \sin \beta \cos \beta)^2 \frac{|p|}{24\pi} \frac{|p|^2}{M_{Z'}^2}. \quad (35)$$

(a) Leading b -jet transverse momentum(b) Leading b -jet pseudorapidity(c) Angular separation of the two leading b -jets

Fig. 45. Comparison of the kinematic distributions for the two leading jets from the Higgs decay in the vector Z' simplified model, when fixing the Z' mass to 1000 GeV and varying the DM mass.

where the center of mass momentum for the decay products is

$$|p| = \frac{1}{2M_{Z'}} \sqrt{(M_{Z'}^2 - (m_h + m_{A^0})^2)(M_{Z'}^2 - (m_h - m_{A^0})^2)}. \quad (36)$$

Fig. 46. Missing transverse momentum distributions at generator level in the scalar mediator scenario, for different values of: the new physics coupling g_b (left), and the mediator-DM coupling g_χ (right).

The Z' can also decay to Zh , leading to the same signature if the Z decays invisibly. The partial width for this decay is:

$$\Gamma_{Z' \rightarrow hZ} = (g_z \sin \beta^2)^2 \frac{|p|}{24\pi} \left(\frac{|p|^2}{M_{Z'}^2} + 3 \frac{M_Z^2}{M_{Z'}^2} \right). \quad (37)$$

We recommend to generate these two decays separately and combine them at a later stage.

Parameter scan. The model is described by five parameters:

- the pseudoscalar mass M_{A^0} ,
- the DM mass m_χ ,
- the Z' mass, $M_{Z'}$,
- $\tan \beta (\equiv v_u/v_d)$,
- the Z' coupling strength g_z .

To study the signal production and kinematic dependencies on these parameters, we produced signal samples varying each of the five parameters through MADGRAPH5_AMC@NLO for the matrix element, PYTHIA 8 for the parton shower, and DELPHES [103] for a parameterized detector-level simulation.

Fig. 47. Missing transverse momentum distributions at generator level in the scalar mediator scenario: for different values of the mixing angle $\sin\theta$.

As seen in Fig. 51, variations of $\tan\beta$ does not lead to any kinematic difference and the production cross section simply scales as a function of $\tan\beta$. Hence we recommend to fix $\tan\beta$ to unity in the signal generation.

Similarly, variations of g_z do not lead to any kinematic changes. The value of g_z for a given $M_{Z'}$ and $\tan\beta$ can be set according to the maximum value allowed by electroweak global fits and dijet constraints, as described in [97]. Since this parameter does not influence the kinematics, we leave it up to individual analyses to decide whether they generate benchmark points only according to these external constraints.

Since the DM pair are produced as a result of the decay of A^0 , there are minimal kinematic changes when varying m_χ as long as $m_\chi < M_{A^0}/2$ so that A^0 production is on-shell, as shown in Figs. 52 and 53 (before detector simulation).

We recommend to produce signal events for a fixed $g_z = 0.8$, $\tan\beta = 1$ and $m_\chi = 100$ GeV. For these values, we scan the 2-D parameter space of $M_{Z'}$, M_{A^0} with $M_{Z'} = 600, 800, 1000, 1200, 1400$ GeV, and $M_{A^0} = 300, 400, 500, 600, 700, 800$ GeV with $M_{A^0} < M_{Z'} - m_h$, for a total of 24 points. The choice of scan is justified by the sensitivity study in [97]: the expected LHC sensitivity for Run-2 is up to $M_{Z'} \sim 1.5$ TeV. For the parameter scan, the DM mass is fixed to 100 GeV. For two $M_{Z'}$, M_{A^0} value sets, we vary the DM mass to obtain sample cross section for rescaling results. All LO cross sections for the various parameter scan points are reported on HEPData. The parameter scan excludes the off-shell region, as the cross-sections are suppressed and the LHC would not have any sensitivity to these benchmark points in early data.

The kinematic distributions with varying $M_{Z'}$ for fixed M_{A^0} are shown in Fig. 54, while the dependency on M_{A^0} is shown in Fig. 55.

This model also allows for an additional source of Higgs plus \cancel{E}_T signal with a similar kinematics (Fig. 56, shown with detector simulation samples) to the signal process from the decay of $Z' \rightarrow hZ$, where the Z decays invisibly. The partial decay width for the Z' is:

$$\Gamma_{Z' \rightarrow hZ} = (g_z \cos\alpha \sin\beta)^2 \frac{|p|}{24\pi} \left(\frac{|p|^2}{M_{Z'}^2} + 3 \frac{M_Z^2}{M_{Z'}^2} \right). \quad (38)$$

Fig. 48. Missing transverse momentum distributions at generator level in the scalar mediator scenario: for different values of the DM mass m_χ and a mediator mass of $M_{\text{med}} = 100$ GeV (left) and $M_{\text{med}} = 1$ TeV (right).

The values for the Z' masses scanned for those samples should follow those of the previous samples, namely values of $M_{Z'} = 600, 800, 1000, 1200, 1400$ GeV. This signal process has no M_A dependence.

3.2. EFT models with direct DM-boson couplings

The EFT operators considered in this section do not have an implementation of a simplified model completion for Dirac fermion Dark Matter available to date. They provide kinematic distributions that are unique to mono-boson signatures, and that in most cases are not reproduced by an equivalent simplified model.¹¹

A complete list of effective operators with direct DM/boson couplings for Dirac DM, up to dimension 7, can be found in [45, 98, 99]. Higher dimensional operators, up to dimension 8, leading

¹¹ Wherever this is the case, for practical reasons one can only generation a simplified model result in the limiting EFT case, as the results can be rescaled and reinterpreted.

to Higgs+ \cancel{E}_T signatures, are mentioned in [45,97]. The first part of this Section outlines the main characteristics for a limited number of these models that could be considered in early Run-2 searches. However, the EFT approximation made for these operators can be

problematic, see Ref. [97] for discussion. For this reason, model-independent results as in Appendix B should be privileged over considering these operators as realistic benchmarks.

However, the Forum discussion highlighted that the EFT approach allows more model-independence when reinterpreting results, and that it is worth still considering interpretation of the

results available in terms of these operators. Furthermore, once simplified models are available for those operators, EFT results can be used as a limiting case for consistency checks. We devote the end of this Section to a discussion on the presentation of results from this model, including an assessment of their reliability using a conservative procedure that is only dependent on EFT parameters.

The studies in this Section have been performed using a UFO model within MADGRAPH5_AMC@NLO v2.2.3, interfaced to PYTHIA 8 for the parton shower. The implementation of these models is discussed further in Section 4.2.2.

3.2.1. Dimension 5 operators

The lowest dimension benchmark operators we consider are effective dimension 5, such as the one depicted in Fig. 57.

Following the notation of [45], models from this category have a Lagrangian that, after electroweak symmetry breaking, includes terms such as:

$$\frac{m_W^2}{\Lambda_5^3} \bar{\chi} \chi W^{+\mu} W_\mu^- + \frac{m_Z^2}{2\Lambda_5^3} \bar{\chi} \chi Z^\mu Z_\mu, \quad (39)$$

where m_Z and m_W are the masses of the Z and W boson, W^μ and Z^μ are the fields of the gauge bosons, χ denotes the Dark Matter

fields and Λ_5 is the effective field theory scale. Note that these operators are of true dimension 7, but reduce to effective dimension 5 once the Higgs vacuum expectation values, contained in the W and Z mass terms, are inserted. As such, one expects that these operators would naturally arise in UV complete models where Dark Matter interacts via a Higgs portal where heavy mediators couple to the Higgs or other fields in an extended Higgs sector. In such models the full theory may be expected to contain additional operators with Higgs-Dark Matter couplings [104]. The above operator also induces signatures with \cancel{E}_T in conjunction with Z and W bosons at tree level, as shown in Fig. 38, while at loop level it induces couplings to photon pairs and $Z\gamma$ through W loops. In these models, a clear relation exists between final states with photons, EW bosons and Higgs boson.

As shown in Fig. 58, the kinematics of this model can be approximated by that of a simplified model including a high-mass scalar mediator exchanged in the s -channel described in Section 2.2.2. For this reason, the list of benchmark models with direct boson-DM couplings for photon, Z and W only includes dimension 7 operators: if the scalar model with initial state radiation of an EW boson is already generated, then its results can be rescaled.

Fig. 53. Missing transverse momentum distributions at generator level in the $Z' + 2\text{HDM}$ scenario for different values of the DM mass m_χ , with $m_{Z'} = 1$ TeV and $m_{A^0} = 300$ GeV (left) and $m_{A^0} = 1$ TeV (right).

The Higgs+ \cancel{E}_T analysis, however, will not consider the scalar simplified model as benchmark, due to the very low sensitivity in early LHC analyses, and will instead use this dimension 5 operator.

Parameter scan. The two parameters of this model are the scale of new physics λ and the DM particle mass. SM-DM coupling and new physics scale are related by $g_\chi = (246 \text{ GeV})/\lambda$.

The initial value of the new physics scale λ chosen for the sample generation is 3 TeV. This is a convention and does not affect the signal kinematics: the cross-section of the samples can be rescaled when deriving the constraints on this scale. However, more care should be given when rescaling Higgs+ \cancel{E}_T operators of higher dimensions, as different diagrams have a different λ dependence.

The DM mass values for the benchmark points to be simulated are chosen to span a sufficient range leading to different kinematics, that is within the LHC sensitivity for early searches and that is consistent across the various signatures and EFT operators.

(c) $\Delta\phi$ distance between the two b -jets

Fig. 54. Kinematic distributions of the signal process varying $M_{Z'}$, for $m_\chi = 100$ GeV, $M_{A^0} = 300$ GeV.

We therefore start the mass scan at $m_\chi = 1$ GeV, where collider experiments are complementary to direct and indirect detection and choose the last point corresponding to a DM mass of 1.3 TeV. We recommend a scan in the following mass points:

$m_\chi = 1, 10, 50, 100, 200, 400, 800, 1300$ GeV.

A set of kinematic distributions from the Higgs+ \cancel{E}_T signature where the Higgs decays into two b -quarks is shown in Fig. 59, for points similar to those of the grid scan proposed.

3.2.2. Dimension 7 operators

The dimension-7 benchmark models contain the $SU(2)_L \times U(1)_Y$ gauge-invariant couplings between DM fields and the kinetic terms of the EW bosons. The CP-conserving scalar couplings

Fig. 57. Diagram for EFT operators giving rise to a Higgs+ \cancel{E}_T signature.

Fig. 58. Comparison of the missing transverse momentum for the simplified model where a scalar mediator is exchanged in the s -channel and the model including a dimension-5 scalar contact operator, in the leptonic $Z + \cancel{E}_T$ final state. All figures in this Section have been performed using a UFO model within MADGRAPH5_AMC@NLO v2.2.3, interfaced to PYTHIA 8 for the parton shower.

of this type can be written as

$$\frac{c_1}{\Lambda_S^3} \bar{\chi} \chi B_{\mu\nu} B^{\mu\nu} + \frac{c_2}{\Lambda_S^3} \bar{\chi} \chi W_{\mu\nu}^i W^{i,\mu\nu}. \quad (40)$$

Here $B_{\mu\nu} = \partial_\mu B_\nu - \partial_\nu B_\mu$ and $W_{\mu\nu}^i = \partial_\mu W_\nu^i - \partial_\nu W_\mu^i + g_2 \epsilon^{ijk} W_\mu^j W_\nu^k$ are the $U(1)_Y$ and $SU(2)_L$ field strength tensor, respectively, and g_2 denotes the weak coupling constant. In the case of the pseudoscalar couplings, one has instead

$$\frac{c_1}{\Lambda_P^3} \bar{\chi} \gamma_5 \chi B_{\mu\nu} \tilde{B}^{\mu\nu} + \frac{c_2}{\Lambda_P^3} \bar{\chi} \gamma_5 \chi W_{\mu\nu}^i \tilde{W}^{i,\mu\nu}, \quad (41)$$

where $\tilde{B}_{\mu\nu} = 1/2 \epsilon_{\mu\nu\lambda\rho} B^{\lambda\rho}$ and $\tilde{W}_{\mu\nu}^i = 1/2 \epsilon_{\mu\nu\lambda\rho} W^{i,\lambda\rho}$ are the dual field strength tensors. In addition to the CP-conserving interactions (40) and (41), there are also four CP-violating couplings that are obtained from the above operators by the replacement $\bar{\chi} \chi \leftrightarrow \bar{\chi} \gamma_5 \chi$.

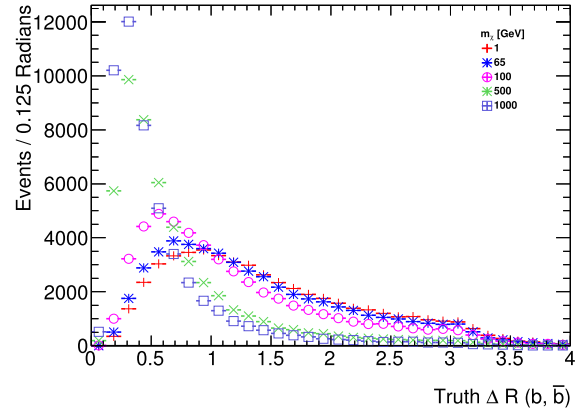

The effective interactions introduced in (40) and (41) appear in models of Rayleigh DM [105]. Ultraviolet completions where the operators are generated through loops of states charged under $U(1)_Y$ and/or $SU(2)_L$ have been proposed in [106] and their LHC signatures have been studied in [107]. If these new charged particles are light, the high- p_T gauge bosons that participate in the \cancel{E}_T processes considered here are able to resolve the substructure of the loops. This generically suppresses the cross sections compared to the EFT predictions [108], and thus will weaken the

bounds on the interaction strengths of DM and the EW gauge bosons to some extent. Furthermore, the light charged mediators may be produced on-shell in pp collisions, rendering direct LHC searches potentially more restrictive than \cancel{E}_T searches. Making the above statements precise would require further studies beyond the timescale of this forum.

Since for $\Lambda_S = \Lambda_P$ the effective interactions (40) and (41) predict essentially the same value of the mono-photon, mono-Z and mono-W cross section [45,99], we consider below only the former couplings. We emphasize however that measurements of the jet-jet azimuthal angle difference in $\cancel{E}_T + 2j$ events may be used to disentangle whether DM couples more strongly to the combination $B_{\mu\nu} B^{\mu\nu}$ ($W_{\mu\nu}^i W^{i,\mu\nu}$) or the product $B_{\mu\nu} \tilde{B}^{\mu\nu}$ ($W_{\mu\nu}^i \tilde{W}^{i,\mu\nu}$) of field strength tensors [98,99].

After EW symmetry breaking the interactions (40) induce direct couplings between pairs of DM particles and gauge bosons. The corresponding Feynman rule reads:

$$\frac{4i}{\Lambda_S^3} g_{V_1 V_2} (p_1^{\mu_2} p_2^{\mu_1} - g^{\mu_1 \mu_2} p_1 \cdot p_2), \quad (42)$$

where p_i (μ_i) denotes the momentum (Lorentz index) of the vector field V_i and for simplicity the spinors associated with the DM fields have been dropped. The couplings $g_{V_1 V_2}$ take the form:

$$\begin{aligned} g_{\gamma\gamma} &= c_w^2 c_1 + s_w^2 c_2, \\ g_{\gamma Z} &= -s_w c_w (c_1 - c_2), \\ g_{ZZ} &= s_w^2 c_1 + c_w^2 c_2, \\ g_{WW} &= c_2, \end{aligned} \quad (43)$$

with s_w (c_w) the sine (cosine) of the weak mixing angle. Note that our coefficients c_1 and c_2 are identical to the coefficients C_B and C_W used in [99], while they are related via $k_1 = c_w^2 c_1$ and $k_2 = s_w^2 c_2$ to the coefficients k_1 and k_2 introduced in [45].

The coefficients c_1 and c_2 appearing in (43) determine the relative importance of each of the \cancel{E}_T channels and their correlations. For example, one observes that:

- Only c_2 enters the coupling between DM and W bosons, meaning that only models with $c_2 \neq 0$ predict a mono- W signal;
- If $c_1 = c_2$ the mono-photon (mono- Z) signal does not receive contributions from diagrams involving Z (photon) exchange;
- Since numerically $c_w^2/s_w^2 \simeq 3.3$ the mono-photon channel is particularly sensitive to c_1 .

Parameter scan. As stated above and shown in Ref. [100], the kinematic distributions for dimension-7 scalar and pseudoscalar operators only shows small differences. This has been verified from a generator-level study: the signal acceptance after a simplified analysis selection ($\cancel{E}_T > 350$ GeV, leading jet $p_T > 40$ GeV, minimum azimuthal angle difference between either of the two jets and the \cancel{E}_T direction > 0.4) is roughly 70% for both models, independent from the coefficients c_1 and c_2 . We therefore only suggest to generate one of the two models.

The differences in kinematics for the various signatures are negligible when changing the coefficients c_1 and c_2 , since these coefficient factorize in the matrix element. Only the case $c_1 = c_2 = 1$ is generated as benchmark; other cases are left for reinterpretation as they will only need a rescaling of the cross-sections (see Fig. 60).

3.2.3. Higher dimensional operators

Many higher dimensional operators can induce signals of photons or $W/Z/H$ bosons in the final state. A complete list can be found in Refs. [47,48,97] and references therein.

Although with lower priority with respect to the operators above, a representative dimension-8 operators can be chosen as benchmark, with the form:

$$\frac{1}{\Lambda^4} \bar{\chi} \gamma^\mu \chi B_{\mu\nu} H^\dagger D^\nu H.$$

Fig. 60. \cancel{E}_T distribution for the dimension-7 model with a hadronically decaying Z in the final state, for the scalar and pseudoscalar operators representing direct interactions between DM and bosons. The values of the coefficients in the legend are multiplied by 100.

In this case, the new physics scale is Λ is related to the coupling of the DM as $y_\chi = \frac{1}{\Lambda^4}$. An advantage of this operator is that it includes all signatures with EW bosons, allowing to assess the relative sensitivity of the various channels with the same model. The kinematics for this operator is different with respect to other operators, leading to a harder \cancel{E}_T spectrum, as illustrated by comparing the leading b -jet distribution for the dimension 5 operator to the dimension 8 operator (see Fig. 61).

3.2.4. Validity of EW contact operators and possible completions

It is important to remember that the operators described in this section may present problems in terms of the validity of the contact interaction approach for the energy scales reached at the LHC.

As outlined in [97], designing very high \cancel{E}_T search signal regions that are exclusively motivated by the hard \cancel{E}_T spectra of the dimension 7 and 8 operators will mean that the momentum transfer in the selected events is larger. This in turn means that processes at that energy scale (mediators, particles exchanged in loops) are accessible, and a simple contact interaction will not be able to correctly describe the kinematics of these signals.

Contact interaction operators like the ones in this section remain useful tools for comparison of the sensitivity of different search channels, and for reinterpretation of other models under the correct assumptions. To date, while UV-complete models are known, their phenomenology has not been studied in full detail as their completion involves loops.¹²

However, this may be the focus of future theoretical exploration, as discussed in Ref. [99]. An example of a complete model for scalar DM corresponding to the dimension-5 operator is provided in the Appendix A. Providing results for the pure EFT limit of these models will prove useful to cross-check the implementation of future.

Given these considerations, we recommend to present results for these models as follows:

¹² An example case for the need of loop completions is a simplified model with an additional scalar exchanged at tree level. The scalar couples to WW and ZZ in a gauge-invariant way, Integrating out the mediator does not lead to the Lorentz structure of a dimension-7 operator, so it is not possible to generate dimension-7 operators that satisfy gauge and Lorentz invariance at the same time. A model with a spin-1 mediator cannot be considered as an candidate for completion either, since dimension-7 operators only have scalar or pseudoscalar couplings.

(a) Dimension 5 operator

(b) Dimension 7 operator

Fig. 61. Comparison of the transverse momentum for the leading b -jet from the Higgs decay for a dimension 5 and dimension 7 operator with direct boson-DM couplings.

- Deliver fiducial limits on the cross section of any new physics events, without any model assumption, according to the guidelines in [Appendix B](#).
- Assess the percentage of events that pass a condition of validity for the EFT approximation that does not depend on a specific completion, and present results removing of the invalid events using the procedure in [Section 5](#) alongside the raw EFT results.

4. Implementation of models

4.1. Implementation of s -channel and t -channel models for $\cancel{E}_T + X$ analyses

In the studies to date, a number of different Monte Carlo tools have been used to simulate DM signals. In this Chapter, we make recommendations on the accuracy at which simulations should be performed for different final states. We also provide explicit examples of codes and implementations (including specific settings) that have been used to obtain the results in this report. We stress that these recommendations are based on the current status of publicly available codes and users should always check whether new results at a better accuracy have appeared in the meantime. We recommend to update the corresponding analyses directly using the new releases and/or codes respectively, and in case this would not be possible, to at least take into account

the new information in the analysis (e.g., via a MC comparison with the latest predictions, or by effectively using global/local K -factors). For all models included in this report, PYTHIA 8 has been used to provide the parton shower simulation. Nevertheless, we note that showering matrix element events with Herwig [[109–112](#)] should be considered as an equally valid alternative.

4.1.1. Implementation of s -channel models for mono-jet signature

These models include those discussed in [Sections 2.1 and 2.2](#). In monojet analyses, i.e. when final states are selected with a few jets and \cancel{E}_T , observables and in particular the \cancel{E}_T spectrum depend upon the accuracy of the simulation of QCD radiation. For the vector and axial vector models, the current state of the art is NLO+PS. It is particularly simple to obtain simulations for these processes at NLO+PS and even for merged samples at NLO accuracy, starting from SM implementations. We therefore recommend simulations to be performed at NLO+PS, and in case multi-jet observables are employed, by merging samples with different multiplicities. Results at such accuracy can be obtained either in dedicated implementations, such as that of POWHEG [[61](#)], or via general purpose NLO tools like MADGRAPH5_AMC@NLO employing available UFO models at NLO. A testing version of the full set of these UFO models has been made available only in June 2015 [[113](#)]. For this reason, it was not used as part of the studies of this Forum on initial Run-2 benchmark models. Nevertheless, we encourage further study of these UFO models by the ATLAS and CMS collaborations.

A study using POWHEG [[61,114](#)] has shown that the NLO corrections result in a substantial reduction in the dependence on the choice of the renormalization and factorization scales and hence a reduced theoretical uncertainty on the signal prediction. For the central choice of renormalization and factorization scales, the NLO corrections also provide a minor enhancement in the cross section due to the jet veto that has been so far employed in Run-1 analyses.

For the scalar and pseudoscalar models, the lowest order process already involves a one-loop amplitude in QCD. Because of the complexity of performing NLO calculations for this class of processes and in particular the absence of general methods for computing two-loop virtual contributions, only LO predictions are currently available. These can be interfaced to shower programs exactly as usual tree-level Born computations, i.e. by considering one parton multiplicity at a time or by merging different parton multiplicities via CKKW or MLM schemes to generate inclusive samples with jet rates at LO accuracy. For spin-0 mediators in the mono-jet final state, the top-quark loop is the most important consideration. The matrix element implementation with exact top-loop dependence of the s -channel spin-0 mediated DM production is available in MCFM [[41,114](#)]¹³ at fixed order and in POWHEG [[43](#)] and MADGRAPH5_AMC@NLO [[113](#)] for event generation at LO+PS level. The POWHEG and MCFM implementations include the finite top quark mass dependence for DM pair production and one extra parton at LO. The same processes are available in MADGRAPH5_AMC@NLO v2.3 and could be made available in the future in codes like SHERPA+OPENLOOPS/GoSAM, including up to two extra partons in the final state. Samples can be merged employing CKKW, K_T -MLM procedures.

Most of the results that have been presented in this document for these processes have been obtained with POWHEG interfaced to PYTHIA 8, matching the state of the art calculation as of Spring 2015. For future reference, we document the specific settings needed to run the POWHEG generation for the dark matter models so they can serve as nominal benchmarks for the early Run-2

¹³ Only the scalar mediator is available in the public release.

ATLAS and CMS DM analyses. POWHEG parameter cards for all models can be found on the Forum Git repository [115–118].

POWHEG configuration for s-channel DM models. The latest POWHEG release is available for download using the instructions at <http://powhegbox.mib.infn.it/>. The Forum recommends using at least version 3059.

- POWHEG can generate either unweighted (uniformly-weighted) or weighted events. The relevant keywords in the input card are `bornsuppfact` and `bornktmin`.

1. unweighted events:

`bornsuppfact`: negative or absent
`bornktmin` PT

This runs the program in the most straightforward way, but it is likely not the more convenient choice, as will be explained below. POWHEG will generate unweighted events using a sharp lower cut (with value PT) on the leading-jet p_T . Since this is a generation cut, the user must check that the choice of `bornktmin` does not change the cross section for signal events passing analysis selections. It is a good practice to use 10–20% smaller \cancel{E}_T value in the input card than the final analysis selection, and check that the final result is independent, by exploring an even smaller value of `bornktmin`. The drawback of using this mode is that it is difficult to populate well, and in a single run, both the low- p_T region as well as the high- p_T tail.

2. weighted events:

`bornsuppfact` PTS
`bornktmin` PT

POWHEG will now produce weighted events, thereby allowing to generate a single sample that provides sufficient statistics in all signal regions. Events are still generated with a sharp lower cut set by `bornktmin`, but the `bornsuppfact` parameter is used to set the event suppression factor according to

$$F(k_T) = \frac{k_T^2}{k_T^2 + \text{bornsuppfact}^2}. \quad (44)$$

In this way, the events at, for instance, low \cancel{E}_T , are suppressed but receive higher weight, which ensures at the same time higher statistics at high \cancel{E}_T . We recommend to set `bornsuppfact` to 1000.

The `bornktmin` parameter can be used in conjunction with `bornsuppfact` to suppress the low \cancel{E}_T region even further. It is recommended to set `bornktmin` to one-half the value of the lowest \cancel{E}_T selection. For instance, for the event selection used in the CMS/ATLAS monojet analyses, assuming the lowest \cancel{E}_T region being defined above 300 GeV, the proposed value for `bornktmin` is 150. However, this parameter should be set keeping in mind the event selection of all the analyses that will use these signal samples, and hence a threshold lower than 150 may be required.

- The POWHEG monojet implementations can generate events using two expressions for the mediator propagators. The default setup (i.e if the keyword `runningwidth` is absent, commented out or set to 0) is such that a normal Breit-Wigner function is used for the propagator: in this case, the expression

$$Q^2 - M^2 + iM\Gamma$$

is used for the propagator's denominator, where Q is the virtuality of the mediator, and M and Γ are its mass and width, respectively. This is the more straightforward, simple and transparent option, and it was used for the Forum studies. It should be the method of choice, unless one approaches regions of parameter space where Γ/M starts to approach order 1 values. In those cases, a more accurate modeling (or at least a check of the validity of the fixed width approach) can be achieved by using a running width: by setting the `runningwidth` token to 1, POWHEG uses as the denominator of the mediator propagator the expression

$$Q^2 - M^2 + iQ^2 \frac{\Gamma}{M},$$

which is known to give a more realistic description. See Ref. [96] for a discussion.

- Set the parameters defining the bounds on the invariant mass of the dark matter pair, `mass_low` and `mass_high`, to -1 . In this way, POWHEG will assign values internally.
- The minimal values for `ncall1`, `itmx1`, `ncall2`, `itmx2` are 250 000, 5, 1 000 000, 5 for the vector model, respectively.
- The minimal values for `ncall1`, `itmx1`, `ncall2`, `itmx2` are 100 000, 5, 100 000, 5 for the scalar top-loop model, respectively.
- When NLO corrections are included (as for instance in the vector model), negative-weighted events could occur and should be kept in the event sample, hence `withnegweights` should be set to 1. If needed, their fraction can be decreased by setting `foldsci` and `foldy` to larger values (2 for instance). `foldphi` can be kept to 1.
- One should use the automatic calculation of systematic uncertainties associated with the choice of hard scale and PDFs as described in Section 6.
- `idDM` is the integer that identifies the DM particle in the Monte Carlo event record. This should be chosen so that other tools can process the POWHEG output properly.

POWHEG in itself is not an event generator and must be interfaced with a tool that provides parton showering, hadronization, etc. For some time, a PYTHIA 8 [119] interface has existed for POWHEG. The PYTHIA 8 runtime configuration is the following:

```
POWHEG: veto = 1
POWHEG: pTdef = 1
POWHEG: emitted = 0
POWHEG: pTemt = 0
POWHEG: pThard = 0
POWHEG: vetoCount = 100
SpaceShower: pTmaxMatch = 2
TimeShower: pTmaxMatch = 2
```

As always, it is recommended to use the latest PYTHIA 8 release, available at <http://home.thep.lu.se/torbjorn/Pythia.html>. At the time of this report, the latest version is 8. 209.

4.1.2. Merging samples with different parton multiplicities

For the models discussed in the previous section, it is important to calculate the hard process as accurately as possible in QCD. For many other signal models, the \cancel{E}_T signature depends more upon the production and decay of the mediator. In some cases, observables built in terms of the jets present in the final state are considered, relying on the assumption that inclusive samples accurate in higher jet multiplicities are available. In these cases, one can employ LO+PS simulations where different parton multiplicities are merged and then matched to parton shower, using schemes such as CKKW or MLM merging.

Here, we consider the example of an EFT model produced in association with up to 2 additional QCD partons. A Monte Carlo sample based on this method could be used in alternative to a NLO+PS sample for describing shapes and jet distributions (but not for the overall normalization which would still be at LO). The methodology described here could also be used for the t -channel model discussed in Section 2.3.

For the calculation of tree-level merged samples for DM signals, tools that can read UFO files and implement multi-parton merging should be employed, such that MADGRAPH5_AMC@NLO (+PYTHIA 8 or HERWIG++) and SHERPA [120]. In this report we have mostly employed MADGRAPH5_AMC@NLO.

MADGRAPH5_AMC@NLO provides a flexible and easy-to-use framework for implementing new models via the FEYNRULES package. MADGRAPH5_AMC@NLO can perform both LO and NLO calculations in QCD, matched/merged to parton showers [83]. For NLO ones, dedicated UFO model implementations at NLO should be used. Several UFO models at NLO are publicly available that although not developed specifically for DM, are suitable to make mode independent simulations at NLO accuracy, including multiparton merging via the FxFx technique [121]. A dedicated DM UFO implementation has been developed and it has been released as a testing version [113].

Merging events generated via matrix elements with different number of partons in the final state can be achieved by a judicious procedure that avoids double counting of the partons from matrix elements and parton showering. Several merging techniques are available. Based on some comparative studies [122], there is some advantage to using the CKKW-L merging scheme [123] implemented in PYTHIA 8. Alternatively, one can use the k_T -MLM scheme also available in PYTHIA 8.

Generation of the LHE file. The example presented here is a D5 EFT model, and includes tree-level diagrams with $\chi\bar{\chi}+0,1,2$ partons. We stress that MADGRAPH5_AMC@NLO, like POWHEG, is not in itself an event generator, but must be interfaced with an event generator through an LHE file. The production of the LHE file proceeds through setting the process parameters and the run parameters.

The process parameters are:

```
import model MODELNAME
generate pp > chi chi ~ [QCD] @0
add process pp > chi chi ~ j [QCD] @1
add process pp > chi chi ~ j j [QCD] @2
```

The runtime parameters are more numerous, and define the collider properties, PDF sets, etc. The specific parameters needed for matching are, for the example of CKKW-L matching:

```
icckw = 0
ktdurham = matching scale
dparameter = 0.4
dokt = T
ptj = 20
drjj = 0
mmjj = 0
ptj1min = 0
```

For different kinds of matching, a different choice of icckw and related parameters would be made.

Implementation of the CKKW-L merging. To illustrate the settings related to merging different multiplicities, the EFT D5 samples were generated with MADGRAPH5_AMC@NLO version 2.2.2 and showered in PYTHIA 8.201, using the Madgraph parameters in the previous section (Section 4.1.2).

The PYTHIA 8 parameters for the CKKW-L k_T -merging scheme are:

```
Merging: ktType = 1
Merging: TMS = matching scale
1000022: all = chi chi ~ 2 0 0 30.0 0.0 0.0 0.0 0.0 0.0
1000022: isvisible = false
Merging: doKTMerging = on
Merging: Process = pp > {chi, 1000022} {chi ~, -1000022}
Merging: nJetMax = 2
```

The matching scales should be the same for the generation and parton showering. In the model implementation, the particle data group ID 1000022 is used for weakly interacting dark matter candidates. Since this is a Majorana particle by default (with no corresponding anti-particle), and the model produces a DM Dirac fermion, the particle properties are changed accordingly. Also, the DM mass is set to 30 GeV. The Merging: Process command specifies the lowest parton emission process generated in MADGRAPH5_AMC@NLO and Merging: nJetMax = 2 gives the maximum number of additional parton emissions with respect to the lowest parton emission process.

In general, it is desired to take the hard parton emissions from the matrix element generation in MADGRAPH5_AMC@NLO and allow PYTHIA 8 to take care of soft emissions only. The transition between these two regimes is defined by the matching scale and its optimal value can be determined by studying the cross-section as a function of the number of jets (differential jet rates). The differential rates $\frac{dN_{i \rightarrow j}}{d \log_{10}(k_{\text{cut}})}$ give the number of events which pass from i jets to j jets as the k_T value increases beyond k_{cut} . An optimal matching scale should lead to smooth differential jet rates.

Two examples of differential jet rates, using matching scale 30 GeV and 80 GeV, from the EFT D5 sample generated as described in the previous section are given in Figs. 62 and 63, respectively. Although a kink is visible around the matching scale value in both cases, the 80 GeV scale leads to smoother distributions. In order to find the optimal matching scale, additional samples with matching scale 50, 70, and 90 GeV are generated as well and a detailed comparison of the differential jet rates close to the transition region is shown in Fig. 64. The largest differences among the samples are visible for the $1 \rightarrow 2$ jets transition where the 30 GeV and 50 GeV scale lead to a drop of the rates around the matching scale values. On the contrary, there is a hint of an increased rate around the matching scale value in the sample generated with the 90 GeV scale. Therefore, we recommend to use 80 GeV as the baseline matching scale.

The prescription for the event generation given in Section 4.1.2 starts with the emission of 0 partons and ends with maximum 2 partons in addition. Producing the samples separately allows to investigate the relative composition of the individual samples in various parts of the phase space. Fig. 65 shows the \cancel{E}_T distribution of the EFT D5 sample with the matching scale at 80 GeV. The plot reveals that the 0-parton sample gives the dominant contribution in the region below the matching scale value that rapidly decreases at higher \cancel{E}_T . Assuming the lowest analysis \cancel{E}_T cut in early Run-2 mono-jet analyses at 300 GeV, the generation of the 0-parton emission sample can be safely omitted as it only gives < 1% contribution at $\cancel{E}_T > 300$ GeV. For the 1- and 2-parton emission samples, one can use a generator cut on the leading parton p_T , ptj1min, in order to avoid generating low \cancel{E}_T events that are irrelevant for the analysis.

In order to describe the signal kinematics correctly and save time during MC production, the parton emissions will only be

Fig. 62. Distributions of differential jet rates $\frac{dN_{i \rightarrow j}}{d \log_{10}(k_{\text{cut}})}$ for EFT D5 sample with CKKW-L matching scale at 30 GeV. The 0-, 1- and 2-parton emission samples are generated separately and indicated in the plots as Prod 1, Prod 2 and Prod 3, respectively. A vertical line is drawn at the matching scale.

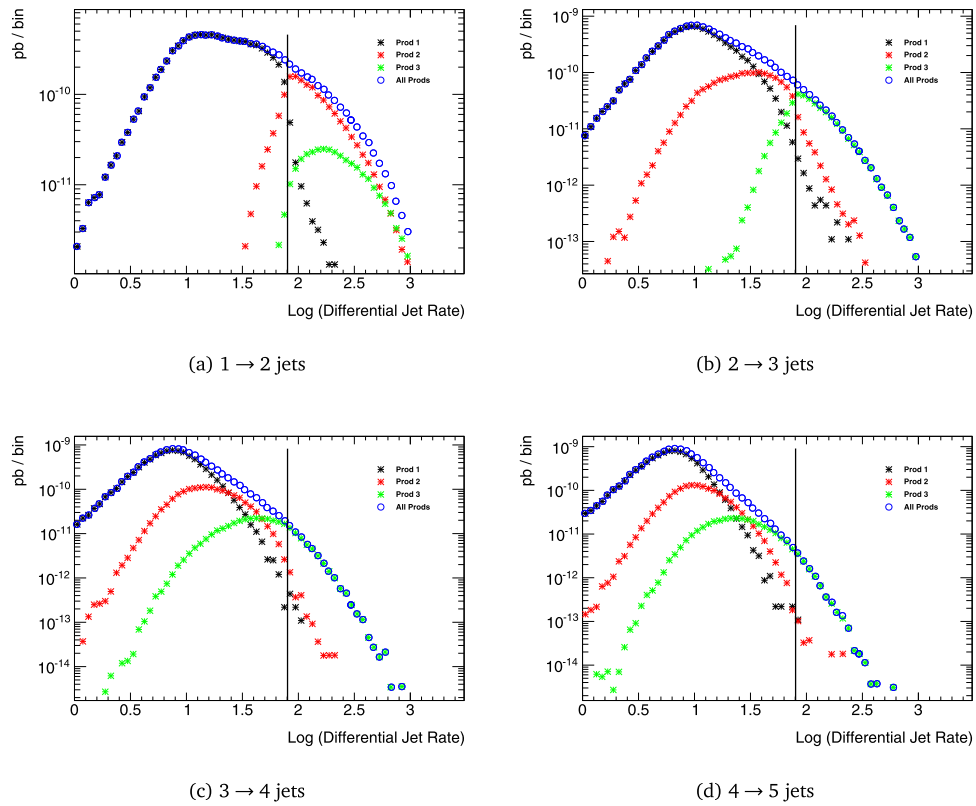

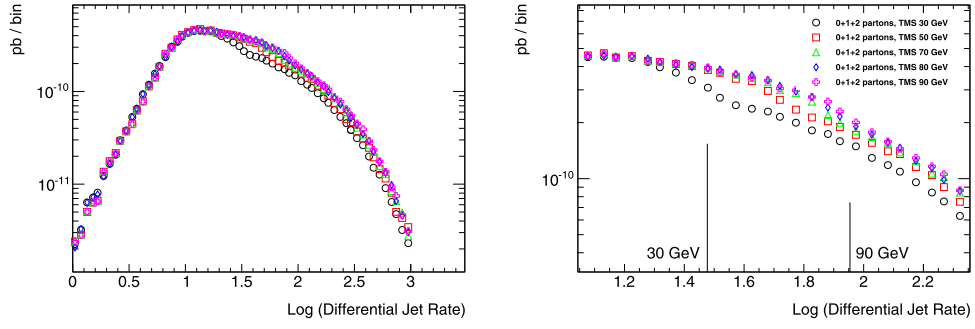

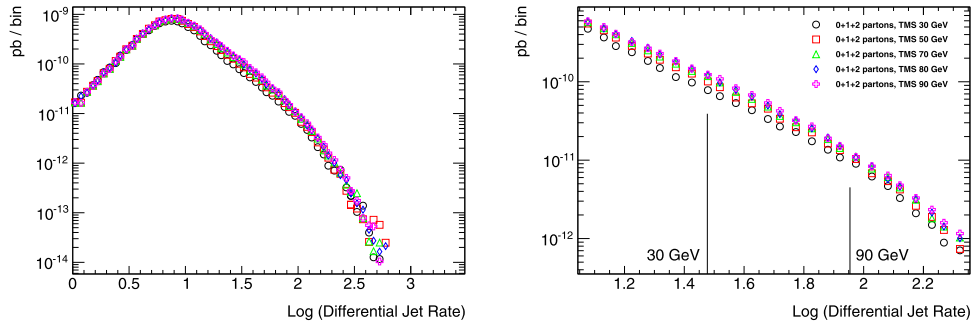

Fig. 63. Distributions of differential jet rates $\frac{dN_{i \rightarrow j}}{d \log_{10}(k_{\text{cut}})}$ for EFT D5 sample with CKKW-L matching scale at 80 GeV. The 0-, 1- and 2-parton emission samples are generated separately and indicated in the plots as Prod 1, Prod 2 and Prod 3, respectively. A vertical line is drawn at the matching scale.

Fig. 64. Distributions of differential jet rates $\frac{dN_{i \rightarrow j}}{d \log_{10}(k_{cut})}$ for EFT D5 sample with CKKW-L matching scale at 30, 50, 70, 80 and 90 GeV. A zoom of the region around the matching scale values is shown on right.

Fig. 65. Missing transverse momentum distributions for EFT D5 sample with CKKW-L matching scale at 80 GeV. Individual contributions from the 0-, 1- and 2-parton emission samples are shown.

generated up to a certain multiplicity. The higher multiplicity samples usually have small enough cross sections and the corresponding parts of the phase space can be sufficiently approximated by parton showering in PYTHIA 8. A dedicated study comparing samples generated with up to 1-, 2-, or 3-parton multiplicities was performed, using again the settings for the CKKW-L k_T -merging with the 80 GeV matching scale and the Merging:nJetMax parameter adjusted accordingly. Fig. 66 shows the \cancel{E}_T distribution of the samples at $\cancel{E}_T > 250$ GeV.

With an event selection requiring \cancel{E}_T and the leading jet p_T being larger than 250 GeV, the sample generated with up to 1 parton has 10.3% larger yield compared to the sample with up to 3 partons, while the yield of the sample with up to 2 partons is only 2.3% larger. If an additional cut is applied allowing for up to 3 jets with $p_T > 30$ GeV, the agreement improves to 3.2% larger for up to 1 parton and 0.7% larger for up to 2 partons, compared with up to 3 partons.

A similar comparison is shown in Fig. 67 for the jet multiplicity in the events with the leading jet $p_T > 250$ GeV, where an agreement at the level of $\sim 3\%$ between the samples with up to 2 and 3 parton emissions is observed for number of jets up to 7. This justifies it is sufficient to produce samples with up to 2 parton emissions only at the generator level and ignore generating higher parton emissions.

4.1.3. Implementation of t -channel models for the jet+ \cancel{E}_T final state

The simulations for t -channel models are available via LO UFO implementations, where events are generated at LO+PS accuracy. The UFO file and parameter cards for the t -channel models with couplings to light quarks only [78] can be found on the Forum Git repository [124]. The model files from Ref. [46] can also be found on the repository [125]. The latter is the implementation that has been used for the studies in this report: in the monojet case there are only cross section differences between this model and the model in [124].

Multi-parton simulation and merging are necessary and require particular care for this model: this has not been a topic of detailed studies within the Forum, and we suggest to follow the procedure outlined in Ref. [78].

4.1.4. Implementation of s -channel and t -channel models with EW bosons in the final state

Currently, simulations for most of these models are available via LO UFO implementations, allowing event generation at the

(a) No jet multiplicity cut

(b) $N_{\text{jet}} \leq 3$

Fig. 66. Missing transverse momentum distributions for EFT D5 sample with CKKW-L matching scale at 80 GeV produced with maximum 1 (black), 2 (red) and 3 (blue) partons emitted at the generator level. The ratios are shown with respect to the latter sample. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

LO+PS accuracy. We note, however, that inclusion of NLO corrections would be possible. In MADGRAPH5_AMC@NLO, for example, this amounts to simply upgrading the currently employed UFO models to NLO, where the calculations exist for this class of processes. However, this was not available within the timescale of the Forum towards simulation of early Run-2 benchmarks. As a consequence, in this work we have used LO UFO implementations within MADGRAPH5_AMC@NLO 2.2.3 interfaced to PYTHIA 8 for the parton shower. The corresponding parameter cards used for the Run-2 benchmark models can be found on the Forum Git repository [126]. This is the implementation that will be used for early Run-2 LHC Dark Matter searches.

None of these models requires merging samples with different parton multiplicities since the visible signal comes from the production of a heavy SM boson whose transverse momentum distribution is sufficiently well described at LO+PS level. As a result, no special runtime configuration is needed for PYTHIA 8.

Fig. 67. Multiplicity of jets with $p_T > 30$ GeV and $|\eta| < 2.8$ for EFT D5 sample with CKKW-L matching scale at 80 GeV produced with maximum 1 (black), 2 (red) and 3 (blue) partons emitted at the generator level. The ratios are shown with respect to the latter sample. The leading jet p_T is required to be larger than 250 GeV. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

4.1.5. Implementation of s -channel and t -channel models with heavy flavor quark signatures

Dedicated implementations for DM signals in this final state are available at LO+PS accuracy. However, the state of the art of the simulations for $t\bar{t}$ and $b\bar{b}$ with a generic scalar and vector mediator is NLO+PS accuracy. For example, simulations for $t\bar{t} + \text{scalar}$ can be obtained via POWHEG and SHERPA starting from the SM implementations. In MADGRAPH5_AMC@NLO, all final relevant final states, spin-0 (scalar and pseudo scalar) and spin-1, (vector and axial) are available at NLO+PS via the dedicated NLO UFO for DM has been released in June 2015 [113]).

Within the scope of the Forum, simulations for the $t\bar{t}$ and $b\bar{b}$ signatures of the scalar mediator model have been generated starting from a leading order UFO with MADGRAPH5_AMC@NLO 2.2.2, using PYTHIA 8 for the parton shower. The UFO file and parameter cards that will be used as benchmarks for early Run-2 searches in these final states can be found on the Forum Git repository [127]. Multi-parton merging has been used for the $b\bar{b}$ case but it has not been studied in detail within this Forum. The b -flavored DM model of Section 2.3.2 is simulated at LO+PS using MADGRAPH5_AMC@NLO v2.2.3 and PYTHIA 8 for the parton shower. The corresponding UFO and parameter files can be found on the Forum Git repository [128].

Quark flavor scheme and masses. In the case of $b\bar{b}$ final state an additional care should be taken when choosing the flavor scheme generation and whether quarks should be treated as massive or massless.

The production of $DM+b\bar{b}$, dark matter in association with b jets via a decay of a (pseudo) scalar boson, is dominated in simplified mediator models by the gluon–gluon initiated production, similar to the production of $Z+b\bar{b}$ at the LHC. The $Z+b\bar{b}$ process has been studied in detail in the $Z(\text{ll})+b$ -jets final state, which can be used to validate both the modeling of $DM+b\bar{b}$ and, its main background, $Z(\nu\nu)+b\bar{b}$. In this context, the p_T of the Z boson is related to the observed MET, whereas the b -jet kinematics determines the ratio of mono- b /di- b signatures in the detector.

For basic kinematic criteria applied to $Z+b\bar{b}$ production, this process leads in $\sim 90\%$ of the events to a signature with only 1 b -jet in the acceptance ($Z+1b$ -jet production’) and only in $\sim 10\%$ of the events to a signature with 2 b -jets in the detector ($Z+2b$ -jets

production’). The production cross section of the $Z+b\bar{b}$ process can be calculated in the ‘five-flavor scheme’, where b quarks are assumed massless, and the ‘four-flavor scheme’, where massive b quarks are used [129–131]. Data slightly favor the cross-section predictions in the five-flavor scheme [132] for the 1 b -jet signature. In this document we have preferred the 5-flavor scheme due to its simplicity and cross section agreement within the SM. The PDF used to calculate these cross section is NNPDF3.0 (lhaid 263000).

On the other hand, both data [132–134] and theoretical studies [135,136] suggest that the best modeling of an inclusive $Z+b\bar{b}$ sample especially for what concerns b -quark observables, is achieved at NLO+PS using a 4-flavor scheme and a massive treatment of the b -quarks. In Fig. 68 we show that, at LO, as expected, no appreciable difference is visible in the kinematics between either flavor scheme used for $DM+b\bar{b}$. In our generation we have used NNPDF3.0 set (lhaid 263400).

4.2. Implementation of specific models for $V + \cancel{E}_T$ analyses

4.2.1. Model implementation for mono-Higgs models

Currently, simulations for most of these models are available via LO UFO implementations, allowing event generation at the LO+PS accuracy. We note, however, that the inclusion of NLO corrections would be possible but not available in time for the conclusion of these studies. In MADGRAPH5_AMC@NLO, for example, this amounts to simply upgrading the currently employed UFO models to NLO. Simulation of loop-induced associated production of DM and Higgs is also possible with the exact top-quark mass dependence. In MADGRAPH5_AMC@NLO, for example, this can be obtained from the NLO UFO SM and 2HDM implementations.

In this work all three Higgs+ \cancel{E}_T models have been generated at leading order with MADGRAPH5_AMC@NLO 2.2.2, using PYTHIA 8 for the parton shower. No merging procedure has been employed. The LO UFO implementations of the scalar and vector models that will be used as early Run-2 benchmarks can be found on the Forum Git repository [137], while the 2HDM model can be found at this link [138].

As a final technical remark, we suggest always to let the shower program handle the h decay (and therefore to generate a stable h at the matrix element level). In so doing a much faster generation is achieved and the h branching ratios are more accurately accounted for by the shower program.

MADGRAPH5_AMC@NLO details for scalar mediator Higgs+MET model. The case of the associated production of a Higgs and scalar mediator via a top-quark loop can be either considered exactly or via an effective Lagrangian where the top-quark is integrated out. While this latter model has been shown not to be reliable [108,139,140], for simplicity we have chosen to perform the study in this tree-level effective formulation. A full study of the process including finite top-quark mass and parton shower effects is possible yet left for future work.

MADGRAPH5_AMC@NLO details for 2HDM Higgs+MET model. While a 2HDM UFO implementation at NLO accuracy to be used with MADGRAPH5_AMC@NLO has been made available at the end of the work of the Forum [113], in this work we have only considered LO simulations.

The two couplings that can be changed in the implemented model follow the nomenclature below:

- T_b - $\tan \beta$
- g_Z - g_z , gauge coupling of Z' to quarks

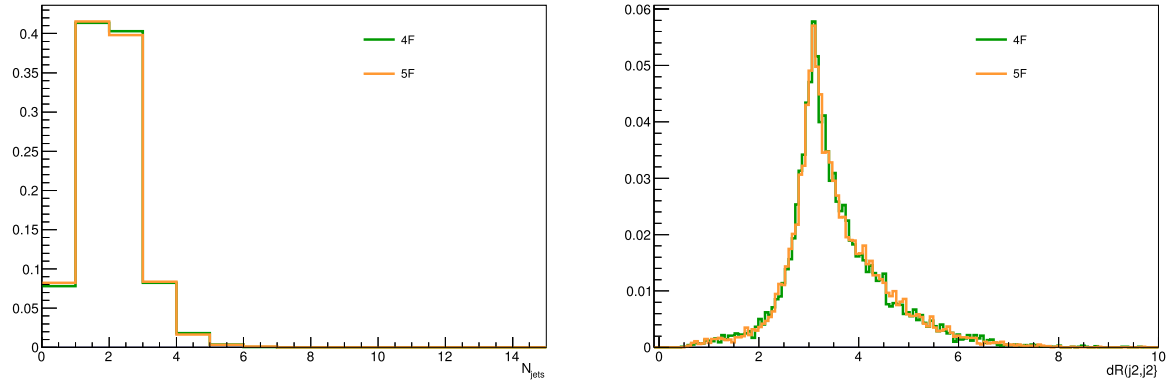

Fig. 68. Comparison of the jet multiplicity (left) and angular correction $\Delta R(j_1, j_2)$ (right) for the DM+ $b\bar{b}$ scalar model generated in the 4-flavor and 5-flavor schemes. The samples are generated for $m_\chi = 1$ GeV and $m_\phi = 10$ GeV.

The other couplings are not changed, including g_X (the $A\bar{\chi}\chi$ coupling) which has little impact on the signal. $\sin\alpha$ is fixed internally such that $\cos(\beta - \alpha) = 0$. The width of the Z' and A can be computed automatically within MADGRAPH5_AMC@NLO. The couplings here do not affect the signal kinematics, so they can be fixed to default values and then the signal rates can be scaled appropriately.

The nomenclature for the masses in the implemented model is:

- MZp - PDG ID 32 - Z'
- MA0 - PDG ID 28 - A
- MX - PDG ID 100022 - dark matter particle

The other masses are unchanged and do not affect the result. Both $Z' \rightarrow hZ(\bar{\nu}\nu)$ and $Z' \rightarrow hA(\bar{\chi}\chi)$ contribute to the final state, scaling different with model parameters. We recommend to generate them separately, and then add the two signal processes together weighted by cross sections.

4.2.2. Implementation of EFT models for EW boson signatures

The state of the art for these models is LO+PS. NLO+PS can be achieved as well, but the corresponding implementation is not yet available. In our simulations we have implemented the models in the corresponding UFO files and generated events at LO via MADGRAPH5_AMC@NLO 2.2.2, using PYTHIA 8 for the parton shower. UFO files and parameter cards that will be used as early Run-2 benchmarks can be found on the Forum Git repository: [137] for operators with Higgs+MET final states and [141] for $W/Z/\gamma$ final states. These models do not require merging.

5. Presentation of EFT results

Most of this report has focused on simplified models of dark matter. In this Chapter, we wish to emphasize the applicability of Effective Field Theories (EFTs) in the interpretation of DM searches at the LHC. Given our current lack of knowledge about the nature of a DM particle and its interactions, it appears mandatory to provide the necessary information for a model independent interpretation of the collider bounds. This approach should be complemented with an interpretation within a choice of simplified models. We note that, even though EFT benchmarks are only valid in given conditions, the results provided by the current list of simplified models cannot always characterize the breadth of SM-DM interactions. In at least one case, composite WIMPs [142–144], the contact interaction framework is the correct one to constrain new confinement scales.

Ideally, experimental constraints should be shown as bounds of allowed signal events in the kinematic regions considered for

the search, as detailed in Appendix B. A problematic situation is the attempt to derive a limit on nucleon–dark matter scattering cross sections from EFT results based on collider data.¹⁴ Experiments that directly probe the nucleon–dark matter scattering cross section are testing the regime of small momentum transfers, where the EFT approximation typically holds. Collider experiments, though, are sensitive to large momentum transfers: We first illustrate the complications that can arise with EFTs at colliders by considering an effective interaction

$$\mathcal{L}_{\text{int}} = \frac{(\bar{q}\gamma_\mu q)(\bar{\chi}\gamma^\mu \chi)}{M_*^2} = (\bar{q}\gamma_\mu q)(\bar{\chi}\gamma^\mu \chi) \frac{g}{\Lambda^2}$$

that couples quarks and DM χ fields.¹⁵ The strength of this interaction is parameterized by $\frac{1}{M_*^2} = \frac{g}{\Lambda^2}$. A monojet signature can be generated from this operator by applying perturbation theory in the QCD coupling. An experimental search will place a limit on M_* . For a fixed M_* , a small value of g will correspond to a small value of Λ . The EFT approximation breaks down if $Q > \Lambda$, where Q is a typical hard scale of the process. The limit on small g can only be reliable if the kinematic region $Q > \Lambda$ is removed from the event generation. However, if a fraction of events is removed from the prediction, the corresponding value of g must increase to match the experimental limit on M_* . On the other hand, if, for the same value of M_* , a large Λ is assumed so that the full set of events fulfill the EFT validity condition, a larger value of g is required. For large enough g , computations based on perturbation theory become unreliable.

In the first part of this Chapter, we summarize two methods that have been advocated to truncate events that do not fulfill the condition necessary for the use of an EFT. These methods are described in detail in Refs. [7,28,80,97,145,146]. We then propose a recommendation for the presentation of EFT results for early Run-2 LHC searches.

5.1. Procedures for the truncation of EFT benchmark models

5.1.1. EFT truncation using the momentum transfer and information on UV completion

In the approach described in Ref. [145], the EFT prediction is modified to incorporate the effect of a propagator for a relatively

¹⁴ Comparisons between constraints from different experiments meant to highlight their complementarity should be expressed as a function of the model parameters rather than on derived observables; however this is a point that should be developed further after the conclusion of the work of this Forum.

¹⁵ The exact operator chosen is not important: as detailed in the following, statements concerning the applicability of an EFT can also be made without a specific relation to simplified models.

light mediator. For a tree-level interaction between DM and the SM via some mediator with mass M_{med} , the EFT approximation corresponds to expanding the propagator for the mediator in powers of $Q_{\text{tr}}^2/M_{\text{med}}^2$, truncating at lowest order, and combining the remaining parameters into a single parameter M_* (connected to the scale of the interaction Λ in the literature). For an example scenario with a Z' -type mediator (leading to some combination of operators D5 to D8 in the notation of [23] for the EFT limit), this corresponds to setting

$$\frac{g_\chi g_q}{Q_{\text{tr}}^2 - M_{\text{med}}^2} = -\frac{g_\chi g_q}{M_{\text{med}}^2} \left(1 + \frac{Q_{\text{tr}}^2}{M_{\text{med}}^2} + \mathcal{O}\left(\frac{Q_{\text{tr}}^4}{M_{\text{med}}^4}\right) \right) \simeq -\frac{1}{M_*^2}, \quad (45)$$

where Q_{tr} is the momentum carried by the mediator, and g_χ , g_q are the DM-mediator and quark-mediator couplings respectively.¹⁶ A minimal condition that must be satisfied for this approximation to be valid is that $Q_{\text{tr}}^2 < M_{\text{med}}^2 = g_\chi g_q M_*^2$. This requirement avoids the regions: $Q_{\text{tr}}^2 \sim M_{\text{med}}^2$, in which case the EFT misses a resonant enhancement; and $Q_{\text{tr}}^2 \gg M_{\text{med}}^2$, in which case the signal cross section should fall according to a power of Q_{tr}^{-1} instead of M_{med}^{-1} . The latter is the problematic kinematic region.

The condition $Q_{\text{tr}}^2 < M_{\text{med}}^2 = g_\chi g_q M_*^2$ was applied to restrict the kinematics of the signal and remove events for which the high-mediator-mass approximation made in the EFT would not be reliable. This leads to a smaller effective cross-section, after imposing the event selection of the analysis. This truncated signal was then used to derive a new, more conservative limit on M_* as a function of $(m_\chi, g_\chi g_q)$.

For the example D5-like operator, where the cross section σ scales as M_*^{-4} , there is a simple rule for converting a rescaled cross section into a rescaled constraint on M_* if the original limit is based on a simple cut-and-count procedure. Defining $\sigma_{\text{EFT}}^{\text{cut}}$ as the cross section truncated such that all events pass the condition $\sqrt{g_\chi g_q} M_*^{\text{rescaled}} > Q_{\text{tr}}$, we have

$$M_*^{\text{rescaled}} = \left(\frac{\sigma_{\text{EFT}}}{\sigma_{\text{EFT}}^{\text{cut}}(M_*^{\text{rescaled}})} \right)^{1/4} M_*^{\text{original}}, \quad (46)$$

which can be solved for M_*^{rescaled} via either iteration or a scan. Similar relations exist for a given UV completion of each operator.

This procedure has been proposed in Ref. [145] and its application to ATLAS results can be found in Ref. [7] for a range of operators. We reiterate: knowledge of the UV completion for a given EFT operator was necessary for this procedure; this introduces a model-dependence that was not present in the non-truncated EFT results.

Currently, simplified models (including the full effect of the mediator propagator) are available for comparison with the data, and since knowledge of the simplified models is needed for the truncation procedure, there is no reason to apply this prescription. Instead, the simplified model limit for large M_* can be presented for interpretation in terms of EFT operators.

5.1.2. EFT truncation using the center of mass energy

The procedure presented in the previous section was predicated on some knowledge of the simplified model. This led to the identification of the mass of the DM pair as the relevant kinematic quantity to use in a truncation procedure. In general, if no assumption is made about the underlying dynamics, it is more conservative to place a limit on the total center of mass energy E_{cm} of the DM production process. Furthermore, the direct

connection between the mass scale of the EFT validity, M_{cut} , and the mass scale that normalizes the EFT operator, M_* , is unknown. For such cases, Refs.[97,146] proposed a procedure to extract model independent and consistent bounds within the EFT that can be applied to any effective Lagrangian describing the interactions between the DM and the SM. This procedure provides conservative limits that can be directly reinterpreted in any completion of the EFT. The condition ensuring that the EFT approximation is appropriate is:

$$E_{\text{cm}} < M_{\text{cut}}. \quad (47)$$

The relationship between M_{cut} and M_* can be parameterized by an *effective coupling strength* g_* , such that $M_{\text{cut}} = g_* M_*$. A scan over values of g_* provides an indication of the sensitivity of the prediction to the truncation procedure. In the Z' -type model considered above, g_* is equal to $\sqrt{g_\chi g_q}$. The resulting plots are shown in [146] for a particular effective operator.

The advantage of this procedure is that the obtained bounds can be directly and easily recast in any completion of the EFT, by computing the parameters M_* , M_{cut} in the full model as functions of the parameters of the complete theory. On the other hand, the resulting limits will be weaker than those obtained using Q_{tr} and a specific UV completion.

5.1.3. Truncation at the generator level

The conditions on the momentum transfer can also be applied directly at the generator level, by discarding events that are invalid and calculating the limits from this truncated shape. This provides the necessary rescaling of the cross section while keeping the information on the change in the kinematic distributions due to the removal of the invalid events. This procedure is more general with respect to rescaling the limit in the two sections above, and it should be followed if a search is not simply a counting experiment and exploits the shapes of kinematic distributions.

5.1.4. Sample results of EFT truncation procedures

An example of the application of the two procedures to the limit on M_* from Ref. [14] as a function of the product of the couplings is shown in Fig. 69. Only the region between the dashed and the solid line is excluded. It can be seen that the procedure from [146] outlined in Section 5.1.2, shown in blue, is more conservative than the procedure from Refs. [7,145], described in Section 5.1.1.

5.1.5. Comments on unitarity considerations

A further consideration applicable to EFT operators at hadron colliders is the potential violation of unitarity. An analysis of the operator $\frac{\bar{q}\gamma_\mu q \bar{\chi}\gamma^\mu \chi}{M_*^2}$ provides the limit:

$$M_* > \beta(s) \sqrt{s} \sqrt{\frac{\sqrt{3}}{4\pi}}, \quad (48)$$

where \sqrt{s} is (maximally) the collider energy and $\beta(s)$ is the DM velocity [24]. Constraints for other operators have also been derived [147]. This constraint on M_* still is open to interpretation, since the relation to M_{cut} is not resolved, except for a specific simplified model. Derived limits on M_* should be compared to this unitarity bound to check for consistency.

5.2. Recommendation for presentation of EFT results

In this report, we make two recommendations for the presentation of collider results in terms of Effective Field Theories for the upcoming Run-2 searches. A full discussion of the presentation of

¹⁶ Here, we ignore potential complications from the mediator width when the couplings are large.

Fig. 69. 95% CL lower limits on the scale of the interaction of the D5 operator at 14 TeV, after the two truncation procedures. The procedure from [146] outlined in Section 5.1.2 is shown in blue, while the procedure from Refs. [7,145], described in Section 5.1.1 is shown in red. Only the region between the dashed and the solid lines is excluded. Even though the intersection between the two lines is not shown in this plot, it should be noted that no limit can be set anymore for sufficiently low couplings, whatever truncation method is used.

collider results in relation to other experiments is left to work beyond this Forum, where ATLAS, CMS, the theory community and the Direct and Indirect Detection communities are to be involved.

We divide the EFT operators in two categories: those that can be mapped to one or more UV-complete simplified models, such as those commonly used in LHC searches so far and detailed in [23], and those for which no UV completion is available to LHC experiments, such as those outlined in Section 3.2.

5.2.1. EFT benchmarks with corresponding simplified models

If a simplified model can be mapped to a given EFT, then the model's high-mediator-mass limit will converge to the EFT. A study of 14 TeV benchmarks for narrow resonances with $g_q = 0.25$ and $g_\chi = 1$ (see Section 2.1.1) shows that a mediator with a mass of at least 10 TeV fully reproduces the kinematics of a contact interaction and has no remaining dependence on the presence of a resonance. A comparison of the main kinematic variables for the s -channel vector mediator model with a width of $0.1 M_{\text{med}}$ is shown in Fig. 70.¹⁷

As already observed in Section 2.1.1, varying the DM mass changes the kinematics, both in the simplified model and in the EFT case. This can be seen in Fig. 71.

Based on these studies, the Forum recommends experimental collaborations to add one grid scan point at very high mediator mass (10 TeV) to the scan, for each of the DM masses for the s -channel simplified models described in Section 2. This will allow to reproduce the results of an equivalent contact interaction as a simple extension of the existing parameter scan.

It should be checked that the high-mass mediator case for the simplified model is correctly implemented

5.2.2. EFT benchmarks with no corresponding simplified models

Whenever a UV completion is not available, an EFT still captures a range of possible theories beyond the simplified models that we already consider. However, in the case of the dimension-7

operators detailed in Section 3.2 we can only roughly control how well the EFT approximation holds, as described in Section 3.2.4. Despite the fact that a propagator was introduced to motivate the truncation procedure for s -channel models, the prescription from Section 5.2.1 depends upon the simplified model to derive the energy scaling that is used for the comparison with the momentum transfer. The simple fact remains that the effective coupling of the operator $-g/\Lambda^n$ should not allow momentum flow $Q > \Lambda$ or $g > 4\pi$. Given our ignorance of the actual kinematics, the truncation procedure recommended for this purpose is the one described in Section 5.1.2, as it is independent from any UV completion details.

Because there is no UV completion, the parameter M_{cut} can be treated more freely than an explicit function of g and Λ . It makes sense to choose M_{cut} such that we identify the transition region where the EFT stops being a good description of UV complete theories. This can be done using the ratio R , which is defined as the fraction of events for which $\hat{s} > M_{\text{cut}}^2$. For large values of M_{cut} , no events are thrown away in the truncation procedure, and $R = 1$. As M_{cut} becomes smaller, eventually all events are thrown away in the truncation procedure, i.e. $R = 0$, and the EFT gives no exclusion limits for the chosen acceptance.

We propose a rough scan over M_{cut} , such that we find the values of M_{cut} for which R ranges from 0.1 to 1. The analysis can then perform a scan over several values of M_{cut} , and show the truncated limit for each one of them.

6. Evaluation of signal theoretical uncertainties

A comprehensive and careful assessment of signal theoretical uncertainties plays in general a more important role for the background estimations (especially when their evaluation is non-entirely data-driven) than it does for signal simulations. Nevertheless, also for signal samples theoretical uncertainties are relevant, and may become even dominant in certain regions of phase space.

The uncertainties on the factorization and renormalization scales are assessed by the experimental collaborations by varying the original scales of the process by factors of 0.5 and 2. The evaluation of the uncertainty on the choice of PDF follows the PDF4LHC recommendation [148] of considering the envelope of different PDF error sets, in order to account for the uncertainty on the various PDFs as well as the uncertainty on the choice of the central value PDF. The Forum has not discussed the uncertainties related to the merging of different samples, nor the uncertainty due to the choice of the modeling of the parton shower. This Chapter provides technical details on how scale and PDF uncertainties can be assessed for events generated with POWHEG and MADGRAPH5_AMC@NLO.

6.1. POWHEG

When using POWHEG [69–71], it is possible to study scale and PDF errors for the dark matter signals. A fast reweighting machinery is available in POWHEG-BOX that allows one to add, after each event, new weights according to different scale or PDF choices, without the need to regenerate all the events from scratch.

To enable this possibility, the variable `storeinfo_rwgt` should be set to 1 in the POWHEG input file when the events are generated for the first time.¹⁸ After each event, a line starting with

```
#rwgt
```

¹⁷ The use of a fixed width rather than the minimal width is exclusive of these plots.

¹⁸ Notice that even if the variable is not present, by default it is set to 1.

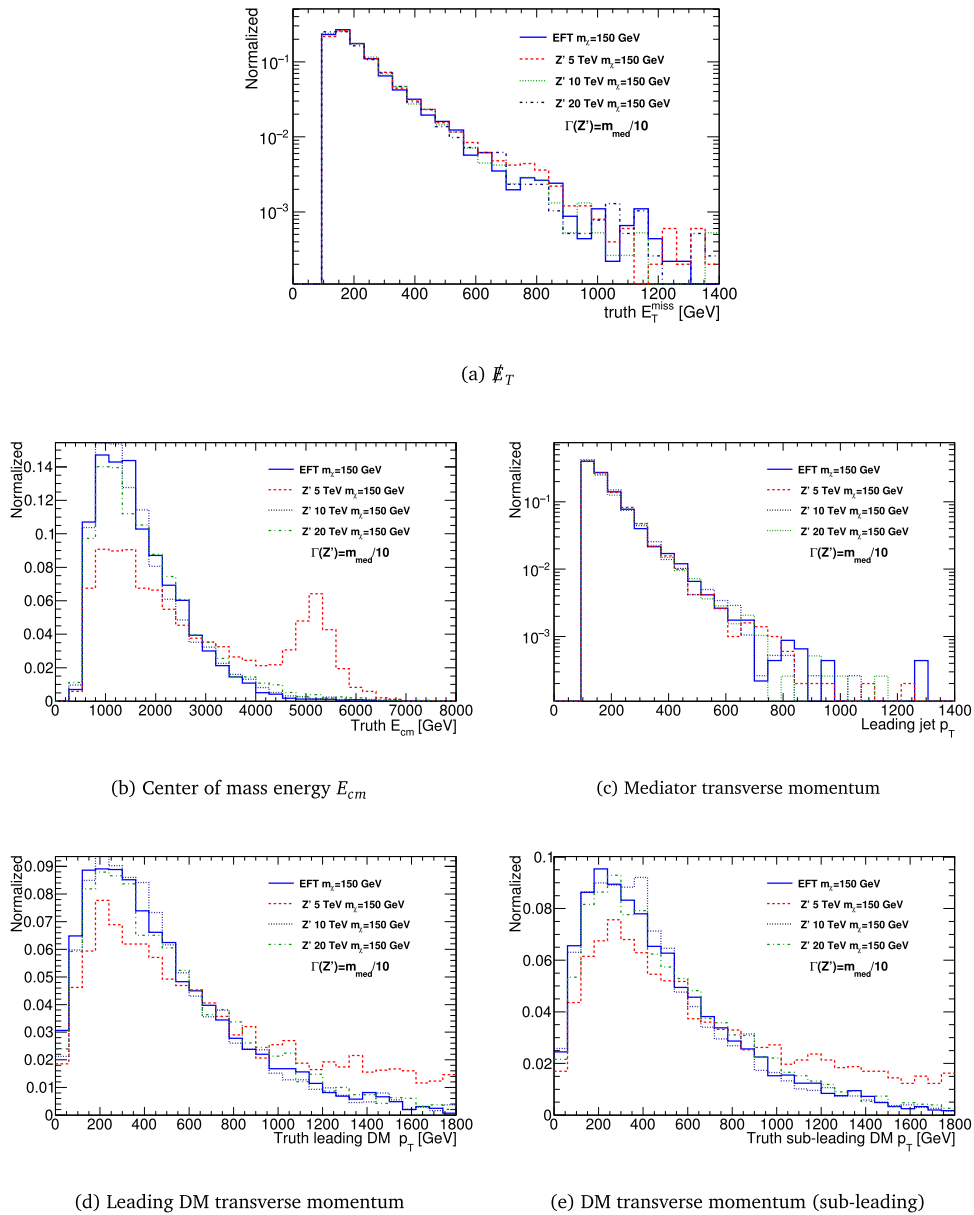

Fig. 70. Comparison of the kinematic distributions at 14 TeV between a narrow s -channel mediator and the corresponding D5 contact operator, at generator level for a $\text{jet}+\cancel{E}_T$ signature.

is appended, containing the necessary information to generate extra weights. In order to obtain new weights, corresponding to different PDFs or scale choice, after an event file has been generated, a line

```
compute_rwgt 1
```

should be added in the input file along with the desired change in parameters. For instance, `renscfact` and `facscfact` allow one to study scale variations on the renormalization and factorization scales around a central value. By running the program again, a new event file will be generated, named `<Original Name>-rwgt.lhe`, with one more line at the end of each event of the form

```
#new weight, renfact, facfact, pdf1, pdf2
```

followed by five numbers and a character string. The first of these numbers is the weight of that event with the new parameters

chosen. By running in sequence the program in the reweighting mode, several weights can be added on the same file. Two remarks are in order.

- The file with new weights is always named `<Original Name>-rwgt.lhe` hence care has to be taken to save it as `<Original Name>.lhe` before each iteration of the reweighting procedure.
- Due to the complexity of the environment where the program is likely to be run, it is strongly suggested as a self-consistency check that the first reweighting is done keeping the initial parameters. If the new weights are not exactly the same as the original ones, then some inconsistency must have happened, or some file was probably corrupted.

It is possible to also have weights written in the version 3 Les Houches format. To do so, in the original run, at least the token `lhweight_id 'ID'`

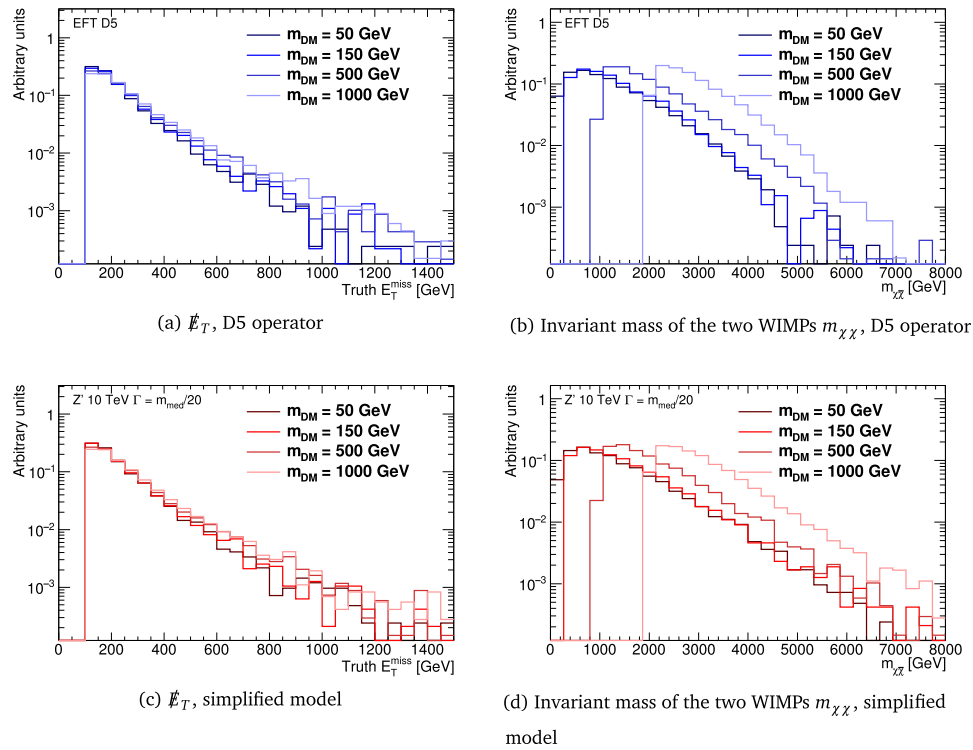

Fig. 71. Comparison of the kinematic distributions for a narrow s -channel mediator, at generator level for a jet+ \cancel{E}_T signature, for varying DM masses.

must be present. The reweighting procedure is the same as described above, but now each new run can be tagged by using a different value for the `lhrwgt_id` keyword. After each event, the following lines will appear:

```
<rwgt>
<wgt id='ID' >
<wgt id='ID1' >
</rwgt>
```

A more detailed explanation of what went into the computation of every single weight can be included in the `<header>` section of the event file by adding/changing the line

```
lhrwgt_descr 'some info'
```

in the input card, before each “reweighting” run is performed. Other useful keywords to group together different weights are `lhrwgt_group_name` and `lhrwgt_group_combine`.

More detailed information can be obtained by inspecting the document in `/Docs/V2-paper.pdf` under the common POWHEG-BOX-V2 directory.

6.2. The SysCalc package in MADGRAPH5_AMC@NLO

SysCALC is a post-processing package for parton-level events as obtained from leading-order calculations in MADGRAPH5_AMC@NLO. It can associate to each event a series of weights corresponding to the evaluation of a certain class of theoretical uncertainties. The event files in input and output are compliant with the Les Houches v3 format. For NLO calculations, PDF and scale uncertainties are instead evaluated automatically by setting corresponding instructions in the `run_card.dat` and no post-processing is needed (or possible).

The requirements of the package as inputs are :

- A systematics file (which can be generated by MadGraph 5 v. 1.6.0 or later) [75,149].
- The Pythia-PGS package (v. 2.2.0 or later) [150]. This is needed only in the case of matching scales variations.

- The availability of LHAPDF5 [151].
- A configuration file (i.e. a text file) specifying the parameters to be varied.

SysCALC supports all leading order computations generated in MADGRAPH5_AMC@NLO including fixed-order computation and matched-merged computation performed in the MLM scheme [152]. MADGRAPH5_AMC@NLO stores additional information inside the event in order to have access to all the information required to compute the convolution of the PDFs with the matrix element for the various supported systematics.

An example configuration file is as follows:

```
# Central scale factors
scalefact:
0.5 1 2
# Scale correlation
# Special value -1: all combination (N**2)
# Special value -2: only correlated variation
# Otherwise list of index N*fac_index + ren_index
# index starts at 0
scalecorrelation:
-1
# alpha_s emission scale factors
alpsfact:
0.5 1 2
# matching scales
matchscale:
30 60 120
# PDF sets and number of members (optional)
PDF:
CT10.LHgrid53
MSTW2008nlo68cl.LHgrid
```

Without matching/merging, SysCALC is able to compute the variation of renormalization and factorization scale (parameter `scalefact`) and the change of PDFs. The variation of the scales

can be done in a correlated and/or uncorrelated way, basically following the value of the scale correlation parameter which can take the following values:

- -1 : to account for all N^2 combinations.
- -2 : to account only for the correlated variations.
- A set of positive values corresponding to the following entries (assuming 0.5, 1, 2 for the scale effect entry):

$$\begin{aligned} 0: & \mu_F = \mu_F^{\text{orig}}/2, \mu_R = \mu_R^{\text{orig}}/2 \\ 1: & \mu_F = \mu_F^{\text{orig}}/2, \mu_R = \mu_R^{\text{orig}} \\ 2: & \mu_F = \mu_F^{\text{orig}}/2, \mu_R = \mu_R^{\text{orig}} * 2 \\ 3: & \mu_F = \mu_F^{\text{orig}}, \mu_R = \mu_R^{\text{orig}}/2 \\ 4: & \mu_F = \mu_F^{\text{orig}}, \mu_R = \mu_R^{\text{orig}} \\ 5: & \mu_F = \mu_F^{\text{orig}}, \mu_R = \mu_R^{\text{orig}} * 2 \\ 6: & \mu_F = \mu_F^{\text{orig}} * 2, \mu_R = \mu_R^{\text{orig}}/2 \\ 7: & \mu_F = \mu_F^{\text{orig}} * 2, \mu_R = \mu_R^{\text{orig}} \\ 8: & \mu_F = \mu_F^{\text{orig}} * 2, \mu_R = \mu_R^{\text{orig}} * 2 \end{aligned}$$

Without correlation, the weight associated to the renormalization scale is the following:

$$\mathcal{W}_{\text{new}}^{\mu_R} = \frac{\alpha_s^N(\Delta * \mu_R)}{\alpha_s^N(\mu_R)} * \mathcal{W}_{\text{orig}}, \quad (49)$$

where Δ is the scale variation considered, $\mathcal{W}_{\text{orig}}$ and \mathcal{W}_{new} are respectively the original/new weights associated to the event. N is the power in the strong coupling for the associated event (interference is not taken account on an event by event basis). The weight associated to the scaling of the factorization scale is:

$$\mathcal{W}_{\text{new}}^{\mu_F} = \frac{f_{1,\text{orig}}(x_1, \Delta * \mu_F) * f_{2,\text{orig}}(x_2, \Delta * \mu_F)}{f_{1,\text{orig}}(x_1, \mu_F) * f_{2,\text{orig}}(x_2, \mu_F)} * \mathcal{W}_{\text{orig}}, \quad (50)$$

where $f_{i,\text{orig}}$ are the probabilities from the original PDF set associated to the incoming partons, which hold a proton momentum fraction x_1 and x_2 for the first and second beam respectively.

The variations for the PDF are given by the corresponding weights associated to the new PDF sets:

$$\mathcal{W}_{\text{new}}^{\text{PDF}} = \frac{f_{1,\text{new}}(x_1, \mu_F) * f_{2,\text{new}}(x_2, \mu_F)}{f_{1,\text{orig}}(x_1, \mu_F) * f_{2,\text{orig}}(x_2, \mu_F)} * \mathcal{W}_{\text{orig}}, \quad (51)$$

where $f_{i,\text{new}}$ is the new PDF probability associated to parton i .

In presence of matching, MADGRAPH5_AMC@NLO associates one history of radiation (initial and/or final state radiation) obtained by a k_T clustering algorithm, and calculates α_s at each vertex of the history to a scale given by the aforementioned clustering algorithm. Furthermore, MADGRAPH5_AMC@NLO reweights the PDF in a fashion similar to what a parton shower would do. SysCALC can perform the associated re-weighting (parameter `alpsfact`) by dividing and multiplying by the associated factor.

For each step in the history of the radiation (associated to a scale $\mu_i = k_{T,i}$), this corresponds to the following expression for a Final State Radiation (FSR):

$$\mathcal{W}_{\text{new}}^{\text{FSR}} = \frac{\alpha_s(\Delta * \mu_i)}{\alpha_s(\mu_i)} * \mathcal{W}_{\text{orig}}, \quad (52)$$

and to the following expression for Initial State Radiation (ISR), associated to a scale μ_i and fraction of energy x_i :

$$\mathcal{W}_{\text{new}}^{\text{ISR}} = \frac{\alpha_s(\Delta * \mu_i) \frac{f_a(x_i, \Delta * \mu_i)}{f_b(x_i, \Delta * \mu_{i+1})}}{\alpha_s(\mu_i) \frac{f_a(x_i, \mu_i)}{f_b(x_i, \mu_{i+1})}} * \mathcal{W}_{\text{orig}}, \quad (53)$$

where μ_{i+1} is the scale of the next step in the (initial state) history of radiation.

SysCALC can include the weight associated to different merging scales in the MLM matching/merging mechanism (for output of the `pythia6` package or `pythia-pgs` package).

In that case, the parton shower does not veto any event according to the MLM algorithm, although in the output file the scale of the first emission is retained. Having this information, SysCALC can test each value of the specified matching scales under the `matchscale` parameter block. SysCALC will then test for each of the values specified in the parameter `matchscale` if the event passes the MLM criteria or not. If it does not, then a zero weight is associated to the event, while if it does, then a weight 1 is kept. As a reminder, those weights are the equivalent of having a (approximate) Sudakov form-factor and removing at the same time the double counting between the events belonging to different multiplicities.

Finally, we give an example of the SysCALC output which follows the LHEF v3 format. The following block appears in the header of the output file:

```
<header>
<ini trwgt>
<weightgroup type="Central scale variation" combine="envelope">
  <weight id="1"> mur=0.5 muf=0.5 </weight>
  <weight id="2"> mur=1 muf=0.5 </weight>
  <weight id="3"> mur=2 muf=0.5 </weight>
  <weight id="4"> mur=0.5 muf=1 </weight>
  <weight id="5"> mur=1 muf=1 </weight>
  <weight id="6"> mur=2 muf=1 </weight>
  <weight id="7"> mur=0.5 muf=2 </weight>
  <weight id="8"> mur=1 muf=2 </weight>
  <weight id="9"> mur=2 muf=2 </weight>
</weightgroup>
<weightgroup type="Emission scale variation" combine="envelope">
  <weight id="10"> alpsfact=0.5</weight>
  <weight id="11"> alpsfact=1</weight>
  <weight id="12"> alpsfact=2</weight>
</weightgroup>
<weightgroup type="CT10nlo.LHgrid" combine="hessian">
  <weight id="13">Member 0</weight>
  <weight id="14">Member 1</weight>
  <weight id="15">Member 2</weight>
  <weight id="16">Member 3</weight>
  ...
  <weight id="65">Member 52</weight>
</weightgroup>
</ini trwgt>
</header>
```

For each event, the weights are then written as follows:

```
<rwt>
<wgt id="1">83214.7</wgt>
<wgt id="2">61460</wgt>
<wgt id="3">47241.9</wgt>
<wgt id="4">101374</wgt>
...
<wgt id="64">34893.5</wgt>
<wgt id="65">41277</wgt>
</rwt>
```

7. Conclusions

The ATLAS/CMS Dark Matter Forum concluded its work in June 2015. Its mandate was focused on identifying a prioritized, compact set of simplified model benchmarks to be used for the design of the early Run-2 LHC searches for $\tilde{E}_T + X$ final states. Its participants included many of the experimenters from both collaborations that are involved in these searches, as well as many of the theorists working actively on these models. This report has documented this basis set of models, as well as studies of the kinematically-distinct regions of the parameter space of the models, to aid the design of the searches. Table 9 summarizes the state of the art of the calculations, event generators, and tools that are available to the two LHC collaborations to simulate

Table 9

Summary table for available benchmark models considered within the works of this Forum. The results in this document have been obtained with the implementations in bold.

Benchmark models for ATLAS and CMS Run-2 DM searches			
Vector/axial vector mediator, s -channel (Section 2.1)			
Signature	State of the art calculation and tools	Implementation	References
jet + \cancel{E}_T	NLO + PS (POWHEG, SVN r3059)	[115,116]	[43,61,69–71]

these models at the start of Run-2. It also describes some that are known to be under development as the report was finalized.

This document primarily presents studies related to simplified models. The presentation of results for EFT benchmark models is also discussed. The studies contained in this report are meant to highlight the use of EFTs as a benchmark that is complementary to simplified models, and to demonstrate how that collider results could be presented a function of the fraction of events that are valid within the contact interaction approximation.

A number of points remain to be developed beyond the scope of this Forum, in order to fully benefit from LHC searches in the global quest for Dark Matter. First and foremost, to accommodate the urgent need of a basis set of simplified models, this work has made many grounding assumptions, as stated in the introduction. Departures from these assumptions have not been fully explored. As a consequence, the list of models and implementations employed by the ATLAS and CMS collaborations for early LHC Run-2 searches is not meant to exhaust the range of possibilities for mediating processes, let alone cover all plausible models of collider dark matter production. Rather, it is hoped that others will continue the systematic exploration of the most generic possibilities for collider dark matter production, building upon the framework used in this report just as this report has relied heavily on the work of many others. This also applies to models that exist in literature but do not have an implementation yet: we hope that this work will further encourage the theory and generator community to improve the implementation of new models as well as the precision of the calculations of existing ones. The role of constraints on the mediator particles from

direct past and present collider searches should also be developed further.

Furthermore, we see the need for broader discussion on the comparison of experimental results amongst collider and non-collider searches for particle dark matter. This point will have to be addressed before the presentation of Run-2 results: The uncertainties in the comparisons between experiments should be discussed and conveyed, so that the different results can be placed in their correct context, and so we can collectively build a fair and comprehensive picture of our understanding of particle dark matter.

Acknowledgments

The authors would like to thank Daniel Whiteson for helping in the review of this document. This research was supported by the Munich Institute for Astro- and Particle Physics (MIAPP) of the DFG cluster of excellence “Origin and Structure of the Universe”. The authors would like to express a special thanks to the Mainz Institute for Theoretical Physics (MITP) for its hospitality and support. P. Pani wishes to thank the support of the Computing Infrastructure of Nikhef. Appendix A. Additional models for dark matter searches

A.1. Models with a single top–quark + \tilde{E}_T

Many different theories predict final states with a single top and associated missing transverse momentum (monotop), some of them including dark matter candidates. A simplified model encompassing the processes leading to this phenomenology is described in Refs. [155–157], and is adopted as one of the benchmarks for Run 2 LHC searches.

The simplified model is constructed by imposing that the model Lagrangian respects the electroweak $SU(2)_L \times U(1)_Y$ gauge symmetry and by requiring minimality in terms of new states to supplement to the Standard Model fields. As a result, two monotop production mechanisms are possible. In the first case, the monotop system is constituted by an invisible (or long-lived with respect to detector distances) fermion χ and a top quark. It is produced as shown in the diagram of A.72(a) where a colored resonance φ lying in the triplet representation of $SU(3)_C$ decays into a top quark and a χ particle. In the second production mode, the monotop state is made of a top quark and a vector state V connected to a hidden sector so that it could decay invisibly into, e.g., a pair of dark matter particles as studied in [157]. The production proceeds via flavor-changing neutral interactions of the top quark with a quark of the first or second generation and the invisible V boson (see the diagrams of A.72(b) and (c)).

Resonant production. In this case, a colored 2/3-charged scalar (φ) is produced and decays into a top quark and a spin-1/2 invisible particle, χ . The dynamics of the new sector is described by the following Lagrangian:

$$\mathcal{L} = \left[\varphi \bar{d}^c \left[a_{SR}^q + b_{SR}^q \gamma_5 \right] d + \varphi \bar{u} \left[a_{SR}^{1/2} + b_{SR}^{1/2} \gamma_5 \right] \chi + \text{h.c.} \right], \quad (\text{A.1})$$

where u (d) stands for any up-type (down-type) quark, the notation SR refers to the monotop production mechanism via a scalar resonance and all flavor and color indices are understood for clarity.

In the notation of [156], the couplings of the new colored fields to down-type quarks are embedded into the 3×3 antisymmetric matrices a_{SR}^q (scalar couplings) and b_{SR}^q (pseudoscalar couplings) while those to the new fermion χ and one single up-type quark are given by the three-component vectors $a_{SR}^{1/2}$ and $b_{SR}^{1/2}$ in flavor space.

Under the form of Eq. (A.1), the Lagrangian is the one introduced in the original monotop search proposal [155]. It has been used by the CMS collaboration for Run I analyses after neglecting all pseudoscalar components of the couplings and adding the vector resonance case for which minimality requirements are difficult to accommodate [18]. In contrast, the study of Ref. [157] has imposed electroweak gauge invariance and required minimality.

This enforces all new couplings to be right-handed so that

$$a_{SR}^{1/2} = b_{SR}^{1/2} = \frac{1}{2} y_s^* \quad \text{and} \quad a_{SR}^q = b_{SR}^q = \frac{1}{2} \lambda_s, \quad (\text{A.2})$$

where the objects y_s and λ_s are a tridimensional vector and a 3×3 matrix in flavor space respectively. This class of scenarios is the one that has been adopted by the ATLAS collaboration for its Run I monotop searches [12] and will be considered by both collaborations for Run II analyses.

The resulting model can be likened to the MSSM with an R -parity violating of a top squark to the Standard Model down-type quarks and an R -parity conserving interaction of a top quark and a top-squark to a neutralino.

Non-resonant production. For non-resonant monotop production, the monotop state is produced via flavor-changing neutral interactions of the top quark, a lighter up-type quark and a new invisible vector particle V . This is the only case considered, as having a new scalar would involve in particular a mixing with the SM Higgs boson and therefore a larger number of free parameters. The Lagrangian describing the dynamics of this non-resonant monotop production case is:

$$\mathcal{L} = \left[V_\mu \bar{u} \gamma^\mu \left[a_{FC}^1 + b_{FC}^1 \gamma_5 \right] u + \text{h.c.} \right], \quad (\text{A.3})$$

where the flavor and color indices are again understood for clarity. The strength of the interactions among these two states and a pair of up-type quarks is modeled via two 3×3 matrices in flavor space a_{FC}^1 for the vector couplings and b_{FC}^1 for the axial vector couplings, the FC subscript referring to the flavor-changing neutral monotop production mode and the (1) superscript to the vectorial nature of the invisible particle.

As for the resonant case, the Lagrangian of Eq. (A.3) is the one that has been used by CMS after reintroducing the scalar option for the invisible state and neglecting all pseudoscalar interactions [18]. As already mentioned, a simplified setup motivated by gauge invariance and minimality has been preferred so that, as shown in Ref. [157], we impose all interactions to involve right-handed quarks only,¹⁹

$$a_{FC}^1 = b_{FC}^1 = \frac{1}{2} a_R \quad (\text{A.4})$$

where a_R denotes a 3×3 matrix in flavor space. This implies the vector field to be an $SU(2)_L$ singlet.

Model parameters and assumptions. The models considered as benchmarks for the first LHC searches contain further assumptions in terms of the flavor structure of the model with respect to the Lagrangians of the previous subsection. In order to have an observable monotop signature at the LHC, the Lagrangians introduced above must include not too small couplings of the new particles to first and second generation quarks. For simplicity, we assumed that only channels enhanced by parton density effects will be considered, so that we fix

$$\begin{aligned} (a_R)_{13} &= (a_R)_{31} = a, \\ (\lambda_s)_{12} &= -(\lambda_s)_{21} = \lambda \quad \text{and} \quad (y_s)_3 = y, \end{aligned} \quad (\text{A.5})$$

all other elements of the matrices and vectors above being set to zero.

Implementation. In order to allow one for the Monte Carlo simulation of events relevant for the monotop production cases

¹⁹ Ref. [158], which became public only after the conclusion of this Forum, introduces both left- and right-handed couplings.

Fig. A.72. Feynman diagrams of leading order processes leading to monotop events: production of a colored scalar resonance φ decaying into a top quark and a spin-1/2 fermion χ (a), s - (b) and t -channel (c) non resonant production of a top quark in association with a spin-1 boson V decaying invisibly.

described above, we consider the Lagrangian

$$\mathcal{L} = \left[aV_\mu \bar{u} \gamma^\mu P_R t + \lambda \varphi \bar{d}^c P_R s + y \varphi \bar{\chi} P_R t + \text{h.c.} \right], \quad (\text{A.6})$$

where P_R stands for the right-handed chirality projector and the new physics couplings are defined by the three parameters a , λ and y . We additionally include a coupling of the invisible vector boson V to a dark sector (represented by a fermion ψ) whose strength can be controlled through a parameter g_{DM} ,

$$\mathcal{L} = g_{DM} V_\mu \bar{\psi} \gamma^\mu \psi. \quad (\text{A.7})$$

This ensures the option to make the V -boson effectively invisible by tuning g_{DM} respectively to a . We implement the entire model in the FEYNRULES package [76] so that the model can be exported to a UFO library [77] to be linked to MADGRAPH5_AMC@NLO [75] for event generation, following the approach outlined in [159].

A.2. Parameter scan

Under all the assumptions of the previous sections, the parameter space of the resonant model is defined by four quantities, namely the mass of the new scalar field φ , the mass of the invisible fermion χ and the strengths of the interactions of the scalar resonance with the monotop system y and with down-type quarks λ . One of both coupling parameters could however be traded with the width of the resonance.

The parameter space of the non-resonant model is defined by two parameters, namely the mass of the invisible state V and its flavor-changing neutral coupling to the up-type quarks a_R .

In the case of the non-resonant model, the invisible vector is connected to a hidden sector that could be, in its simplest form, parameterized by a new fermion [157]. This has effects on the width of the invisible V state.

A consensus between the ATLAS and CMS collaborations has been reached in the case of non-resonant monotop production. The results have been described above. In contrast, discussions in the context of resonant monotop production are still on-going. The related parameter space contains four parameters and must thus be further simplified for practical purposes. Several options are possible and a choice necessitates additional studies that will be achieved in a near future.

It has been verified that the kinematics do not depend on the width of the invisible state in the case where this width is at most 10% of the V -mass. This is illustrated in Fig. A.73, where we show the transverse-momentum spectra of the V -boson when it decays into a top-up final state and for different V -boson masses. The results are independent of the visible or invisible decay modes as we are only concerned with the kinematic properties of the invisible state.

A.3. Single top model implementation

Card files for MADGRAPH5_AMC@NLO are provided on the Forum Git repository [160] and correspond to the Lagrangian that has been implemented in FEYNRULES. Each coupling constant of the model can be set via the block COUPX of the parameter card. Its entries 1, 2 and 3 respectively correspond to the monotop-relevant parameters a , λ and y , while the width (and in particular the invisible partial width) of the V -boson can be tuned via the g_{DM} parameter to given in the entry 10 of the COUPX block.

The masses of the particles are set in the MASS block of the parameter card, the PDG codes of the new states being 32 (the vector state V), 1000006 (the φ colored resonance), 1000022 (the invisible fermion χ) and 1000023 (the fermion ψ connecting the V state to the dark sector). The width of the new vector has to be computed from all open tree-level decays (after fixing g_{DM} to a large value and setting the relevant entry to Auto in the DECAY

Fig. A.73. Distributions of the transverse momentum of the V boson in the case of the process $pp \rightarrow tV \rightarrow t(\bar{t}u + \text{c.c.})$. We have imposed that the V -boson is produced on-shell and have chosen its mass to be $m_V = 200, 600$ and 1000 GeV (left, central and right panels). We have considered three possible cases for the total width of the V -boson, which has been fixed to 0.61% , 0.1% and 10% of the mass.

block of the parameter card), while the way to calculate the width of the resonance ϕ is under discussion by both the ATLAS and CMS collaborations. The χ and ψ fermions are taken stable so that their width vanishes.

A.4. Further $W + \cancel{E}_T$ models with possible cross-section enhancements

As pointed out in Ref. [67], the mono- W signature can probe the iso-spin violating interactions of dark matter with quarks. The relevant operator after the electroweak symmetry breaking is

$$\frac{1}{\Lambda^2} \bar{\chi} \gamma_\mu \chi (\bar{u}_L \gamma^\mu u_L + \xi \bar{d}_L \gamma^\mu d_L). \quad (\text{A.8})$$

Here, we only keep the left-handed quarks because the right-handed quarks do not radiate a W -gauge boson from the weak interaction. As the LHC constrains the cutoff to higher values, it is also important to know the corresponding operators before the electroweak symmetry. At the dimension-six level, the following operator

$$\frac{c_6}{\Lambda^2} \bar{\chi} \gamma_\mu \chi \bar{Q}_L \gamma^\mu Q_L \quad (\text{A.9})$$

conserves iso-spin and provides us $\xi = 1$ [67]. At the dimension-eight level, new operators appear to induce iso-spin violation and can be

$$\frac{c_8^d}{\Lambda^4} \bar{\chi} \gamma_\mu \chi (H \bar{Q}_L) \gamma^\mu (Q_L H^\dagger) + \frac{c_8^u}{\Lambda^4} \bar{\chi} \gamma_\mu \chi (\tilde{H} \bar{Q}_L) \gamma^\mu (Q_L \tilde{H}^\dagger). \quad (\text{A.10})$$

After inputting the vacuum expectation value of the Higgs field, we have

$$\xi = \frac{c_6 + c_8^d v_{EW}^2 / 2\Lambda^2}{c_6 + c_8^u v_{EW}^2 / 2\Lambda^2}. \quad (\text{A.11})$$

For a nonzero c_6 and $v_{EW} \ll \Lambda$, the iso-spin violation effects are suppressed. On the other hand, the values of c_6 , c_8^d and c_8^u depend on the UV-models.

There is one possible UV-model to obtain a zero value for c_6 and non-zero values for c_8^d and c_8^u . One can have the dark matter and the SM Higgs field charged under a new $U(1)$ symmetry. There is a small mass mixing between SM Z -boson and the new Z' with a mixing angle of $\mathcal{O}(v_{EW}^2 / M_{Z'}^2)$. After integrating out Z' , one has different effective dark matter couplings to u_L and d_L fields, which are proportional to their couplings to the Z boson. For this model, we have $c_6 = 0$ and

$$\xi = \frac{-\frac{1}{2} + \frac{1}{3} \sin^2 \theta_W}{\frac{1}{2} - \frac{2}{3} \sin^2 \theta_W} \approx -2.7 \quad (\text{A.12})$$

and order of unity.

A.5. Simplified model corresponding to dimension-5 EFT operator

As an example of a simplified model corresponding to the dimension-5 EFT operator described in Section 3.2, we consider a Higgs portal with a scalar mediator. Models of this kind are among the most concise versions of simplified models that produce couplings of Dark Matter to pairs of gauge-bosons. Scalar fields may couple directly to pairs of electroweak gauge bosons, but must carry part of the electroweak vacuum expectation value. One may thus consider a simple model where Dark Matter couples to a scalar singlet mediator, which mixes with the fields in the Higgs sector.

$$L \subset \frac{1}{2} m_s S^2 + \lambda S^2 |H|^2 + \lambda' S |H|^2 + y S \chi \bar{\chi} \quad (\text{A.13})$$

where H is a field in the Higgs sector that contains part of the electroweak vacuum expectation value, S is a heavy scalar singlet and χ is a Dark Matter field. There is then an s -channel diagram where DM pairs couple to the singlet field S , which then mixes with a Higgs-sector field, and couples to W and Z bosons. This diagram contains 2 insertions of EW symmetry breaking fields, corresponding in form to the effective dimension-5 operator in Section 3.2.1.

A.6. Inert two-Higgs Doublet Model (IDM)

For most of the simplified models included in this report, the mass of the mediator and couplings/width are non-trivial parameters of the model. In these scenarios, we remain agnostic about the theory behind the dark matter sector and try to parameterize it in simple terms.

We have not addressed how to extend the simplified models to realistic and viable models which are consistent with the symmetries of the Standard Model. Simplified models often violate gauge invariance which is a crucial principle for building a consistent BSM model which incorporates SM together with new physics. For example, with a new heavy gauge vector boson mediating DM interactions, one needs not just the dark matter and its mediator, but also a mechanism which provides mass to this mediator in a gauge invariant way.

Considering both the simplified model and other elements necessary for a consistent theory is a next logical step. The authors of [161] term these Minimal Consistent Dark Matter (MCDM) models. MCDM models are at the same time still toy models that can be easily incorporated into a bigger BSM model and explored via complementary constraints from collider and direct/indirect DM search experiments as well as relic density constraints.

Fig. A.76. Feynman diagrams for $q\bar{q} \rightarrow h_1 h_1 + Z$ process contributing to mono-Z signature.
Source: Adapted from [161].

The idea of an inert Two-Higgs Doublet Model (IDM) was introduced more than 30 years ago in Ref [162]. The IDM was first proposed as a Dark Matter model in Ref. [163] and its phenomenology further studied in Refs. [14,161,164–173]. It is an extension of the SM with a second scalar doublet ϕ_2 with no direct coupling to fermions. This doublet has a discrete Z_2 symmetry, under which ϕ_2 is odd and all the other fields are even. The Lagrangian of the odd sector is,

$$\mathcal{L} = \frac{1}{2}(D_\mu \phi_2)^2 - V(\phi_1, \phi_2) \quad (\text{A.14})$$

with the potential V containing mass terms and $\phi_1 - \phi_2$ interactions:

$$\begin{aligned} V = & -m_1^2(\phi_1^\dagger \phi_1) - m_2^2(\phi_2^\dagger \phi_2) + \lambda_1(\phi_1^\dagger \phi_1)^2 + \lambda_2(\phi_2^\dagger \phi_2)^2 \\ & + \lambda_3(\phi_2^\dagger \phi_2)(\phi_1^\dagger \phi_1) + \lambda_4(\phi_2^\dagger \phi_1)(\phi_1^\dagger \phi_2) \\ & + \frac{\lambda_5}{2} [(\phi_1^\dagger \phi_2)^2 + (\phi_2^\dagger \phi_1)^2], \end{aligned} \quad (\text{A.15})$$

where ϕ_1 and ϕ_2 are SM and inert Higgs doublets respectively carrying the same hypercharge. These doublets can be parameterized as

$$\phi_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v + H \end{pmatrix} \quad \phi_2 = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}h^+ \\ h_1 + ih_2 \end{pmatrix} \quad (\text{A.16})$$

In addition to the SM, the IDM introduces four more degrees of freedom coming from the inert doublet in the form of a Z_2 -odd charged scalar h^\pm and two neutral Z_2 -odd scalars h_1 and h_2 . The lightest neutral scalar, h_1 is identified as the dark matter candidate. Aspects of the IDM collider phenomenology have been studied in [161,163,173–184]. Its LHC signatures include dileptons [179,184], trileptons [180] and multileptons [181] along with

missing transverse energy, modifications of the Higgs branching ratios [173,182,183], as well as $\cancel{E}_T + \text{jet}$, Z , and Higgs and $\cancel{E}_T + \text{VBF}$ signals (see Figs. A.74–A.79).

Based on the various LHC search channels, DM phenomenology issues and theoretical considerations, numerous works have proposed benchmark scenarios for the IDM, see e.g. [173,181] while a FeynRules implementation (including MadGraph, CalcHEP and micrOMEGAs model files) was provided in [181]. An updated analysis of the parameter space has recently been performed in Ref. [161].

The authors suggested to study mono-X signatures that are relevant to model-independent collider DM searches, and evaluated their rates presented below. They have implemented and cross-checked the IDM model into CalcHEP and micrOMEGAs, with an implementation publicly available on the HEPMDB database, including loop-induced HHG and $\gamma\gamma H$ models. They propose an additional set of benchmark points, mostly inspired by mono-X and VBF searches (Table A.10). Though the overall parameter space of IDM is 5-dimensional, once all relevant constraints are applied the parameter space relevant to a specific LHC signature typically reduces to 1–2 dimensional. In the mono-jet case, one can use two separate simplified models, a $gg \rightarrow h_1 h_1 + g$ process (via Higgs mediator) and a $q\bar{q} \rightarrow h_1 h_2 + g$ ($gq \rightarrow h_1 h_2 + q$) process (through a Z -boson mediator) to capture the physics relevant to the search. The cross sections for the various mono-X and VBF signatures produced by this model are displayed in Fig. A.80.

Table A.10

Five benchmarks for IDM in $(M_{h_1}, M_{h_2}, M_{h_{\pm}}, \lambda_2, \lambda_{345})$ parameter space. We also present the corresponding relic density (Ωh^2), the spin-independent cross section for DM scattering on the proton (σ_{SI}), and the LHC cross section at 13 TeV for mono-jet process $pp \rightarrow h_1, h_1 + jet$ for $p_T^{jet} > 100$ GeV cut (σ_{LHC}).

BM	1	2	3	4	5
M_{h_1} (GeV)	48	53	70	82	120
M_{h_2} (GeV)	55	189	77	89	140
$M_{h_{\pm}}$ (GeV)	130	182	200	150	200
λ_2	0.8	1.0	1.1	0.9	1.0
λ_{345}	-0.010	-0.024	+0.022	-0.090	-0.100
Ωh^2	3.4×10^{-2}	8.1×10^{-2}	9.63×10^{-2}	1.5×10^{-2}	2.1×10^{-3}
σ_{SI} (pb)	2.3×10^{-10}	7.9×10^{-10}	5.1×10^{-10}	4.5×10^{-10}	2.6×10^{-9}
σ_{LHC} (fb)	1.7×10^2	7.7×10^2	4.3×10^{-2}	1.2×10^{-1}	2.3×10^{-2}

When collider searches present results with the recommended benchmarks, we suggest the following:

- Provide limits in collider language, on fundamental parameters of the interaction: the couplings and masses of particles in simplified model.
- Translate limits to non-collider language, for a range of assumptions, in order to convey a rough idea of the range of possibilities. The details of this point are left for work beyond the scope of this Forum.

- Provide all necessary material for theorists to reinterpret simplified model results as building blocks for more complete models (e.g. signal cutflows, acceptances, etc.). This point is detailed further in this appendix.
- Provide model-independent results in terms of limits on cross-section times efficiency times acceptance of new phenomena for all cases, but especially when EFTs are employed as benchmarks. This recommendation has been issued before: see Ref. [185] for detailed suggestions.

Fig. A.80. LHC cross section at 13 TeV for various signatures, from [161].

- Provide easily usable and clearly labeled results in a digitized format, e.g. [186] entries, ROOT histograms and macros or tables available on analysis public pages.

This appendix describes further considerations for reinterpretation and reimplementing of the analyses, as well as for the use of simplified model results directly given by the collaborations.

B.1. Reinterpretation of analyses

In the case of reinterpretation for models different than those provided by the experimental collaborations, the information needed primarily includes expected and observed exclusion lines along with their $\pm 1\sigma$ uncertainty, expected and observed upper limits in case of simplified models, efficiency maps and kinematic distributions as reported in the analysis. If the kinematics of the new model to be tested in the reinterpretation is similar to that of the original model provided by the collaboration, it will be straight-forward to rescale the results provided to match the new model cross-section using this information.

B.2. Reimplementation of analyses

One of the important developments in recent years is an active development of software codes [84,85,187–190] necessary for recasting analyses. The aim of these codes is to provide a public library of LHC analyses that have been reimplemented and validated, often by the collaborations themselves. Such libraries can then be used to analyze validity of a BSM scenario in a systematic and effective manner. The availability of public libraries further facilitates a unified framework and can lead to an organized and central structure to preserve LHC information long term. The reimplementation of an analysis consists of several stages. Typically, the analysis note is used as a basis for the implementation of the preselection and event selection cuts in the user analysis code within the recasting frameworks. Signal events are generated, and passed through a parameterized detector simulation using software such as Delphes or PGS [103,191]. The reconstructed objects are then analyzed using the code written in the previous step, and the results in terms of number of events are passed through a statistical analysis framework to compare with the backgrounds provided by the collaborations.

In order to be able to effectively use such codes, it is important to get a complete set of information from the collaborations.

For what concerns the generation of the models, it is desirable to have the following items as used by the collaborations:

- Monte Carlo generators: Monte Carlo generators along with the exact versions used to produce the event files should be listed.
- Production cross sections: The order of production cross sections (e.g. LO,NLO,NLL) as well as the codes which were used to compute them should be provided. Tables of reference cross sections for several values of particle masses are useful as well.
- Process Generation: Details of the generated process, detailing number of additional partons generated.
- LHE files: selected LHE files (detailing at least a few events if not the entire file) corresponding to the benchmarks listed in the analysis could also be made available in order to cross check process generation. Experimental collaborations may generate events on-the-fly without saving the intermediate LHE file; we advocate that the cross-check of process generation is straight-forward if this information is present, so we encourage the generation of a few selected benchmark points allowing for a LHE file to be saved. Special attention should be paid to list the parameters which change the production cross section or kinematics of the process e.g. mixing angles.
- Process cards: Process cards including PDF choices, details of matching algorithms and scales and details of process generation. If process cards are not available, the above items should be clearly identified.
- Model files: For models which are not already implemented in MADGRAPH5_AMC@NLO, the availability of the corresponding model files in the UFO format [77] is highly desired. This format details the exact notation used in the model and hence sets up a complete framework. In case MADGRAPH5_AMC@NLO is not used, enough information should be provided in order to clearly identify the underlying model used for interpretations and reproduce the generation.

The ATLAS/CMS Dark Matter Forum provides most of the information needed within its Git repository [59].

Efficiency maps and relevant kinematic distributions as reported in the analysis should be provided, in a digitized format with clearly specified units. If selection criteria cannot be easily simulated through parameterized detector simulation, the collaborations should provide the efficiency of such cuts. Overall reconstruction and identification efficiencies of physics objects are given as an input to the detector simulation software. It is thus very useful to get parameterized efficiencies for reconstructed objects (as a function of the rapidity η and/or transverse momentum p_T), along with the working points at which they were evaluated (e.g. loose, tight selection). Object definitions should be clearly identifiable. Digitized kinematic distributions are often necessary for the validation of the analysis so that the results from the collaboration are obtained, and so are tables containing the events passing each of the cuts.

The availability of digitized data and backgrounds is one of the primary requirements for fast and efficient recasting. Platforms such as HepData [186] can be used as a centralized repository; alternatively, analysis public pages and tables can be used for dissemination of results. Both data and Standard Model backgrounds should be provided in the form of binned histogram that can be interpolated if needed.

Fig. C.81. Cross section of the $pp \rightarrow H\chi\bar{\chi}$ process as a function of $g_{hZ'Z'}$ for $m_{Z'} = 100$ GeV (left) and $m_{Z'} = 1$ TeV (right). The fit functions are shown in the text.

A detailed description of the likelihood used in order to derive the limits from the comparison of data to signal plus background should be given. This can be inferred from the analysis documentation itself, however direct availability of the limit setting code as a workspace in RooStats or HistFitter [192] is highly desirable.

Finally, the collaborations can also provide an analysis code directly implemented in one of the public recasting codes detailed above. Such codes can be published via INSPIRE [193] in order to track versioning and citations.

B.3. Simplified model interpretations

Dark Matter searches at the LHC will include simplified model interpretations in their search results. These interpretations are simple and can be used for a survey of viability of parameter space. Codes such as [194–196] can make use of the simplified model results given in the form of 95% Confidence Level (CLs) upper limit or efficiency maps in order to test Beyond the Standard Model parameter space. As mentioned above, it will thus be extremely useful if the results are given in a digitized form that is easily usable by the theory community.

The parameter space of these models should be clearly specified. For example, for a simplified model containing dark matter mass m_χ , mediator mass M_{med} and couplings g_χ , g_q it will be very useful to have upper limits on the product of couplings $\sqrt{g_\chi g_q}$ or cross section times branching ratio as a function of m_χ , M_{med} . Limits on visible cross sections of the simplified models considered for interpretations should be made available.

The usage of simplified model results relies on interpolating between upper limit values. In order to facilitate the interpolation, regions where large variation of upper limits is observed should contain denser grid, if a uniform grid over the entire plane is not possible. For simplified model involving more than three parameters (two masses and product of couplings), slices of upper limits in the additional dimensions will be necessary for reinterpretation.

As already mentioned in the introduction to this Chapter, acceptance and efficiency maps for all the signal regions involved in the analysis should be made available. These results are not only useful for model testing using simplified models but also to validate implementation of the analysis. Information about the most sensitive signal regions as a function of new particle masses is also useful in order to determine the validity of approximate limit setting procedures commonly used by theorists.

Appendix C. Additional details and studies within the forum

Further information for baryonic Z' model

Cross-section scaling

The dependence of the cross section of the $pp \rightarrow H\chi\bar{\chi} + X$ process on $g_{hZ'Z'}$ is shown in Fig. C.81. The curves have been fit to second-order polynomials, where y is the cross-section and x is the coupling $g_{hZ'Z'}$.

For $m_{\text{med}} = 100$ GeV, the fit function is

$$y = -0.12 - 3.4 \times 10^{-3}x + 2.7 \times 10^{-4}x^2. \quad (\text{C.1})$$

For $M_{\text{med}} = 1$ TeV, the fit function is:

$$y = 0.0012 - 2.4 \times 10^{-7}x + 1.5 \times 10^{-7}x^2. \quad (\text{C.2})$$

We show that coherent transition radiation from the electrically-neutral transverse geomagnetic current (CTR-GM) in a cosmic-ray air shower provides a natural, standard model, explanation to the recent “anomalous” events observed by the ANITA detector. We demonstrate that for zenith angles less than ~ 70 degrees, combined with high surface elevation, the inclusion of CTR-GM can significantly alter the emitted electric field from a cosmic-ray air shower. CTR-GM therefore has to be included in radio emission models to provide a full description of the radio emission from a high-energy cosmic-ray air shower traversing a dielectric boundary.

Introduction— During propagation through the atmosphere, the electrons and positrons of a cosmic ray air shower will be deflected in Earth’s magnetic field, inducing a net transverse current in the shower front. This results in geomagnetically induced radio emission up to GHz frequencies [1–4], which allows the shower to be detected with radio instruments. A second radio emission source is the net negative excess charge in the shower, first predicted by Askaryan in 1962 [5] and experimentally confirmed in 2001 [6].

Detection of high energy cosmic rays using radio is currently a well established method [7, 8], with development stretching back to the initial efforts of the 1960’s [9]. In addition to cosmic-ray air shower radio detectors, several radio detectors are currently under development to probe particle cascades induced by high-energy (> 10 PeV) cosmic neutrinos interacting in more dense media such as ice or rock [10–13].

In recent works [14–16] another important emission mechanism is discussed, coherent transition radiation (CTR) from a high-energy particle cascade traversing different media. The considered source of the transition radiation is the net excess charge predicted by Askaryan (CTR-A). Other works considering particle cascades moving through dielectrics concern the EXTASIS experiment [17], for which the emission at ground based cosmic-ray detection set-ups due to the absorption of the cosmic-ray air shower by Earth was treated in Ref. [18]. Recently, CTR-A was confirmed experimentally at the Telescope Array Electron Light Source facility, where the emission from a high-energy electron beam leaving the accelerator was quantified in detail [19], earlier works on CTR-A using electron beams are found in Refs. [20, 21].

In this work, we present a second CTR contribution that is expected for cosmic-ray air showers hitting a boundary surface. We show that strong coherent transition radiation from the geomagnetically-induced current (CTR-GM) can be expected once a significantly large particle number crosses a boundary surface. We also show that this condition in general is satisfied for high-energy cosmic-ray air showers with shallow zenith angles ($\lesssim 70^\circ$) incident upon high surface elevations ($\gtrsim 2.5$ km). If these criteria are not satisfied, the particle

content at the boundary is too small for the coherent transition radiation to be significant [14, 18].

We discuss the obtained results in the context of the two so-called ‘anomalous events’ detected by the stratospheric balloon-borne ANITA instrument [22][23]. Though primarily a neutrino detector, ANITA also observes the emission from downward-going cosmic-ray air showers after reflection from the ice. The anomalous cosmic-ray like events detected by ANITA have the same polarization as a typical cosmic-ray, but an inverted polarity. *Polarization* is a measure of the plane of oscillation of the electric field, while *polarity* is a measure of the sign of the dominant peak(s) of this field. Consequently, the inverted polarity of the anomalous events has been interpreted as emission from an upward-going shower of some kind.

Such an upward moving cascade, however, is only possible for primary particles having traversed a long path through the earth. Plausible standard-model explanations for such events are largely ruled out by ANITA exposure limits [24], and other explanations require physics beyond the standard model [25–34].

In this work, we show that CTR-GM from a down-going cosmic ray shower provides a natural explanation for the observed inverted polarity signals. We show that CTR-GM significantly affects the expected electric field pulse shapes and that the two anomalous events have cascade geometries for which strong coherent transition radiation is expected, which is not the case for the majority of the cosmic-ray events observed by the ANITA detector.

Coherent transition radiation— To calculate the coherent transition radiation from the geomagnetically-induced air shower current, we follow the approach presented in Ref. [14]. In what follows, we denote z as the axis normal to the ice surface, the subscript b refers to the air/ice boundary, and primed quantities are ‘retarded’ or ‘emission’ times.

Since the particle cascade is moving relativistically, the emission will be boosted along its direction of motion. In the following we will therefore only consider emission in the forward direction. In the left half of Fig. 1, the forward emission from a cosmic-ray air shower while propagating in air is illustrated by the full black cone. The signal gets ‘split’ at the boundary z_b , where part of the emission gets transmitted into

* krijn.de.vries@vub.ac.be

† prohira.1@osu.edu

FIG. 1. The geometry for coherent transition radiation just before (left) and just after (right) the relativistic shower front crosses the air/ice boundary z_b at retarded time t'_b . The geomagnetic current is indicated by \vec{J} . The direct emission from this current is given by the solid black cone on the left figure, which reflects up (label 1) for an in-air observer and refracts down for an in-ice observer (label 2). At time $t'_b + \epsilon$, the path to the in-air observer has vanished.

the ice given by the dashed line (label 2) and part of the signal gets reflected off the surface, shown by the full line (label 1). After the cascade penetrates the ice at time t_b (Fig. 1, right), the reflected path completely vanishes and only the direct path remains (label 3).

From Fig. 1, it immediately follows that the observed emission depends strongly on the observer location. For an in-ice observer, one has to consider paths 2 and 3, where for an in-air observer only path 1 has to be considered. In the following, we derive the expected fields due to coherent transition radiation for both situations separately.

CTR for an in-ice observer.— The in-air potential obtained at an infinitesimal distance ϵ above the boundary is observed through a completely different refracted path (Fig. 1, left, label 2), compared to the emission emitted an infinitesimal distance ϵ below the boundary (Fig. 1, right, label 3). A direct consequence of this discontinuity in the path length is a discontinuity in the observed potentials, leading to strong emission from the boundary, coherent transition radiation. It also follows that this is a geometrical effect, and as such is not limited to the net excess charge predicted by Askaryan, but applies equally well to the geomagnetically-induced air shower current.

To calculate the transition radiation from the geomagnetically-induced current for a typical cosmic-ray air shower, we consider the three dimensional current distribution given by $J^x(t', \vec{r}, h) = N_e(t') ev_d w(\vec{r}, h)$. Here, $N_e(t')$ denotes the number of leptons at the emission time t' , to be observed at the observer time t . The drift velocity $v_d = 0.04 c$ is the average velocity induced by Earth's magnetic field for electrons and positrons in a typical cosmic-ray air shower [35]. The function $w(\vec{r}, h)$ gives the particle distribution within the charge cloud, where \vec{r} denotes the lateral distance and h the longitudinal distance within the cloud which moves by definition with the speed of light along

the cascade axis. The total particle number, as well as the particle distributions within the charge cloud are parameterized following Ref. [35] and the detailed parameterizations are presented in the supplementary materials.

Closely following the formalism for a net excess charge presented in Ref. [14], the potential for the geomagnetically-induced air shower current crossing a boundary surface is given by,

$$A^x(\vec{x}, t) = \frac{\mu_0}{4\pi} \int d^2\vec{r} dh \mathcal{T}_{air-ice} \frac{J^x(t', r, h)}{|\mathcal{D}_2|} \theta(z - z_b) \Big|_{t'} + \frac{\mu_0}{4\pi} \int d^2\vec{r} dh \frac{J^x(t', r, h)}{|\mathcal{D}_3|} \theta(z_b - z) \Big|_{t'}. \quad (1)$$

Here, $\mathcal{T}_{air-ice}$ denotes the Fresnel transmission coefficient, and the different path lengths are included in the retarded distance $\mathcal{D} = L \frac{dt}{dt'}$, where L denotes the optical path length from the emission point at emission time t' to the observer, where the signal arrives at the observer time t . The electric fields are now obtained through the standard relation $\vec{E} = -dA^0/d\vec{x} - d\vec{A}/d(ct)$. These derivatives work on all terms under the integral. The specific contribution where the derivatives operate on the Heaviside step function $\theta(z)$ is called CTR and gives rise to the fields

$$E^x(\vec{x}, t) = \frac{\mu_0}{4\pi} \lim_{\epsilon \rightarrow 0} \int d^2\vec{r} \mathcal{T}_{air-ice} \frac{J^x(t', r, h)}{|\mathcal{D}_2|} \Big|_{z=z_b+\epsilon} - \frac{\mu_0}{4\pi} \lim_{\epsilon \rightarrow 0} \int d^2\vec{r} \frac{J^x(t', r, h)}{|\mathcal{D}_3|} \Big|_{z=z_b-\epsilon}. \quad (2)$$

CTR for an in-air observer.— The derivation for coherent transition radiation for an in-air observer is similar to the derivation for an in-ice observer outlined above. For an in-air observer, however, the reflected path through which the potential is observed (Fig. 1, left, label 1) instantly vanishes below the boundary. Though the (backward) emission from the cascade propagation below the ice reaches the detector, due to relativistic beaming this component is negligible compared to the reflected component from the in-air emission. As such, it is safe to ignore this in-ice contribution to the potential. We continue to use the term “transition radiation,” however, because the transition from air to ice is explicitly responsible for the induced shock in the potential. The potential from the geomagnetically-induced air shower current for an in-air observer is thus given by,

$$A^x(\vec{x}, t) = \frac{\mu_0}{4\pi} \int d^2\vec{r} dh \mathcal{R}_{air-ice} \frac{J^x(t', r, h)}{|\mathcal{D}_1|} \theta(z - z_b) \Big|_{t'}, \quad (3)$$

using the Fresnel reflection coefficient $\mathcal{R}_{air-ice}$. We subsequently obtain the field due to the vanishing of the potential at the boundary,

$$\vec{E}^x(\vec{x}, t) = \frac{\mu_0}{4\pi} \lim_{\epsilon \rightarrow 0} \int d^2\vec{r} \mathcal{R}_{air-ice} \frac{J^x(t', r, h)}{|\mathcal{D}_1|} \Big|_{z=z_b+\epsilon}. \quad (4)$$

The ANITA anomalous events.— In this section we investigate if coherent transition radiation from the

FIG. 2. The ratio of the number of charged particles hitting the ice boundary (N_b) to the maximum number of charged particles in the shower (N_{max}), versus zenith angle of the shower. Both the ANITA-I cosmic rays as well as the ANITA-I and ANITA-III anomalous events are shown. The error on the ANITA-1 CR sample is due to the reported error in the energy estimate. The shaded region is excluded by ANITA’s field of view.

geomagnetically-induced air shower current can provide an explanation for the ANITA anomalous events. For strong coherent transition radiation to occur, a significant part of the cosmic-ray air shower has to hit Earth’s surface. From Fig. 7 in Ref. [14], it follows that this restricts us to cosmic-ray air showers with zenith angles below ~ 70 degrees for the typical environments in which the ANITA detector operates.

To quantify this, a set of Monte-Carlo (MC) showers has been made using the CX-MC-GEO package presented in Ref [35]. This package allows to obtain the three dimensional charge and current distributions located inside the high-energy cascade front and is based on the full MC cascade mode of CONEX [36, 37]. The showers have been produced in the zenith angle range from 40-80 degrees, containing 10 simulations for each degree interval. The considered showers are induced by a 10^{18} eV proton primary, and the air-ice boundary is chosen at 3 km above sea level similar to conditions at Antarctica.

The results are shown by the green plane in Fig. 2. Here we plot the number of particles hitting the air-ice boundary, N_b , with respect to the maximum number of shower particles, N_{max} . From this we indeed confirm that for zenith angles larger than 70 degrees the particle content at the boundary becomes small.

Additionally, the shaded area in Fig. 2 shows the range of zenith angles excluded by the ANITA antenna array field of view [10]. To investigate in more detail if the ANITA anomalous events lie within the region of interest for coherent transition radiation to be significant, we ran 10 Monte-Carlo showers for each anomalous event within their given reconstruction errors. These errors are obtained by using the event param-

eters published by the ANITA collaboration [23], including energy (the reported energies for the anomalous events, provided for a direct shower, have been scaled by the empirically determined surface reflectivity coefficients attained on recent ANITA flights [38]), zenith angle, and surface elevation. A similar procedure has been made for the normal cosmic-ray air shower events detected during the ANITA-1 flight [39, 40].

From Fig. 2, it indeed follows that the ANITA anomalous events lie within the region of interest, separated from the majority of the ANITA cosmic-ray sample. For the CTR-GM signal to be significant, a combination of three variables of each event has to be considered: the event must be high energy, arrive at a zenith angle $\lesssim 70$ degrees, and impact the surface at a high elevation. It happens that in these variables, the ANITA anomalous events are within the region of interest and live in the tails of the typical CR distribution.

To quantify if coherent transition radiation can be an explanation for the ANITA anomalous events, as well as the normal cosmic-ray air showers observed in this region, in Fig. 3, we show the expected field for one of the ANITA anomalous events with a reconstructed zenith angle of 55 degrees and a surface elevation of 2.7 km, that is seen by an observer located 30 km above the air-ice boundary. The field is simulated at different viewing angles of $\alpha = 0, 1.7, 3.9$ degrees with respect to the specular angle of the cascade axis. It follows that, depending on the observer geometry, the expected transition radiation can be large compared to the geomagnetic emission in air, inverting the field polarity (Fig. 3 (b)). Furthermore, the time-ordering of the peaks can be reversed, (Fig. 3 (a)). These effects are absent for observer geometries further out from the specular angle (Fig. 3 (c)). For comparison, in Fig. 3 (d), we show the expected emission observed at a viewing angle of $\alpha = 1.7$ degree for a primary of the same energy and surface elevation, only adapting the zenith angle to 70 degrees, typical of an ANITA-1 CR. As expected in this situation, the transition radiation becomes negligible.

We further note that, being derived from the geomagnetic current, the CTR-GM signal is aligned with the local geomagnetic angle, and thus it has the same polarization—but inverted polarity—to the in-air signal from the induced geomagnetic current, a fact which has so far not been explained without significant tension with the standard model. Additionally, an interesting signature to distinguish the expected CTR-GM signal from the in-air emission is found in the received spectrum, increasing the high-frequency content due to the sharp shock in the potential. As such, a detailed comparison of the spectra of events that satisfy the CTR-GM criteria—anomalous or not—to the spectra of those events which are not expected to be influenced by CTR-GM can be used to confirm the presented hypothesis. Finally, since the CTR-GM signal is expected to dominate at small zenith angles we suggest an increased exposure for the ANITA detector towards these angles in future flights which will increase their cosmic-ray statistics within the region of interest for the CTR-GM signal.

Conclusions— We have shown that coherent transition radiation is not limited to a net excess charge, but applies equally well to a (net charge-neutral) transverse current traversing different media. We investigated if the anoma-

FIG. 3. The expected radio emission (full purple lines) from a downgoing cosmic ray air shower hitting an air-ice boundary at 3 km above sea level for a shower with a zenith angle of 55 degrees observed at: a) the specular angle of the shower axis, the CTR-GM (striped blue line) is seen before the in-air emission (dotted red line), b) 1.7 degrees from the specular angle, the CTR-GM emission is strong and arrives approximately at the same time as the in-air emission, c) 3.9 degrees from the shower axis, the CTR-GM emission is seen after the in-air emission. The situation for a 70 degrees inclined shower at 1.7 degree from the specular angle, is given in d), where it is observed that the CTR-GM emission is negligible.

ous events observed by the ANITA detector can be explained by coherent transition radiation from the geomagnetically-induced air shower current hitting the Antarctic surface. It is shown that the anomalous events have a particularly high particle content at the air-ice boundary compared to the typical cosmic-ray events detected by ANITA. Furthermore, we show that for showers with relatively small zenith angles $\lesssim 70$ degrees, similar to the two anomalous events detected by ANITA, the expected electric field at the detector can be dominated by coherent transition radiation, and even more interestingly, the apparent polarity can be inverted. For larger zenith angles, the particle content at the boundary is too

small to have a significant influence on the expected electric fields. It follows that coherent transition radiation from the geomagnetically-induced air shower current provides a natural, standard model explanation for the ANITA anomalous events. We recommend a more detailed event-by-event investigation to confirm this hypothesis.

Appendix A: Particle distribution parameterization—

The electric field calculations presented in Fig. 3 are based on the obtained field equations presented in Eq. 6. The three dimensional distribution $J^x(t')$ describing the geomagnetically induced air shower current is parameterized as,

$$J^x(t', \vec{r}, h) = N_e(t') ev_d w(\vec{r}, h). \quad (5)$$

The total particle number as function of the emission time t' is obtained directly from the NKG formalism [41, 42], and outlined in detail in [14]. Following [35], the drift velocity $v_d = 0.04 c$ is taken constant throughout the 3D particle distribution in the cascade front. This distribution is assumed to be radially symmetric and subdivided as $w(\vec{r}, h) = 2\pi w_1(r) w_2(r, h)$. The radial particle distribution $w_1(r)$ is obtained through,

$$w_1(r) = \frac{\Gamma(4.5 - p)}{\Gamma(p)\Gamma(4.5 - 2p)} \left(\frac{r}{r_0}\right)^{p-1} \left(\frac{r}{r_0} + 1\right)^{p-4.5} \quad (6)$$

Here $p = 1.1$, and $r_0 = 80$ m are fit parameters fixed to their values obtained close to shower maximum from the CX-MC-GEO package [35]. The longitudinal particle distribution is a function of distance from the shower axis and given by,

$$w_2(r, h) = \frac{4h}{(h_1)^2} \exp(-2h/h_1). \quad (7)$$

The radial dependence is hidden in the width parameter $h_1(r) = 5(0.02 + 0.1r)$ m fitted by comparison of this parameter with results obtained by the CX-MC-GEO package, corresponding to an effective width of 10 cm at the shower axis up to 10 meters at a radial distance of 100 m away from the shower axis (see Fig [10] of [35]).

We report the observation of radar echoes from the ionization trails of high-energy particle cascades. These data were taken at the SLAC National Accelerator Laboratory, where the full electron beam ($\sim 10^9$ e⁻ at ~ 10 GeV/e⁻) was directed into a plastic target to simulate an ultra high-energy neutrino interaction. This target was interrogated with radio waves, and coherent radio reflections from the cascades were detected, with properties consistent with theoretical expectations. This is the first definitive observation of radar echoes from high-energy particle cascades, which may lead to a viable neutrino detection technology for energies $\gtrsim 10^{16}$ eV.

Introduction.— Ultra high energy (UHE; $\gtrsim 10^{16}$ eV) astrophysical neutrinos offer great discovery potential. They would probe the accelerators of UHE cosmic rays, which are detected up to $\sim 10^{20}$ eV. Unlike cosmic rays, which are down-scattered on the cosmic microwave background and also deflected in magnetic fields, detected neutrinos will point back to their sources. UHE neutrino-nucleon interactions probe center-of-mass energies above the energy scale of colliders, allowing sensitive tests of new physics. To fully exploit the scientific potential of UHE neutrinos, we ultimately need an observatory with sufficient exposure to collect high statistics even in pessimistic flux scenarios.

When UHE neutrinos interact in matter, they produce a relativistic cascade of particles, as well as a trail of non-relativistic electrons and nuclei produced through the energy loss of the relativistic particles. The time-integrated cascade profile is a ellipsoid of length ~ 10 m and radius ~ 0.1 m, and nearly all of the primary interaction energy goes into ionization of the medium.

The incoherent optical Cherenkov emission from individual cascade electrons and positrons can be detected in TeV–PeV detectors like IceCube [1] and similar experiments [2–4]. However, the optical portion of the proposed successor IceCube-Gen2 [5] is too small to be an adequate UHE observatory, due to the steeply falling neutrino spectrum. Therefore, there are several proposed and implemented methods to detect these cascades from UHE neutrinos. First, the coherent radio-frequency Cherenkov emission from a net charge asymmetry in the cascade (the Askaryan effect [6]) has been observed in the lab [7], and is the focus of a variety of past [8], present [9–11], and proposed [12, 13] experiments. Radio methods can instrument large volumes more sparsely than optical detectors due to the transparency of radio in ice [14–16] making the construction of a large detector more cost-effective. Second, a τ neutrino, interacting in the earth, can produce a τ lepton—carrying much of the primary ν_τ energy—that exits the earth and decays in air, producing a

cascade. A current is induced in this cascade as it moves relativistically through the earth’s geomagnetic field, leading to coherent radio emission [17–21] that might be detected by proposed experiments [22–24]. Third, the optical Cherenkov light from such in-air decays can be detected by balloon-or satellite-borne experiments [25, 26]. All of these methods have potential for discovery at very high energies. However, they all have limited sensitivity at the lower end of the UHE range, between 10-100 PeV, just above the reach of optical Cherenkov detectors like IceCube.

Finally, it has been proposed that cascades can be detected by radar reflections off the ionization trail left in their wake. This technique shows promising projected sensitivity [27, 28], and is the only technique forecasted to have peak sensitivity in the 10-100 PeV range, with the potential to close the gap between optical Cherenkov detectors and the high energy technologies listed above. To that end, several recent experimental efforts [29–31] have made incremental progress toward the detection of a radar echo from a cascade in a dense medium.

In this letter, we present the first definitive observation of a radar echo from a particle cascade. This observation was made by experiment T576 at the SLAC National Accelerator Laboratory, where their electron beam was used to produce a particle cascade with a density equivalent to that of a $\sim 10^{19}$ eV neutrino interaction in ice, and with a similar shower profile. A transmitting antenna (TX) broadcast continuous-wave (CW) radio into the target, and several receiving antennas (RX) monitored the target for a radar reflection. We report on the observation of a signal consistent with theoretical predictions. Below, we detail the experiment, analysis technique, and results.

Experimental setup and data collection.— The experiment, depicted in Fig. 1, took place at End Station A at SLAC, a large, open hall with a rich history of discovery. Designated T576, the experiment had two runs during 2018, one in May after which a suggestion of a reflection was reported [32], and a second run in October, which is the focus of the present

FIG. 1. Cartoon of the radar method and T576. 1) A transmitter (TX) illuminates a target. 2) The beam passes through the integrating current toroid (ICT, to monitor beam charge and align the data during analysis) and creates a cascade inside the target, leaving behind an ionization cloud. The transmitted signal is reflected to a monitoring receiver (RX). Not to scale.

article. We broadcast CW radio at a range of frequencies between 1 and 2.1 GHz and a range of amplitudes, using a signal generator, 50 W power amplifier, and transmitting antenna (TX) toward a target of high-density polyethylene (HDPE), into which the electron beam was directed. Receiving antennas (RX) were also directed at this target to measure the radar reflection. The data presented in this article were captured by a Tektronix 4 channel, 20 GS/s oscilloscope.

Two different types of antennas were used in this analysis. One was a Vivaldi-style, ultra-wide-band antenna (0.6–6 GHz) with a measured forward gain of +12 dBi at 2 GHz, and the other was a custom-built 0.9–4 GHz log-periodic dipole antenna (LPDA). The LPDA was used in conjunction with a parabolic dish reflector, with a measured forward gain of +18 dBi at 2 GHz. Surrounding the beam pipe exit was an integrating current toroid (ICT), which gave a precise measurement of the charge in each bunch, and provided a very stable reference point for post-run alignment of the dataset.

The data taking was separated into sub-runs consisting of 100–500 events. Between sub-runs, certain parameters (TX frequency, TX amplitude, TX position and RX position) were varied. Runs in which data was taken for analysis are called signal-runs. Other sub-runs were reserved for taking background data, which will be discussed in the data analysis section, and are called background-runs. The run lasted 8 days, with over 4 full days of beam time acquired in 12-hour increments.

Expectations.—The radar method had been suggested for

cosmic-ray initiated extensive-air-shower (EAS) detection in the atmosphere as early as 1940 [33, 34], with further development in the 1960s [35], followed by stagnation, and then renewed interest in the early 2000s [36–38]. Recent experimental searches from terrestrial radar systems [39] and a dedicated experiment, Telescope Array Radar (TARA), [40, 41] reported no signal due to collisional losses—which limit the efficiency of the scattering—and insufficient ionization density in air. Short free-electron lifetimes ($\tau \sim \text{ns}$) in air at EAS altitudes cause the ionization to vanish before a sufficient density to reflect incident RF can be achieved. Cascades in ice or other dense media do not suffer from this problem.

The theory for radar is well-established, and models of radar detection of cascades in dense media have evolved to maturity in recent years. Whether built up from a macroscopic [27] or first-principles [28] viewpoint, the properties of a reflection are well-defined, and subject to several properties of the material in which the cascade happens. The maximum density of the ionization is directly proportional to the density of the medium. Another critical parameter is the mean ionization lifetime of the material. This lifetime τ dictates the longitudinal extent of the ionization deposit, and thus the overall length scale of the reflector. For ice, τ ranges from $\mathcal{O}(1 - 10 \text{ ns})$ and is strongly dependent upon the temperature of the ice [42]. For HDPE, the lifetimes are comparable to those of cold polar ice [43].

For a given transmitter and receiver, the spectral content of the reflected signal is a function of τ and the cascade geometry. For a compact cascade, as was the case for T576, any lifetime exceeding 1 ns would produce a significant radar reflection at the transmitted frequency. (In nature, an UHE cascade of similar density would be longer by a factor of $\sim \text{few}$ in ice, which is expected to cause an effective Doppler shift depending upon the radar geometry.) We transmitted at a peak power of 50 W, with no amplification on our receivers. The expected signal for T576 was a radar return of a few ns in duration, at the transmitter frequency, at a level of a few mV.

Data analysis.— The data analysis for T576 was challenging because of the high-amplitude backgrounds. When a charge bunch such as the SLAC beam traverses media with differing indices of refraction, or effective indices of refraction, transition radiation of various forms [44–46] is produced. These signals—which would not be present in nature¹—exceeded our expected radar signal by a factor of 10–100 in amplitude. We call the total RF background caused by the beam ‘beam splash’ owing to its overall messy character. Fortunately, the beam splash was quite stable, and therefore able to be characterized and filtered using a sensitive matrix-decomposition technique, detailed in [47] and based on [48],

¹ Except for the case of a cascade crossing the air/ice boundary, either an in-ice neutrino cascade breaking out into the air, or an in-air cosmic ray cascade breaking into the ice. Sensitivity to such events is subject to the orientation of transmit and receive antennas, and will be explored.

that we call singular-value-decomposition filtration, or SVD-filtration.

There are four nominal components to the signal-run data: CW, beam splash, noise, and signal (a radar reflection). The background-run data contains only beam-splash and thermal noise. Assuming that the response of our system is linear for the range of signals received (which we confirmed subsequently in the lab with independent measurements, discussed below) then the total background to our signal can be formed by a linear combination of CW, beam splash, and thermal noise. We call this linear combination ‘null data.’ To build the null data, we added pre-signal-region CW from signal-run data to signal-region beam splash in background-run data.

SVD-filtration identifies and removes patterns. Patterns are features in the data that are found in multiple individual measurements, such as the beam splash and CW. The SVD-filtration characterizes these patterns within a set of carefully aligned null data, producing a filter basis. Then a filter is produced for each individual event by expanding it in the filter basis. After applying this filter, the only thing remaining in the event should be random, featureless background noise, and any putative signal present in the real data.

The filtration process was a blind procedure, having been tuned on a number of sub-runs comprising $<10\%$ of the data. In addition to the null data produced to build the SVD-filter basis, a null event was constructed for every real event in the full dataset, to serve as the null hypothesis. An SVD-filter was constructed for each signal-run according to its associated background-run, and both datasets (real and null) were filtered using the same SVD-filter basis. The resultant filtered data was then analyzed for excess.

Results.—After filtration, the dataset was further processed using a method devised during the run-1 analysis. To investigate both the time and spectral content of the signal, a time-versus-frequency spectrogram was generated for each filtered event in a signal-run, and these spectrograms were averaged. The result of such a process is shown in Figure 2, where a clear excess is visible in the real data—and not in the null data—at the transmitter frequency of 2.1 GHz with a duration of a few ns. A similar excess was observed at many different transmit frequencies, antenna positions, and in different antennas, but no excess is observed at the same time and frequency point in the null data. Signal and sideband regions are indicated by the solid and dashed lines respectively, used in significance calculations defined below.

The highest amplitude signal was expected and received during runs with a horizontally-polarized, high-gain antenna at the specular angle, where the resultant (SVD-filtered) signal was large enough to extract a time-domain waveform through careful alignment and averaging. The alignment was performed so that the events could shift by no more than a fraction of a transmit period, and they were averaged. A resultant time-domain average is shown in Figure 3, where only events that had high enough SNR for reliable cross-correlation are used in order to facilitate qualitative comparison to simulation. Also in Figure 3 is a comparison to an FDTD sim-

FIG. 2. (Top) Time-versus-frequency (spectrogram) representation of the observed signal in data. This is the average of 200 events in a single signal-run. (Bottom) The same representation for the associated null data set for this sub-run. In both plots, the cross-hairs indicate the signal and sideband regions, used to calculate the significance as described in the main text.

ulation of the same signal-run (including models of the actual antennas used, the same ionization profile, and the same target material), and a comparison to the RadioScatter simulation code [49], which is particle-level and runs within GEANT4 [50]. The simulations have been scaled by a few percent to allow comparison of the waveform shapes and aligned in time with the data. The plasma lifetime is set to $\tau = 3$ ns in the simulation.

Several checks were performed to establish that the observed signal has properties consistent with a radar scatter. The first and most obvious is the observation that the signal scales with the transmitter output power. This is shown in Figure 4, where we plot the effective scattering cross section, σ_{eff} ,

FIG. 3. An example time-domain average of the highest-SNR reflections from a signal-run (solid black), compared to the output of an FDTD simulation for the same signal-run (dashed red), and a RadioScatter simulation for the same signal-run (dashed cyan). The plasma lifetime for the simulation is 3 ns.

FIG. 4. The effective scattering cross section, σ_{eff} , as a function of transmitter output power, for various receiving antennas (LPDA+dish and Vivaldi) and 2 different frequencies. Errors are statistical and systematic, and dominated by the latter. Each set of 4 points has been clustered around the true X axis value, for clarity, with the offset indicated in the figure legend. The solid bands are σ_{eff} from RadioScatter including statistical and systematic errors.

as a function of transmitter power. This expression, discussed in [28], is a measure of the effective ‘size’ of the reflecting region, should have a weak dependence on frequency at these energies, and should be constant with transmit power. All of these attributes are observed for the signal, which is shown in comparison to RadioScatter simulation (solid bands, including systematic error of HDPE collisional frequency, which is

Systematic	Est. error (dB)	dependence
Room effects	3	A,F,G
Antenna gain/orientation	1	A,F
Cable loss measurement	1	P
TX output power	2	P,G

TABLE I. Sources of systematic error (in dB of received power), and their associated estimated errors, used in Figure 4. Indicated in the right column is the dependence of the individual systematic on the data, either antenna-to-antenna dependent (A), frequency dependent (F), power dependent (P) or globally dependent (G).

ionization energy dependent [51]). The errors in the measurement of σ_{eff} include statistical and systematic uncertainties, and the systematic errors are tabulated in Table I along with the dependence of each error. Some errors affect the overall level of all received signal amplitudes (globally dependent) while others would, for example, introduce systematic offsets between antennas (antenna-to-antenna dependent). Trending of the signal with TX or RX baselines was not observed, owing to the fact that our antennas were not in the diffractive far field. This non-observation of such trends was verified by FDTD simulations.

Because the signal is so small relative to the beam splash, and the null hypothesis relies on a linear combination of background components, an obvious concern is a non-linearity in the overall system. After the run, a series of tests were performed in which CW at the same frequency and amplitude as T576 was amplified and broadcast via a Vivaldi antenna, and another Vivaldi, connected to an oscilloscope, was set up as a receiver. A high-voltage pulse with similar spectral content to the beam splash was broadcast simultaneously. The same analysis technique explained here, involving construction of null data and SVD-filtration, was performed on these data, and no excess was observed.

To establish a significance against a random fluctuation of the background, we generated $N = 10^7$ sets of 100 null events via bootstrapping, made an average spectrogram (like in Figure 2) for each set, and evaluated a test statistic of the sideband-subtracted power excess in the signal region. The signal region, tuned on a discarded subset of the data, is outlined in Figure 2. The value of the test statistic (μW ns) in the null data is $TS_{\text{null}} = 2.20_{-6.20}^{+6.56}$. The value of the test statistic in the measured data is $TS_{\text{data}} = 61.2_{-6.58}^{+7.40}$, well in excess of the 5σ quantile.

Conclusions.— In this letter, we have presented the observation of a radar reflection from a particle-shower induced cascade in a dense material. We have shown that the signal is in good agreement with theoretical expectations, and has a negligible probability of being a background fluctuation. This detection has promising implications for UHE neutrino detection, particularly in the 10-100 PeV range.

Acknowledgments.— We thank the personnel at SLAC for providing us with excellent, stable beam and a safe, productive work environment. We also thank David Saltzberg for invaluable assistance during both runs of T576, and John Beacom for comments and revisions of early drafts of this letter. This work was performed in part under SLAC DOE Contract DE-AC02-76SF00515. SP was partially supported by a US Department of Energy Office of Science Graduate Student Research (SCGSR) award, administered by the Oak Ridge Institute for Science and Education for the DOE under contract DE-SC-0014664. Computing resources were provided by the Ohio Supercomputer Center. KDdV was supported in part by the Flemish Foundation for Scientific Research FWO-12L3715N, and the European Research Council under the European Unions Horizon 2020 research and innovation programme (grant agreement No 805486). JN and CYK were supported by the Vanguard program from the Taiwan Ministry of Science and Technology.

Multi-messenger observations of a flaring blazar coincident with high-energy neutrino IceCube-170922A

The IceCube, *Fermi*-LAT, MAGIC, *AGILE*, ASAS-SN, HAWC, H.E.S.S., *INTEGRAL*, Kanata, Kiso, Kapteyn, Liverpool telescope, Subaru, *Swift*/*NuSTAR*, VERITAS, and VLA/17B-403 teams ^{*†}

Individual astrophysical sources previously detected in neutrinos are limited to the Sun and the supernova 1987A, whereas the origins of the diffuse flux of high-energy cosmic neutrinos remain unidentified. On 22 September 2017 we detected a high-energy neutrino, IceCube-170922A, with an energy of ~ 290 terra-electronvolts. Its arrival direction was consistent with the location of a known γ -ray blazar TXS 0506+056, observed to be in a flaring state. An extensive multi-wavelength campaign followed, ranging from radio frequencies to γ -rays. These observations characterize the variability and energetics of the blazar and include the first detection of TXS 0506+056 in very-high-energy γ -rays. This observation of a neutrino in spatial coincidence with a γ -ray emitting blazar during an active phase suggests that blazars may be a source of high-energy neutrinos.

Since the discovery of a diffuse flux of high-energy astrophysical neutrinos (1, 2), IceCube has searched for its sources. The only non-terrestrial neutrino sources identified previously are the Sun and the supernova 1987A, producing neutrinos with energies millions of times lower than the high-energy diffuse flux, such that the mechanisms and the environments responsible for the high-energy cosmic neutrinos are still to be ascertained (3, 4). Many candidate source types exist, with Active Galactic Nuclei (AGN) among the most prominent (5), in particular the small fraction of them designated as radio-loud (6). In these AGNs, the central super-massive black hole converts gravitational energy of accreting matter and/or the rotational energy of the black hole into powerful relativistic jets, within which particles can be accelerated to

high energies. If a number of these particles are protons or nuclei, their interactions with the radiation fields and matter close to the source would give rise to a flux of high-energy pions that eventually decay into photons and neutrinos (7). In blazars (8) – AGNs that have one of the jets pointing close to our line of sight – the observable flux of neutrinos and radiation is expected to be greatly enhanced owing to relativistic Doppler boosting. Blazar electromagnetic (EM) emission is known to be highly variable on time scales from minutes to years (9).

Neutrinos travel largely unhindered by matter and radiation. Even if high-energy photons (TeV and above) are unable to escape the source owing to intrinsic absorption, or are absorbed by interactions with the extragalactic background light (EBL) (10, 11), high-energy neutrinos may escape and travel unimpeded to Earth. An association of observed astrophysical neutrinos with blazars would therefore imply that high-energy protons or nuclei up to energies of at least tens of PeV are produced in blazar jets, suggesting that they may be the birthplaces of the most energetic particles observed in the Universe, the ultra-high energy cosmic rays (12). If neutrinos are produced in correlation with photons, the coincident observation of neutrinos with electromagnetic flares would greatly increase the chances of identifying the source(s). Neutrino detections must therefore be combined with the information from broad-band observations across the electromagnetic spectrum (multi-messenger observations).

To take advantage of multi-messenger opportunities, the IceCube neutrino observatory (13) has established a system of real-time alerts that rapidly notify the astronomical community of the direction of astrophysical neutrino candidates (14). From the start of the program in April 2016 through October 2017, 10 public alerts have been issued for high-energy neutrino candidate events with well-reconstructed directions (15).

We report the detection of a high-energy neutrino by IceCube and the multi-wavelength/multi-instrument observations of a flaring γ -ray blazar, TXS 0506+056, which was found to be positionally coincident with the neutrino direction (16). Chance coincidence of the IceCube-170922A event with the flare of TXS 0506+056 is statistically disfavored at the level of 3σ in models evaluated here associating neutrino and γ -ray production.

The neutrino alert

IceCube is a neutrino observatory with more than 5000 optical sensors embedded in 1 km³ of the Antarctic ice-sheet close to the Amundsen-Scott South Pole Station. The detector consists of 86 vertical strings frozen into the ice 125 m apart, each equipped with 60 digital optical modules (DOMs) at depths between 1450 and 2450 m. When a high-energy muon-neutrino interacts with an atomic nucleus in or close to the detector array, a muon is produced moving through the ice at superluminal speed and creating Cherenkov radiation detected by the DOMs. On 22 September 2017 at 20:54:30.43 Coordinated Universal Time (UTC), a high-energy neutrino-induced muon track event was detected in an automated analysis that is part of IceCube’s real-time alert system. An automated alert was distributed (17) to observers 43 seconds later, providing an initial estimate of the direction and energy of the event. A sequence

of refined reconstruction algorithms was automatically started at the same time, using the full event information. A representation of this neutrino event with the best-fitting reconstructed direction is shown in Figure 1. Monitoring data from IceCube indicate that the observatory was functioning normally at the time of the event.

A Gamma-ray Coordinates Network (GCN) Circular (18) was issued ~ 4 h after the initial notice including the refined directional information (offset 0.14° from the initial direction, see Figure 2). Subsequently, further studies were performed to determine the uncertainty of the directional reconstruction arising from statistical and systematic effects, leading to a best-fitting right ascension (RA) $77.43_{-0.65}^{+0.95}$ and declination (Dec) $+5.72_{-0.30}^{+0.50}$ (degrees, J2000 equinox, 90% containment region). The alert was later reported to be in positional coincidence with the known γ -ray blazar TXS 0506+056 (16), which is located at RA 77.36° and Dec $+5.69^\circ$ (J2000) (19), 0.1° from the arrival direction of the high-energy neutrino.

The IceCube alert prompted a follow-up search by the Mediterranean neutrino telescope ANTARES (acronym for Astronomy with a Neutrino Telescope and Abyss environmental RE-Search) (20). The sensitivity of ANTARES at the declination of IceCube-170922A is about one-tenth that of IceCube's (21) and no neutrino candidates were found in a ± 1 day period around the event time (22).

An energy of 23.7 ± 2.8 TeV was deposited in IceCube by the traversing muon. To estimate the parent neutrino energy, we performed simulations of the response of the detector array, considering that the muon-neutrino might have interacted outside the detector at an unknown distance. We assumed the best-fitting power-law energy spectrum for astrophysical high-energy muon neutrinos, $dN/dE \propto E^{-2.13}$ (2) where N is the number of neutrinos as a function of energy E . The simulations yielded a most probable neutrino energy of 290 TeV, with a 90% confidence level (C.L.) lower limit of 183 TeV, depending only weakly on the assumed astrophysical energy spectrum (25).

The vast majority of neutrinos detected by IceCube arise from cosmic-ray interactions within Earth's atmosphere. Although atmospheric neutrinos are dominant at energies below 100 TeV, their spectrum falls steeply with energy, allowing astrophysical neutrinos to be more easily identified at higher energies. The muon-neutrino astrophysical spectrum, together with simulated data, was used to calculate the probability that a neutrino at the observed track energy and zenith angle in IceCube is of astrophysical origin. This probability, the so-called signalness of the event (14), was reported to be 56.5% (17). Although IceCube can robustly identify astrophysical neutrinos at PeV energies, for individual neutrinos at several hundred TeV, an atmospheric origin cannot be excluded. Electromagnetic observations are valuable to assess the possible association of a single neutrino to an astrophysical source.

Following the alert, IceCube performed a complete analysis of relevant data prior to 31 October 2017. Although no additional excess of neutrinos was found from the direction of TXS 0506+056 near the time of the alert, there are indications at the 3σ level of high-energy neutrino emission from that direction in data prior to 2017, as discussed in a companion paper (26).

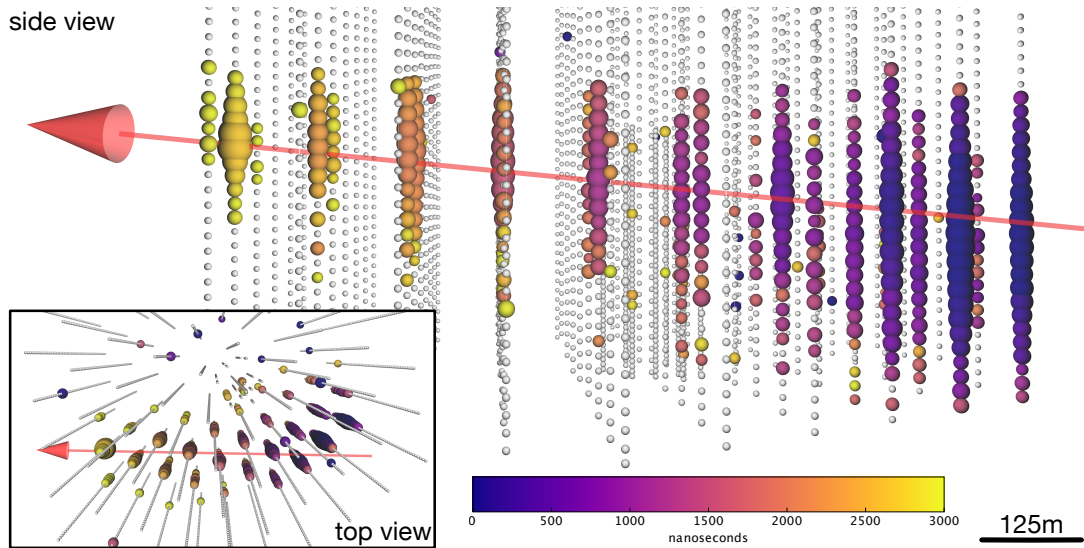

Figure 1: **Event display for neutrino event IceCube-170922A.** The time at which a DOM observed a signal is reflected in the color of the hit, with dark blues for earliest hits and yellow for latest. Time shown are relative to the first DOM hit according to the track reconstruction, and earlier and later times are shown with the same colors as the first and last times, respectively. The total time the event took to cross the detector is ~ 3000 ns. The size of a colored sphere is proportional to the logarithm of the amount of light observed at the DOM, with larger spheres corresponding to larger signals. The total charge recorded is ~ 5800 photoelectrons. Inset is an overhead perspective view of the event. The best-fitting track direction is shown as an arrow, consistent with a zenith angle $5.7^{+0.50}_{-0.30}$ degrees below the horizon.

Figure 2: **Fermi-LAT and MAGIC observations of IceCube-170922A's location.** Sky position of IceCube-170922A in J2000 equatorial coordinates overlaying the γ -ray counts from *Fermi*-LAT above 1 GeV (A) and the signal significance as observed by MAGIC (B) in this region. The tan square indicates the position reported in the initial alert and the green square indicates the final best-fitting position from follow-up reconstructions (18). Gray and red curves show the 50% and 90% neutrino containment regions, respectively, including statistical and systematic errors. *Fermi*-LAT data are shown as a photon counts map in 9.5 years of data in units of counts per pixel, using detected photons with energy of 1 to 300 GeV in a 2° by 2° region around TXS0506+056. The map has a pixel size of 0.02° and was smoothed with a 0.02 degree-wide Gaussian kernel. MAGIC data are shown as signal significance for γ -rays above 90 GeV. Also shown are the locations of a γ -ray source observed by *Fermi*-LAT as given in the *Fermi*-LAT Third Source Catalog (3FGL) (23) and the Third Catalog of Hard *Fermi*-LAT Sources (3FHL) (24) source catalogs, including the identified positionally coincident 3FGL object TXS 0506+056. For *Fermi*-LAT catalog objects, marker sizes indicate the 95% C.L. positional uncertainty of the source.

High-energy γ -ray observations of TXS 0506+056

On 28 September 2017, the *Fermi* Large Area Telescope (LAT) Collaboration reported that the direction of origin of IceCube-170922A was consistent with a known γ -ray source in a state of enhanced emission (16). *Fermi*-LAT is a pair-conversion telescope aboard the *Fermi* Gamma-ray Space Telescope sensitive to γ -rays with energies from 20 MeV to greater than 300 GeV (27). Since August 2008, it has operated continuously, primarily in an all-sky survey mode. Its wide field of view of ~ 2.4 steradian provides coverage of the entire γ -ray sky every 3 hours. The search for possible counterparts to IceCube-170922A was part of the *Fermi*-LAT collaboration's routine multi-wavelength/multi-messenger program.

Inside the error region of the neutrino event, a positional coincidence was found with a previously cataloged γ -ray source, 0.1° from the best-fitting neutrino direction. TXS 0506+056 is a blazar of BL Lacertae (BL Lac) type. Its redshift of $z = 0.3365 \pm 0.0010$ was measured only recently based on the optical emission spectrum in a study triggered by the observation of IceCube-170922A (28).

TXS 0506+056 is a known *Fermi*-LAT γ -ray source, appearing in three catalogs of *Fermi* sources (23, 24, 29) at energies above 0.1, 50, and 10 GeV, respectively. An examination of the *Fermi* All-Sky Variability Analysis (FAVA) (30) photometric light curve for this object showed that TXS 0506+056 had brightened considerably in the GeV band starting in April 2017 (16). Independently, a γ -ray flare was also found by *Fermi*'s Automated Science Processing (ASP, (25)). Such flaring is not unusual for a BL Lac object, and would not have been followed up as extensively if the neutrino were not detected.

Figure 3 shows the *Fermi*-LAT light curve and the detection time of the neutrino alert. The light curve of TXS 0506+056 from August 2008 to October 2017 was calculated in bins of 28 days for the energy range above 0.1 GeV. An additional light curve with 7-day bins was calculated for the period around the time of the neutrino alert. The γ -ray flux of TXS 0506+056 in each time bin was determined through a simultaneous fit of this source and the other *Fermi*-LAT sources in a 10° by 10° region of interest along with the Galactic and isotropic diffuse backgrounds, using a maximum likelihood technique (25). The integrated γ -ray flux of TXS 0506+056 for $E > 0.1$ GeV, averaged over all *Fermi*-LAT observations spanning 9.5 years, is $(7.6 \pm 0.2) \times 10^{-8} \text{ cm}^{-2} \text{ s}^{-1}$. The highest flux observed in a single 7-day light curve bin was $(5.3 \pm 0.6) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$, measured in the week 4 to 11 July 2017. Strong flux variations were observed during the γ -ray flare, the most prominent being a flux increase from $(7.9 \pm 2.9) \times 10^{-8} \text{ cm}^{-2} \text{ s}^{-1}$ in the week 8 to 15 August 2017 to $(4.0 \pm 0.5) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$ in the week 15 to 22 August 2017.

The Astro-Rivelatore Gamma a Immagini Leggero (*AGILE*) γ -ray telescope (31) confirmed the elevated level of γ -ray emission at energies above 0.1 GeV from TXS 0506+056 in a 13-day window (10 to 23 September 2017). The *AGILE* measured flux of $(5.3 \pm 2.1) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$ is consistent with the *Fermi*-LAT observations in this time period.

High-energy γ -ray observations are shown in Figures 3 and 4. Details on the *Fermi*-LAT and *AGILE* analyses can be found in (25).

Figure 3: Time-dependent multi-wavelength observations of TXS 0506+056 before and after IceCube-170922A. Significant variability of the electromagnetic emission can be observed in all displayed energy bands, with the source being in a high emission state around the time of the neutrino alert. From top to bottom: (A) VHE γ -ray observations by MAGIC, H.E.S.S. and VERITAS; (B) high-energy γ -ray observations by *Fermi*-LAT and *AGILE*; (C and D) x-ray observations by *Swift* XRT; (E) optical light curves from ASAS-SN, Kiso/KWFC, and Kanata/HONIR; and (F) radio observations by OVRO and VLA. The red dashed line marks the detection time of the neutrino IceCube-170922A. The left set of panels shows measurements between MJD 54700 (22 August, 2008) and MJD 58002 (6 September, 2017). The set of panels on the right shows an expanded scale for time range MJD 58002 – MJD 58050 (24 October, 2017). The *Fermi*-LAT light curve is binned in 28 day bins on the left panel, while finer 7 day bins are used on the expanded panel. A VERITAS limit from MJD 58019.40 (23 September, 2017) of $2.1 \times 10^{-10} \text{ cm}^{-2} \text{ s}^{-1}$ is off the scale of the plot and not shown.

Very-high-energy γ -ray observations of TXS 0506+056

Following the announcement of IceCube-170922A, TXS 0506+056 was observed by several ground based Imaging Atmospheric Cherenkov Telescopes (IACTs). A total of 1.3 hours of observations in the direction of the blazar TXS 0506+056 were taken using the High-Energy Stereoscopic System (H.E.S.S.) (32), located in Namibia, on 23 September, 2017 (Modified Julian Date (MJD) 58019), ~ 4 hours after the circulation of the neutrino alert. A 1-hour follow-up observation of the neutrino alert under partial cloud coverage was performed using the Very Energetic Radiation Imaging Telescope Array System (VERITAS) γ -ray telescope array (33), located in Arizona, USA, later on the same day, ~ 12 hours after the IceCube detection. Both telescopes made additional observations on subsequent nights but neither detected γ -ray emission from the source [see Figure 3 and (25)]. Upper limits at 95% C.L. on the γ -ray flux were derived accordingly (assuming the measured spectrum, see below): $7.5 \times 10^{-12} \text{ cm}^{-2} \text{ s}^{-1}$ during the H.E.S.S. observation period, and $1.2 \times 10^{-11} \text{ cm}^{-2} \text{ s}^{-1}$ during the VERITAS observations, both for energies $E > 175 \text{ GeV}$.

The Major Atmospheric Gamma Imaging Cherenkov (MAGIC) Telescopes (34) observed TXS 0506+056 for 2 hours on 24 September 2017 (MJD 58020) under non-optimal weather conditions and then for a period of 13 hours from 28 September to 4 October 2017 (MJD 58024–58030) under good conditions. MAGIC consists of two 17 m telescopes, located at the Roque de los Muchachos Observatory on the Canary Island of La Palma (Spain).

No γ -ray emission from TXS 0506+056 was detected in the initial MAGIC observations on 24 September 2017, and an upper limit was derived on the flux above 90 GeV of $3.6 \times 10^{-11} \text{ cm}^{-2} \text{ s}^{-1}$ at 95% C.L. (assuming a spectrum $dN/dE \propto E^{-3.9}$). However, prompted by the *Fermi*-LAT detection of enhanced γ -ray emission, MAGIC performed another 13 hours of observations of the region starting 28 September 2017. Integrating the data, MAGIC detected a significant very-high-energy (VHE) γ -ray signal (35) corresponding to 374 ± 62 excess photons, with observed energies up to about 400 GeV. This represents a 6.2σ excess over expected background levels (25). The day-by-day light curve of TXS 0506+056 for energies above 90 GeV is shown in Figure 3. The probability that a constant flux is consistent with the data is less than 1.35%. The measured differential photon spectrum (Figure 4) can be described over the energy range of 80 to 400 GeV by a simple power law $dN/dE \propto E^\gamma$ with a spectral index $\gamma = -3.9 \pm 0.4$ and a flux normalization of $(2.0 \pm 0.4) \times 10^{-10} \text{ TeV}^{-1} \text{ cm}^{-2} \text{ s}^{-1}$ at $E = 130 \text{ GeV}$. Uncertainties are statistical only. The estimated systematic uncertainties are $< 15\%$ in the energy scale, 11 to 18% in the flux normalization and ± 0.15 for the power-law slope of the energy spectrum (34). Further observations after 4 October 2017 were prevented by the full Moon.

An upper limit to the redshift of TXS 0506+056 can be inferred from VHE γ -ray observations using limits on the attenuation of the VHE flux due to interaction with the EBL. Details on the method are available in (25). The obtained upper limit ranges from 0.61 to 0.98 at a 95% C.L., depending on the EBL model used. These upper limits are consistent with the measured redshift of $z = 0.3365$ (28).

No γ -ray source above 1 TeV at the location of TXS 0506+056 was found in survey data of the High Altitude Water Cherenkov (HAWC) γ -ray observatory (36), either close to the time of the neutrino alert, or in archival data taken since November 2014 (25).

VHE γ -ray observations are shown in Figures 3 and 4. All measurements are consistent with the observed flux from MAGIC, considering the differences in exposure, energy range and observation periods.

Radio, optical and x-ray observations

The Karl G. Jansky Very Large Array (VLA) (37) observed TXS 0506+056 starting 2 weeks after the alert in several radio bands from 2 to 12 GHz (38), detecting significant radio flux variability and some spectral variability of this source. The source is also in the long-term blazar monitoring program of the Owens Valley Radio Observatory (OVRO) 40-m telescope at 15 GHz (39). The light curve shows a gradual increase in radio emission during the 18 months preceding the neutrino alert.

Optical observations were performed by the All-Sky Automated Survey for Supernovae (ASAS-SN) (40), the Liverpool telescope (41), the Kanata Telescope (42), the Kiso Schmidt Telescope (43), the high resolution spectrograph (HRS) on the Southern African Large Telescope (SALT) (44), the Subaru telescope Faint Object Camera and Spectrograph (FOCAS) (45) and the X-SHOOTER instrument on the Very Large Telescope (VLT) (46). The V band flux of the source is the highest observed in recent years, and the spectral energy distribution has shifted towards blue wavelengths. Polarization was detected by Kanata in the R band at the level of 7%. Redshift determination for BL Lac objects is difficult owing to the non-thermal continuum from the nucleus outshining the spectral lines from the host galaxies. Attempts were made using optical spectra from the Liverpool, Subaru and VLT telescopes to measure the redshift of TXS 0506+056, but only limits could be derived, [see, e.g., (47)]. The redshift of TXS0506+056 was later determined to be $z = 0.3365 \pm 0.0010$ using the Gran Telescopio Canarias (28).

X-ray observations were made by the x-Ray Telescope (XRT) on the *Neil Gehrels Swift Observatory* (0.3 to 10 keV) (48), *MAXI* Gas Slit Camera (GSC) (2 to 10 keV) (49), Nuclear Spectroscopic Telescope Array (*NuSTAR*) (3 to 79 keV) (50) and the INTERNATIONAL Gamma-Ray Astrophysics Laboratory (*INTEGRAL*) (20 to 250 keV) (51), with detections by *Swift* and *NuSTAR*. In a 2.1 square degree region around the neutrino alert, *Swift* identified nine x-ray sources, including TXS 0506+056.

Swift monitored the x-ray flux from TXS 0506+056 for 4 weeks after the alert, starting 23 September 2017 00:09:16 UT, finding clear evidence for spectral variability (see Figure 3D). The strong increase in flux observed at VHE energies over several days up until MJD 58030 (4 October 2017) correlates well with an increase in the x-ray emission in this period of time. The spectrum of TXS 0506+056 observed in the week after the flare is compatible with the sum of two power-law spectra, a soft spectrum with index -2.8 ± 0.3 in the soft x-ray band covered

by *Swift* XRT and a hard spectrum with index -1.4 ± 0.3 in the hard x-ray band covered by *NuSTAR* (25). Extrapolated to 20 MeV, the *NuSTAR* hard-spectrum component connects smoothly to the plateau (index -2) component observed by the *Fermi*-LAT between 0.1 and 100 GeV and the soft VHE γ -ray component observed by MAGIC (compare Fig. 4). Taken together, these observations provide a mostly complete, contemporaneous picture of the source emissions from 0.3 keV to 400 GeV, more than nine orders of magnitude in photon energy.

Figures 3 and 4 summarize the multi-wavelength light curves and the changes in the broad-band spectral energy distribution (SED), compared to archival observations. Additional details about the radio, optical, and x-ray observations can be found in (25).

Chance coincidence probability

Data obtained from multi-wavelength observations of TXS 0506+056 can be used to constrain the blazar-neutrino chance coincidence probability. This coincidence probability is a measure of the likelihood that a neutrino alert like IceCube-170922A is correlated by chance with a flaring blazar, considering the large number of known γ -ray sources and the modest number of neutrino alerts.

Given the large number of potential neutrino source classes available, no a priori blazar-neutrino coincidence model was selected ahead of the alert. After the observation, however, several correlation scenarios were considered and tested to quantify the a posteriori significance of the observed coincidence. Testing multiple models is important as the specific assumptions about the correlation between neutrinos and γ rays have an impact on the chance coincidence probability. In each case, the probability to obtain, by chance, a degree of correlation at least as high as that observed for IceCube-170922A was calculated using simulated neutrino alerts and the light curves of *Fermi*-LAT γ -ray sources. Given the continuous all-sky monitoring of the *Fermi*-LAT since 2008, all tests utilized 28-day binned γ -ray light curves above 1 GeV from 2257 extragalactic *Fermi*-LAT sources, derived in the same manner as used for the analysis of TXS 0506+056 γ -ray data.

To calculate the chance probabilities, a likelihood ratio test is used that allows different models of blazar-neutrino flux correlation to be evaluated in a consistent manner. All models assume that at least some of the observed γ -ray flux is produced in the same hadronic interactions that would produce high-energy neutrinos within the source. Our first model assumes that the neutrino flux is linearly correlated with the high-energy γ -ray energy flux (4). In this scenario, neutrinos are more likely to be produced during periods of bright, hard γ -ray emission. In the second model, the neutrino flux is modeled as strongly tied to variations in the observed γ -ray flux, regardless of the average flux of γ -rays. Here, a weak or a strong γ -ray source is equally likely to be a neutrino source if the neutrino is temporally correlated with variability in the γ -ray light curve. Third, we consider a correlation of the neutrino flux with the VHE γ -ray flux. Because hadronic acceleration up to a few PeV is required to explain the detected neutrino energy, VHE γ -ray sources are potential progenitors. Full details and results from these

Figure 4: **Broadband spectral energy distribution for the blazar TXS 0506+056.** The SED is based on observations obtained within 14 days of the detection of the IceCube-170922A event. The $E^2 dN/dE$ vertical axis is equivalent to a νF_ν scale. Contributions are provided by the following instruments: VLA (38), OVRO (39), Kanata Hiroshima Optical and Near-Infrared camera (HONIR) (52), Kiso and the Kiso Wide Field Camera (KWFC) (43), South-eastern Association for Research in Astronomy Observatory (SARA/UA) (53), ASAS-SN (54), *Swift* Ultraviolet and Optical Telescope (UVOT) and XRT (55), *NuSTAR* (56), *INTEGRAL* (57), *AGILE* (58), *Fermi-LAT* (16), MAGIC (35), VERITAS (59), H.E.S.S. (60) and HAWC (61). Specific observation dates and times are provided in (25). Differential flux upper limits (shown as colored bands and indicated as “UL” in the legend) are quoted at the 95% C.L. while markers indicate significant detections. Archival observations are shown in gray to illustrate the historical flux level of the blazar in the radio-to-keV range as retrieved from the ASDC SED Builder (62), and in the γ -ray band as listed in the *Fermi-LAT* 3FGL catalog (23) and from an analysis of 2.5 years of HAWC data. The γ -ray observations have not been corrected for absorption owing to the EBL. SARA/UA, ASAS-SN, and Kiso/KWFC observations have not been corrected for Galactic attenuation. The electromagnetic SED displays a double-bump structure, one peaking in the optical-ultraviolet range and the second one in the GeV range, which is characteristic of the non-thermal emission from blazars. Even within this 14-day period, there is variability observed in several of the energy bands shown (see Figure 3) and the data are not all obtained simultaneously. Representative $\nu_\mu + \bar{\nu}_\mu$ neutrino flux upper limits that produce on average one detection like IceCube-170922A over a period of 0.5 (solid black line) and 7.5 years (dashed black line) are shown assuming a spectrum of $dN/dE \propto E^{-2}$ at the most probable neutrino energy (311 TeV).

analyses are presented in (25).

The neutrino IceCube-170922A was found to arrive in a period of flaring activity in high-energy γ -rays. Prior to IceCube-170922A, nine public alerts had been issued by the IceCube real-time system. Additionally, 41 archival events have been identified among the IceCube data recorded since 2010, before the start of the real-time program in April 2016, which would have caused alerts if the real-time alert system had been in place. These events were also tested for coincidence with the γ -ray data.

Chance coincidence of the neutrino with the flare of TXS 0506+056 is disfavored at the 3σ level in any scenario where neutrino production is linearly correlated with γ -ray production or with γ -ray flux variations. This includes look-elsewhere corrections for all 10 alerts issued previously by IceCube and the 41 archival events. One of the neutrino events that would have been sent as an alert and had a good angular resolution ($<5^\circ$) is in a spatial correlation with the γ -ray blazar 3FGL J1040.4+0615. However, this source was not in a particularly bright emission state at the detection time of the corresponding neutrino. Therefore, a substantially lower test statistic would be obtained in the chance correlation tests defined in this paper (25).

We have investigated how typical the blazar TXS 0506+056 is among those blazars that might have given rise to a coincident observation similar to the one reported here. A simulation that assumes that the neutrino flux is linearly correlated with the blazar γ -ray energy flux shows that in 14% of the signal realizations we would find a neutrino coincident with a similarly bright γ -ray state as that observed for TXS 0506+056 (25). The detection of a single neutrino does not allow us to probe the details of neutrino production models or measure the neutrino-to- γ -ray production ratio. Further observations will be needed to unambiguously establish a correlation between high-energy neutrinos and blazars, as well as to understand the emission and acceleration mechanism in the event of a correlation.

Discussion

Blazars have often been suggested as potential sources of high-energy neutrinos. The calorimetric high-energy output of certain candidate blazars is high enough to explain individual observed IceCube events at 100 TeV to 1 PeV energies (63). Spatial coincidences between catalogs of blazars and neutrinos have been examined in (64), while (65) investigated one shower-like event with several thousand square degrees angular uncertainty observed in time coincidence with a blazar outburst. A track-like event, IceCube-160731, has been previously connected to a flaring γ -ray source (66). However, the limited evidence for a flaring source in the multi-wavelength coverage did not permit an identification of the source type of the potential counterpart (66).

Owing to the precise direction of IceCube-170922A, combined with extensive multi-wavelength observations, a chance correlation between a high-energy neutrino and the potential counterpart can be rejected at the 3σ level. Considering the association between IceCube-170922A and TXS 0506+056, γ -ray blazars are strong candidate sources for at least a fraction of the observed astrophysical neutrinos. Earlier studies of the cross-correlation between IceCube events

and the γ -ray blazar population observed by *Fermi*-LAT demonstrated that these blazars can only produce a fraction of the observed astrophysical neutrino flux above 10 TeV (4). Although these limits constrain the contribution from blazars to the diffuse neutrino background, the potential association of one or two high-energy neutrinos to blazars over the total observing time of IceCube is fully compatible with the constraint.

Adopting cosmological parameters (67) $H_0 = 67.8$, $\Omega_m = 0.308$, $\Omega_\lambda = 0.692$, where H_0 is the Hubble constant, Ω_m is the matter density and Ω_λ is the dark energy density, the observed redshift of $z = 0.3365$ implies an isotropic γ -ray luminosity between 0.1 GeV and 100 GeV of 1.3×10^{47} erg s⁻¹ in the ± 2 weeks around the arrival time of the IceCube neutrino, and a luminosity of 2.8×10^{46} erg s⁻¹, averaged over all *Fermi*-LAT observations. Observations in the optical, x-ray, and VHE γ -ray bands show typical characteristics of blazar flares: strong variability on time scales of a few days, and an indication of a shift of the synchrotron emission peak towards higher frequencies. VHE γ -ray emission is found to change by a factor of ~ 4 within just 3 days. Similarly, the high-energy γ -ray energy band shows flux variations up to a factor of ~ 5 from 1 week to the next.

No other neutrino event that would have passed the selection criteria for a high-energy alert was observed from this source since the start of IceCube observations in May 2010. The muon neutrino fluence for which we would expect to detect one high-energy alert event with IceCube in this period of time is 2.8×10^{-3} erg cm⁻². A power-law neutrino spectrum is assumed in this calculation with an index of -2 between 200 TeV and 7.5 PeV, the range between the 90% C.L. lower and upper limits for the energy of the observed neutrino (see (25) for details).

The fluence can be expressed as an integrated energy flux if we assume a time period during which the source was emitting neutrinos. For a source that emits neutrinos only during the ~ 6 month period corresponding to the duration of the high-energy γ -ray flare, the corresponding average integrated muon neutrino energy flux would be 1.8×10^{-10} erg cm⁻² s⁻¹. Alternatively, the average integrated energy flux of a source that emits neutrinos over the whole observation period of IceCube, *i.e.* 7.5 years, would be 1.2×10^{-11} erg cm⁻² s⁻¹. These two benchmark cases are displayed in Figure 4. In an ensemble of faint sources with a summed expectation of order 1, we would anticipate observing a neutrino even if the individual expectation value is $\ll 1$. This is expressed by the downward arrows on the neutrino flux points in Figure 4.

The two cases discussed above correspond to average isotropic muon neutrino luminosities of 7.2×10^{46} erg s⁻¹ for a source that was emitting neutrinos in the ~ 6 month period of the high-energy γ -ray flare, and 4.8×10^{45} erg s⁻¹ for a source that emitted neutrinos throughout the whole observation period. This is similar to the luminosity observed in γ -rays, and thus broadly consistent with hadronic source scenarios (68).

A neutrino flux that produces a high-energy alert event can, over time, produce many lower-energy neutrino-induced muons in IceCube. A study of neutrino emission from TXS 0506+056 prior to the high-energy γ -ray flare, based on the investigation of these lower-energy events, is reported in a companion paper (26).

Acknowledgements

MAGIC: We would like to thank the Instituto de Astrofísica de Canarias for the excellent working conditions at the Observatorio del Roque de los Muchachos in La Palma.

AGILE: We thank ASI personnel involved in the operations and data center of the AGILE mission.

ASAS-SN: We thank Las Cumbres Observatory and its staff for their continued support of ASAS-SN.

VERITAS: We acknowledge the excellent work of the technical support staff at the Fred Lawrence Whipple Observatory and at the collaborating institutions in the construction and operation of the instrument.

Funding

IceCube Collaboration: The IceCube collaboration gratefully acknowledge the support from the following agencies and institutions: USA – U.S. National Science Foundation-Office of Polar Programs, U.S. National Science Foundation-Physics Division, Wisconsin Alumni Research Foundation, Center for High Throughput Computing (CHTC) at the University of Wisconsin–Madison, Open Science Grid (OSG), Extreme Science and Engineering Discovery Environment (XSEDE), U.S. Department of Energy–National Energy Research Scientific Computing Center, Particle astrophysics research computing center at the University of Maryland, Institute for Cyber-Enabled Research at Michigan State University, and Astroparticle physics computational facility at Marquette University; Belgium – Funds for Scientific Research (FRS-FNRS and FWO), FWO Odysseus and Big Science programmes, and Belgian Federal Science Policy Office (Belspo); Germany – Bundesministerium für Bildung und Forschung (BMBF), Deutsche Forschungsgemeinschaft (DFG), Helmholtz Alliance for Astroparticle Physics (HAP), Initiative and Networking Fund of the Helmholtz Association, Deutsches Elektronen Synchrotron (DESY), and High Performance Computing cluster of the RWTH Aachen; Sweden – Swedish Research Council, Swedish Polar Research Secretariat, Swedish National Infrastructure for Computing (SNIC), and Knut and Alice Wallenberg Foundation; Australia – Australian Research Council; Canada – Natural Sciences and Engineering Research Council of Canada, Calcul Québec, Compute Ontario, Canada Foundation for Innovation, WestGrid, and Compute Canada; Denmark – Villum Fonden, Danish National Research Foundation (DNRF); New Zealand – Marsden Fund; Japan - Japan Society for Promotion of Science (JSPS) and Institute for Global Prominent Research (IGPR) of Chiba University; Korea – National Research Foundation of Korea (NRF); Switzerland – Swiss National Science Foundation (SNSF).

Fermi-LAT collaboration: The *Fermi*-LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique / Institut National de Physique Nucléaire et de Physique des Particules in France, the Agen-

zia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden.

Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d'Études Spatiales in France. This work performed in part under DOE Contract DE-AC02-76SF00515.

MAGIC collaboration: The financial support of the German BMBF and MPG, the Italian INFN and INAF, the Swiss National Fund SNF, the ERDF under the Spanish MINECO (FPA2015-69818-P, FPA2012-36668, FPA2015-68378-P, FPA2015-69210-C6-2-R, FPA2015-69210-C6-4-R, FPA2015-69210-C6-6-R, AYA2015-71042-P, AYA2016-76012-C3-1-P, ESP2015-71662-C2-2-P, CSD2009-00064), and the Japanese JSPS and MEXT is gratefully acknowledged. This work was also supported by the Spanish Centro de Excelencia “Severo Ochoa” SEV-2012-0234 and SEV-2015-0548, and Unidad de Excelencia “María de Maeztu” MDM-2014-0369, by the Croatian Science Foundation (HrZZ) Project IP-2016-06-9782 and the University of Rijeka Project 13.12.1.3.02, by the DFG Collaborative Research Centers SFB823/C4 and SFB876/C3, the Polish National Research Centre grant UMO-2016/22/M/ST9/00382 and by the Brazilian MCTIC, CNPq and FAPERJ.

AGILE: AGILE is an ASI space mission developed with scientific and programmatic support from INAF and INFN. Research partially supported through the ASI grant no. I/028/12/2. Part of this work is based on archival data, software or online services provided by the ASI Space Science Data Center (SSDC, previously known as ASDC).

ASAS-SN: ASAS-SN is funded in part by the Gordon and Betty Moore Foundation through grant GBMF5490 to the Ohio State University, NSF grant AST-1515927, the Mt. Cuba Astronomical Foundation, the Center for Cosmology and AstroParticle Physics (CCAPP) at OSU, and the Chinese Academy of Sciences South America Center for Astronomy (CASSACA). A. F. was supported by the Initiative and Networking Fund of the Helmholtz Association. J. F. B. is supported by NSF Grant PHY-1714479. S.D. acknowledges Project 11573003 supported by NSFC. J. L. P. is supported by FONDECYT grant 1151445 and by the Ministry of Economy, Development, and Tourism's Millennium Science Initiative through grant IC120009, awarded to The Millennium Institute of Astrophysics, MAS. This research was made possible through the use of the AAVSO Photometric All-Sky Survey (APASS), funded by the Robert Martin Ayers Sciences Fund.

HAWC: HAWC acknowledges the support from: the US National Science Foundation (NSF) the US Department of Energy Office of High-Energy Physics; the Laboratory Directed Research and Development (LDRD) program of Los Alamos National Laboratory; Consejo Nacional de Ciencia y Tecnología (CONACyT), México (grants 271051, 232656, 260378, 179588, 239762, 254964, 271737, 258865, 243290, 132197, 281653)(Cátedras 873, 1563), Laboratorio Nacional HAWC de rayos gamma; L'OREAL Fellowship for Women in Science 2014; Red HAWC, México; DGAPA-UNAM (grants IG100317, IN111315, IN111716-3, IA102715,

109916, IA102917, IN112218); VIEP-BUAP; PIFI 2012, 2013, PROFOCIE 2014, 2015; the University of Wisconsin Alumni Research Foundation; the Institute of Geophysics, Planetary Physics, and Signatures at Los Alamos National Laboratory; Polish Science Centre grant DEC-2014/13/B/ST9/945; Coordinación de la Investigación Científica de la Universidad Michoacana. Thanks to Scott Delay, Luciano Díaz and Eduardo Murrieta for technical support.

H.E.S.S.: The support of the Namibian authorities and of the University of Namibia in facilitating the construction and operation of H.E.S.S. is gratefully acknowledged, as is the support by the German Ministry for Education and Research (BMBF), the Max Planck Society, the German Research Foundation (DFG), the Helmholtz Association, the Alexander von Humboldt Foundation, the French Ministry of Higher Education, Research and Innovation, the Centre National de la Recherche Scientifique (CNRS/IN2P3 and CNRS/INSU), the Commissariat à l'énergie atomique et aux énergies alternatives (CEA), the U.K. Science and Technology Facilities Council (STFC), the Knut and Alice Wallenberg Foundation, the National Science Centre, Poland grant no. 2016/22/M/ST9/00382, the South African Department of Science and Technology and National Research Foundation, the University of Namibia, the National Commission on Research, Science & Technology of Namibia (NCRST), the Austrian Federal Ministry of Education, Science and Research and the Austrian Science Fund (FWF), the Australian Research Council (ARC), the Japan Society for the Promotion of Science and by the University of Amsterdam. We appreciate the excellent work of the technical support staff in Berlin, Zeuthen, Heidelberg, Palaiseau, Paris, Saclay, Tübingen and in Namibia in the construction and operation of the equipment. This work benefited from services provided by the H.E.S.S. Virtual Organisation, supported by the national resource providers of the EGI Federation.

INTEGRAL: INTEGRAL is an ESA space mission, with its instruments and science data center funded by the ESA member states (specifically the PI countries: Denmark, France, Germany, Italy, Switzerland, Spain), and with additional participation of Russia and the USA. The INTEGRAL SPI instrument was provided through Co-PI institutes IRAP (Toulouse/France) and MPE (Garching/Germany), the SPI project was coordinated and managed by CNES (Toulouse/France). The INTEGRAL IBIS instrument was provided through Co-PI institutes IAPS (Rome/Italy) and CEA (Saclay/France). The SPI-ACS detector system has been provided by MPE Garching/Germany. The SPI team is grateful to ASI, CEA, CNES, DLR, ESA, INTA, NASA and OSTC for their support. The Italian INTEGRAL team acknowledges the support of ASI/INAF agreement n. 2013-025-R.1. JR acknowledges support from the European Union's Horizon 2020 Programme under the AHEAD project (grant n. 654215). RD acknowledges the German INTEGRAL support through DLR grants 50 OG 1101 and 1601.

Kanata, Kiso and Subaru observing teams: Observations with the Kanata and Kiso Schmidt telescopes were supported by the Optical and Near-infrared Astronomy Inter-University Cooperation Program and the Grants-in-Aid of the Ministry of Education, Science, Culture, and Sport JP23740143, JP25800103, JP16H02158, JP17K14253, JP17H04830, JP26800103, JP24103003. This work was also based in part on data collected at Subaru Telescope, which is operated by the National Astronomical Observatory of Japan.

Kapteyn: The Jacobus Kapteyn telescope is operated at the Observatorio del Roque de los

Muchachos on the Spanish island of La Palma by the SARA consortium, whose member institutions (listed at <http://saraobservatory.org>) fund its operation. Refitting for remote operations and instrumentation were funded by the National Science Foundation under grant 1337566 to Texas A&M University—Commerce.

Liverpool telescope: The Liverpool Telescope is operated on the island of La Palma by Liverpool John Moores University in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias with financial support from the UK Science and Technology Facilities Council.

Swift/NuSTAR: AK and DFC acknowledge support from the National Aeronautics and Space Administration Swift Guest Investigator Program under grant NNX17AI95G. The Swift team at the Mission Operations Center (MOC) at Penn State acknowledges support from NASA contract NAS5-00136. Swift is supported at the University of Leicester by the UK Space Agency.

VERITAS: This research is supported by grants from the U.S. Department of Energy Office of Science, the U.S. National Science Foundation and the Smithsonian Institution, and by NSERC in Canada.

VLA/17B-403 The National Radio Astronomy Observatory (NRAO) is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. AJT is supported by a Natural Sciences and Engineering Research Council of Canada (NSERC) Post-Graduate Doctoral Scholarship (PGSD2-490318-2016). AJT and GRS are supported by NSERC Discovery Grants (RGPIN-402752-2011 and RGPIN-06569-2016). JCAMI is the recipient of an Australian Research Council Future Fellowship (FT140101082).

Author contributions

IceCube: The IceCube Collaboration designed, constructed and now operates the the IceCube Neutrino Observatory. Data processing and calibration, Monte Carlo simulations of the detector and of theoretical models, and data analyses were performed by a large number of collaboration members, who also discussed and approved the scientific results presented here. It was reviewed by the entire collaboration before publication, and all authors approved the final version of the manuscript.

Fermi-LAT: The Fermi-LAT contact authors and internal reviewers are SB, AF, YT, KB, EC, and MW.

MAGIC: EB is the MAGIC multi-messenger contact and PI of the neutrino follow-up program. KS is co-convenor of the MAGIC transient working group. LF and MP are the main analyzers of the MAGIC data presented here. AM and EP derived an upper limit to the redshift inferred from MAGIC data.

AGILE: All co-authors contributed to the scientific results presented in the paper. FL and MT wrote the part of the manuscript related to the *AGILE* results.

ASAS-SN: AF, BJS and SH installed an automatic follow up to IceCube triggers which provided additional early data on this event. KZS, CSK, JFB, TAT, TWSH, SD, JLP and BJS built

the telescopes and developed the data processing pipelines.

HAWC: TW is convener of the HAWC extragalactic working group. MH is the HAWC multi-messenger contact. IT, RL and IMC are the main analysers of the HAWC data presented here.

H.E.S.S.: AT is convener of the H.E.S.S. extragalactic working group. FS is the H.E.S.S. multi-messenger contact and PI of the neutrino follow-up program. CH is the main analyser of the H.E.S.S. data presented here. SO provided a cross-check of the presented analysis.

INTEGRAL: VS has performed the INTEGRAL analysis presented here. CF is the PI of INTEGRAL Science Data Center. RD is the co-PI of the SPI instrument. EK is INTEGRAL Project Scientist. PL and PU are co-PIs of INTEGRAL/IBIS instrument. SM is responsible for the INTEGRAL/IBAS. All of the collaborators provided contribution to the text.

Kanata, Kiso and Subaru observing teams: YTT and YU developed the follow-up strategy to search for IceCube counterparts. TN and MK conducted the near-infrared imaging and polarimetric observations of the TXS 0506+056 using the HONIR instrument on the Kanata telescope, which were processed by the data reduction system developed by RI. The reduced images were mainly examined by HM and HN. MY reduced the polarimetric data. KSK supervised all of the above. TM conducted the optical imaging observations of TXS 0506+056 with the KWFC instrument on the Kiso Schmidt telescope. He also reduced the data. These two observations contribute to Figures 3 and 4. YM conducted optical spectroscopic observations of the TXS 0506+056 with the FOCAS spectrograph on the 8.2 m Subaru telescope. The data are reduced and examined by MY, TM, and KO. The spectra are shown in Figure S5.

Kapteyn: WCK obtained and reduced the optical observations at the Kapteyn telescope.

Liverpool telescope: IS and CC obtained, reduced and analysed the Liverpool Telescope spectra presented in this paper.

Swift/NuSTAR: AK led reduction of Swift XRT data, and JJD led reduction of NuSTAR data. DBF carried out the joint Swift XRT + NuSTAR analysis, and AK managed author contributions to this section.

VERITAS: The construction, operation, and maintenance of the VERITAS telescopes, as well as the tools to analyze the VERITAS data, are the work of the the VERITAS Collaboration as a whole. The VERITAS Collaboration contacts for this paper are MS and DAW.

VLA/17B-403: GRS wrote the Director's Discretionary Time proposal whose VLA data are used in this paper (VLA/17B-403). AJT performed the VLA data reduction and analyses in consultation with the rest of the team. AJT and GRS wrote the VLA-related text in consultation with the rest of the team. GRS contributed to significant copy editing of the entire paper.

Competing interests

IceCube: There are no competing interests to declare.

Fermi-LAT: There are no competing interests to declare.

MAGIC: There are no competing interests to declare.

AGILE: There are no competing interests to declare.

ASAS-SN: There are no competing interests to declare.

HAWC: There are no competing interests to declare.

H.E.S.S.: There are no competing interests to declare.

INTEGRAL: There are no competing interests to declare.

Liverpool Telescope: There are no competing interests to declare.

Kanata, Kiso and Subaru observing teams: There are no competing interests to declare.

Kapteyn: There are no competing interests to declare.

Swift/NuSTAR: There are no competing interests to declare.

VERITAS: There are no competing interests to declare.

VLA/17B-403: There are no competing interests to declare.

Data and materials availability

IceCube: All IceCube data related to the the results presented in this paper are provided in (25).

Fermi-LAT: Fermi-LAT data are available from the Fermi Science Support Center (<http://fermi.gsfc.nasa.gov/ssc>) and https://www-glast.stanford.edu/pub_data/1483/.

MAGIC: The MAGIC collaboration routinely releases published graphics, tables and analysis results on a database linked from the official web pages. For this paper we will additionally release underlying data in the form of a list of the MAGIC observed events, after reconstruction and analysis cuts, and simplified instrument response functions.

Both resources (published analysis results as well as data releases for specific publications, like in this case) are accessible at the MAGIC public data website:

<https://magic.mpp.mpg.de/public/public-data/>

We note that the format we choose for our data release, aims to make MAGIC data accessible to the wider community, without requiring the use of internal proprietary software.

To exactly reproduce the published results, advanced software programs are necessary together with training on how to use them. Access to all data, analysis software and necessary training will be made available on request.

AGILE: Data and materials availability: All the *AGILE* data used in this paper are public and available from the *AGILE* Data Center webpage at the following URL: <http://www.ssdsc.asi.it/mmia/index.php?mission=agilemmia>. The *AGILE* data analysis software and calibrations are also public and available at the URL: <http://agile.ssdsc.asi.it/publicsoftware.html>.

ASAS-SN: ASAS-SN light curves are available through the ASAS-SN sky patrol <https://asas-sn.osu.edu>

HAWC: Data used for the presented results are available at:

<https://data.hawc-observatory.org/datasets/ic170922/index.php>.

H.E.S.S.: Data used for the presented results are available at https://www.mpi-hd.mpg.de/hfm/HESS/pages/publications/auxiliary/auxinfo_TXS0506.html

INTEGRAL: Data and software used for the presented results are available at <https://www.isdc.unige.ch/>.

Kanata, Kiso and Subaru observing teams: All the raw data taken with the Kiso, Kanata, and Subaru telescopes are available in the SMOKA, which is operated by the Astronomy Data

Center, National Astronomical Observatory of Japan. The Subaru data were taken in the open-use program S16B-0711.

Kapteyn: The numerical magnitude/flux data to produced the published results here are available in at <http://www.astronomerstelegam.org/?read=10831>

Liverpool Telescope: Data used for the presented results are available in the telescope archive at <http://telescope.livjm.ac.uk>.

Swift/NuSTAR: Link to the archived Swift data:

<http://www.swift.ac.uk/archive/obs.php>

The initial tiling observations (shortly after the IceCube trigger) targetIDs: 10308-10326. Monitoring ObsIDs used for this analysis (from Sept 23 to Oct 23): 00010308001, 00083368001-006, 00010308008-013.

Link to the archived NuSTAR data:

<https://heasarc.gsfc.nasa.gov/FTP/nustar/data/obs/03/9//90301618002/>

ObsID used for this analysis: 90301618002.

VERITAS: Data used for the presented results is available at <https://veritas.sao.arizona.edu/veritas-science/veritas-results-mainmenu-72/490-ic-result>

VLA/17B-403 team: The VLA/17B-403 team would like to thank the NRAO for granting us DDT VLA time to observe this source and the NRAO staff for rapidly executing our observations. The original data from the VLA observations presented in this paper are publicly available through the NRAO Science Data Archive (<https://archive.nrao.edu/archive/advquery.jsp>, using the Project Code 17B-403).

Supplementary Materials for:
Multi-messenger observations of a flaring blazar
coincident with high-energy neutrino IceCube-170922A

IceCube

IceCube is a cubic-kilometer-sized neutrino detector (13) installed in the ice at the geographic South Pole, Antarctica between depths of 1450 m and 2450 m. The detector consists of 5160 digital optical modules (DOMs) attached to 86 cables (called strings), each instrumented with 60 DOMs. The strings are arranged in a hexagonal pattern with 125 m average horizontal spacing. Each DOM consists of a glass pressure-resistant sphere containing a photomultiplier and electronics, and operates independently producing digital signals, which are transmitted to the surface along the string. Detector construction was completed in 2010, and IceCube has operated with an $\sim 99\%$ duty cycle since then.

IceCube does not directly observe neutrinos, but rather the secondary particles produced in the neutrino interaction with matter. IceCube detects these particles by observing the Cherenkov light emitted as they travel through the ice. The ability to accurately determine the direction of a neutrino event recorded in IceCube is highly dependent on the ability to reconstruct the trajectories of these secondary particles. The secondary particles produce two distinct classes of signals within the instrumented volume: tracks and cascades. Track events, the primary focus of the IceCube alert system, are produced by muons, arising primarily from the charged-current interaction of muon-type neutrinos, which produce tracks with lengths of the order of a few kilometers. These tracks can be reconstructed with a directional uncertainty less than 1 deg, but with a large uncertainty on the neutrino energy since an unmeasured fraction of their energy is deposited outside the instrumented volume.

The IceCube neutrino alerts are generated in real time by applying direction and energy estimates to all events as the data are collected (14), and notifying the astronomical community immediately of a candidate astrophysical neutrino event. IceCube-170922A was generated by the “EHE” through-going track selection in the real-time alert system. The event selection was inspired by the event requirements used to search for cosmogenic/GZK neutrinos (69) and was modified for online use to give a larger number of astrophysical neutrinos. The sensitivity of this event selection is highlighted by the effective area for several zenith angle ranges, shown in Figure S1. The zenith angle of IceCube-170922A ($\cos(\text{zenith}) = -0.1$) was in the most sensitive zenith acceptance range, a direction where atmospheric muons are easily blocked, but neutrino absorption in the Earth has not depleted the high-energy neutrino flux.

Calculations of systematic uncertainties for IceCube-170922A The directional resolution of muon tracks passing through the IceCube detector is limited by the stochastic nature of the detected light, the finite density of DOMs where Cherenkov light is detected and the uncertainty in the optical properties of the glacial ice (70). We modeled the expected uncertainty due to these statistical and systematic effects by re-simulating a large sample of candidate events similar to the observed event, and studying the distance of their best-fitting directions from their true simulated direction.

A dedicated simulation set was generated containing muon tracks passing through the same part of the detector as the originally observed event (closer than 30 m from the original best-

Figure S1: **Neutrino effective area for the through-going track alert channel.** Effective area for the online through-going track (“EHE”) selection in three zenith angle ranges. The zenith angle of IceCube-170922A was $\cos(\text{zenith}) = -0.1$, a preferred direction for this event selection. In the range -0.55 to -0.45 (~ 30 deg below the horizon) a strong absorption by the Earth at the highest neutrino energies is seen, while in the interval 0.25 to 0.35 (~ 20 deg above the horizon) strong cuts on track energy are needed to suppress the background from cosmic-ray muons, limiting sensitivity below 1 PeV. The most probable neutrino energy of 290 TeV is also shown.

fitting track at any point within the instrumented volume and within 2 deg of the best-fitting direction) and with a similar energy loss pattern (total deposited charge within $\pm 20\%$ of the original charge). Each event was simulated using an ice model sampled from the space of ice models compatible with the current baseline best-fitting ice model (71).

Each event in this simulation set is reconstructed using the same method as is applied to the observed event and a test statistic (TS), defined as the difference in log-likelihood (L) between the best-fitting direction and the true direction is recorded as $TS = 2(\log L_{\text{true}} - \log L_{\text{best}})$. The 50% and 90% percentiles of the distribution of TS over this simulation set are recorded and used to draw the 50% and 90% contour lines in the reconstructed likelihood fit at the corresponding likelihood ratios.

This algorithm allows us to include the uncertainty in the modeling of optical properties of the glacial ice into the fit uncertainty providing a combined statistical and systematic error (taking into account ice model systematics only). By construction, this method is not able to shift the best-fitting direction of the reconstruction and will include systematic bias on average only.

Calculation of the neutrino energy As IceCube detects the secondary muon produced in the neutrino's interaction in or near the instrumented volume, a precise determination of the neutrino energy is generally not possible for track events. However, for high-energy muons, a robust estimation of the energy of the muon as it traverses the instrumented volume is available (72, 73). Muons above ~ 1 TeV experience large stochastic energy losses due to pair production, bremsstrahlung, and photo-nuclear interactions. These energy losses grow with muon energy and can be used to estimate the energy as the muon passes through the detector.

Figure S2 presents the measured muon energy (72) observed in simulation of neutrino track events for a wide range of neutrino energies. The exact distribution of muon energies will depend on the assumed neutrino spectral index. For the observed muon energy of the IceCube-170922A track, the most-probable neutrino energy and the 90% C.L. lower limit can be calculated, and is shown in Figure S2 for three spectral indices. Using the measured spectral index of -2.13 (-2.0) for the estimated diffuse astrophysical muon neutrino spectrum (2), the most-probable neutrino energy of 290 TeV (311 TeV), a 90% C.L. lower limit on the neutrino energy of 183 TeV (200 TeV), and a 90% C.L. upper limit on the neutrino energy of 4.3 PeV (7.5 PeV) are determined.

High-energy γ -ray observations

Generation of the *Fermi*-LAT light curves of TXS 0506+056 The light curve is based on Pass 8 SOURCE class photons detected in the time interval from the start of the science phase of the mission in 4 August, 2008 to 24 October, 2017. This is the recommended class for most analyses and provides good sensitivity for analysis of point sources. Standard good-time intervals were selected excluding time intervals when the field of view of the LAT intersected the Earth, and during which bright γ -ray bursts and solar flares were observed.

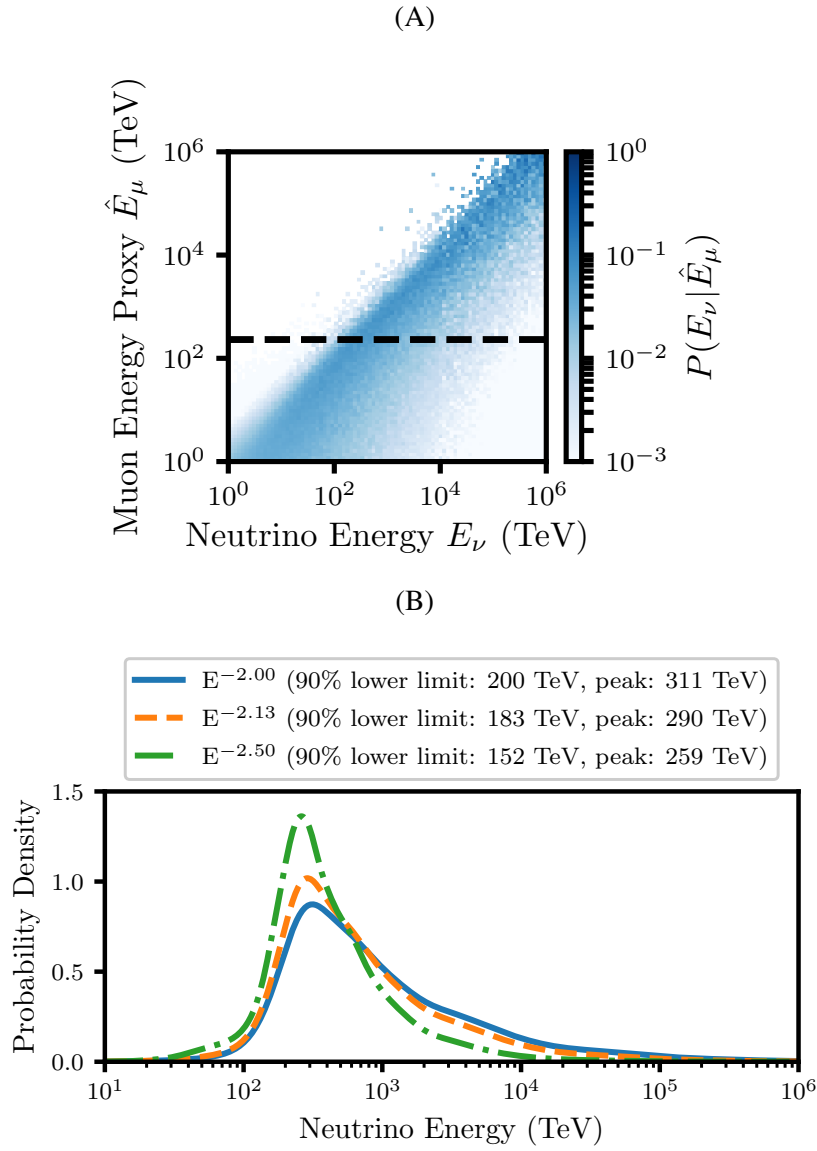

Figure S2: **Estimate of neutrino energy for IceCube-170922A.** Estimate of the neutrino energy of IceCube-170922A derived from an estimator of the muon energy in the detector (72). Note that the muon energy estimator is not equivalent to the deposited energy as the muon passed through the detector. The deposited muon energy sets a lower limit on the neutrino and muon energies. Panel A presents the 2-D distribution of neutrino energy vs. muon energy estimator (“Muon Energy Proxy”) from simulation. The observed energy estimator is indicated by a horizontal dashed black line. Assuming a prior distribution of true neutrino energies (modeled as power-law spectra with various indices), a probability distribution of true neutrino energies for the event can be derived (Panel B). For each neutrino spectral index, the 90% C.L. lower limit and most probable (“peak”) neutrino energies are listed. The result is only weakly dependent on the chosen spectral index.

A binned maximum likelihood technique (binned in space and energy) was applied using the standard *Fermi*-LAT Science-Tools package version v11r05p02 available from the *Fermi* Science Support Center (FSSC) (74) and the P8R2_SOURCE_V6 instrument response functions. Data in the energy range of 100 MeV to 1 TeV were binned into eight equally spaced logarithmic energy intervals per decade. To minimize the contamination from the γ -rays produced in Earth's upper atmosphere, a zenith angle cut of < 90 deg was applied.

A $10 \text{ deg} \times 10 \text{ deg}$ region of interest (ROI) was selected centered on the assumed source position and binned in 0.1 deg pixels. The input model for the ROI included all known γ -ray sources from the *Fermi*-LAT Third Source Catalog (3FGL) (23). We refined the best-fitting position of TXS 0506+056, including the additional data taken since the release of the 3FGL catalog. Similarly, we searched for additional sources in the ROI that may be significantly detected in the current data set, but were too faint to be included in this catalog, a standard procedure (75). The model of the ROI included the isotropic and Galactic diffuse components (gll_iem_ext_v06.fits and iso_P8R2_SOURCE_V6_v06.txt). To build the light curve, the spectral functional forms given in the 3FGL/3FHL (24) catalog for each source in the ROI were adopted. For each time interval analyzed for the light curve, the flux normalization of TXS 0506+056 and of other sources within 3 deg of it were free parameters, while the spectral shapes were fixed to their forms in the overall best-fitting model for the entire 9.5-year dataset starting in August 2008. Light curves for TXS 0506+056 were created with a time binning of 28 days over the full *Fermi*-LAT observation period, and a binning of 7 days around the time of the IceCube neutrino alert.

Similar light curves, but with an energy threshold of 1 GeV and using 28 day bins only, were compiled for all extragalactic *Fermi*-LAT sources (time binning and energy threshold were chosen to reduce the required computing resources). All sources from the four-year source catalog (3FGL) and the six-year hard source catalog (3FHL) (24) which are classified as extragalactic objects were included. Unclassified sources were added if they were more than 5 deg from the Galactic equator. Sources that were marked with an analysis flag (23), were removed. In total, 2257 sources were selected. These light curves were used in the calculation of the chance coincidence probability of the apparent neutrino-flaring blazar correlation. Very bright sources were modeled with log-parabolic spectra. For the light curve generation, the spectra of the sources were kept fixed to the values obtained from a fit over the total observation period. The limited statistics in the 28 day time bins do not allow fitting bin-by-bin spectral parameters for most sources.

***Fermi*-LAT real-time follow up pipelines** Following the neutrino alert, the quick recognition of the coincident blazar flare was made possible by automated high-level software pipelines developed by the LAT collaboration that provide continuous monitoring of the γ -ray sky. The Automated Science Processing (ASP) (76) and the *Fermi* All-sky Variability Analysis (FAVA) (30) are model independent techniques that search for variations in γ -ray flux, on timescales from hours to one week. The statistical significances of the candidate sources identified by ASP and FAVA are subsequently evaluated with the more robust maximum-likelihood technique, and

further inspected by the so-called Flare Advocates in the LAT collaboration, who communicate significant results to the external scientific community through the *Fermi* multi-wavelength mailing list, Astronomer’s Telegrams, and direct e-mail (77). Significant flares seen with ASP are reported automatically as Gamma-ray Coordinates Network notices (78).

ASP is based on the source detection algorithm PGWave (79), used also in the *Fermi*-LAT catalog pipeline to identify candidate sources. PGWave applies a two-dimensional Mexican Hat wavelet filtering to find significant clusters of photons in the LAT data from different intervals (6-hour, 1-day and 1-week) and in three energy ranges (0.1 GeV – 300 GeV, 0.1 GeV – 1 GeV and 1 GeV – 300 GeV).

FAVA searches for γ -ray variability on a weekly time scale in a low and high energy bands, *i.e.*, from 0.1 GeV to 0.8 GeV and from 0.8 GeV to 300 GeV. A photometric technique is used to compare the weekly flux to the long-term average flux over the first four years of the mission in a grid of regions covering the entire sky. If the photometric technique finds a deviation from the average in at least one of the two energy bands with a significance greater than 4σ , a maximum likelihood analysis is applied. This models the ROI, including background sources and the diffuse emission, taking into account the LAT PSF that is applied to accurately assess the statistical significance.

The FAVA results are updated in real time and are displayed in a public web interface (80). FAVA has been used as a tool to quickly find potentially variable sources in the neutrino error circle. In the time bin during which IceCube-170922A arrived, FAVA reported a significance at the position of TXS 0506+056 obtained in the likelihood analysis of 6.5σ in the low-energy band and 6.9σ in the high-energy band.

AGILE The γ -ray satellite *AGILE* (31) monitors the sky in spinning mode in the energy range 30 MeV–30 GeV. *AGILE* detected enhanced γ -ray emission above 100 MeV from the IceCube-170922A/TXS 0506+056 region and reported this in an Astronomer’s Telegram, issued 7 days after the neutrino detection (58).

A refined analysis of the data acquired with the *AGILE* imaging γ -ray detector leads to significant detections from this region on short and long timescales before and near the time of the IceCube neutrino alert, compatible with the flaring activity observed by *Fermi*-LAT from TXS 0506+056.

The *AGILE* γ -ray flux above 100 MeV from TXS 0506+056, estimated with the *AGILE* Maximum Likelihood (ML) algorithm (81) in a time window of 13 days centered at MJD 58012.5 (16 September, 2017) is found to be $(5.3 \pm 2.1) \times 10^{-7} \text{ cm}^{-2} \text{ s}^{-1}$. The corresponding energy flux density of this *AGILE* observation, scaled at 200 MeV assuming a power-law index of -2, is $(8.8 \pm 3.5) \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$.

Very-high-energy γ -ray observations

MAGIC MAGIC followed-up 4 of the 10 IceCube alerts that had been issued by 1 October, 2017. The properties of the events that were followed-up are listed in Table S1. For the alerts

Figure S3: **Significance of the VHE γ -ray signal from TXS 0506+056 as measured by MAGIC.** Distribution of the squared angular distance, θ^2 , between the re-constructed source position and the nominal source position (blue points) or the background estimation position (shaded area) for the direction of the blazar TXS 0506+056. Statistical uncertainties on the number of signal (blue markers) or background (red markers) events are shown as vertical error bars. The number of excess events ($N_{\text{ex}} = 374 \pm 62$) and significance (82) are calculated in the region from 0 to the vertical dashed line. The estimated energy threshold is 90 GeV.
